Type Consistency Problems for Queries in Object-Oriented Databases

Yasunori ISHIHARA
Hiroyuki SEKI
Minoru ITO

Nara Institute of Science and Technology

This paper discusses the computational complexity of type consistency problems for queries in object-oriented databases (OODBs). A database instance is said to be consistent under a database schema if, for every method invocation $m$, the definition of $m$ to be bound is uniquely determined. In this paper, we adopt update schemas introduced by Hull et al. as a model of OODB schemas, and show that (1) the problem of determining whether there exists an inconsistent instance under a given recursion-free update schema and (2) the problem of determining whether there exists an inconsistent acyclic instance under a given recursion-free update schema are both NEXPTIME-complete. It is also shown that (3) the problem of determining whether there exists an inconsistent acyclic instance under a given arbitrary update schema is undecidable.

1 Introduction

Among many features of object-oriented programming languages, method invocation (or message passing) mechanism is an essential one. It is based on method name overloading and late binding by method inheritance along the class hierarchy. For a method name $m$, different classes may have different definitions (codes, implementations) of $m$. When $m$ is applied to an object $o$, one of its definitions is selected depending on the class which $o$ belongs to, and is bound to $m$ in run-time (late binding or dynamic binding).

This paper discusses the computational complexity of type consistency problems for queries in object-oriented databases (OODBs). A database instance is said to be consistent under a database schema if, for every method invocation $m$, the definition of $m$ to be bound is uniquely determined by using the class hierarchy with inheritance. Then the type consistency problem is to determine whether there exists an inconsistent instance under a given database schema.

Abiteboul et al. [1] introduced method schemas, which correspond to a model of OODB schemas without updating database instances. In Ref. [1], it is shown that
1. the type consistency problem for method schemas is undecidable in general,
2. NP-complete if every method is recursion-free, and
3. solvable in polynomial time if a given method schema is monadic (i.e., every method in the schema has at most one argument).

On the other hand, Hull et al. [2] introduced update schemas, in which updating database instances is simply modeled as assignment of objects or basic values to attributes of objects. Every method in update schemas is monadic. In Ref. [2], it is shown that the type consistency problem for update schemas is undecidable in general. In Ref. [3], a subclass of update schemas, called non-branching update schemas, is introduced. And, it is shown that the problem of determining whether there exists an inconsistent acyclic instance under a given non-branching update schema is solvable in polynomial time.

Update schemas have all of the basic features of OODBs such as class hierarchy, inheritance, complex objects, and so on. In this paper, we adopt update schemas as a model of OODB schemas, and show that
1. the problem of determining whether there exists an inconsistent instance under a given recursion-free update schema is NEXPTIME-complete,
2. the problem of determining whether there exists an inconsistent acyclic instance under a given recursion-free update schema is also NEXPTIME-complete, and
3. the problem of determining whether there exists an inconsistent acyclic instance under a given arbitrary update schema is undecidable (see Table 1).

†: Results of this paper.
2 Definitions

2.1 Syntax of Database Schemas

A database schema is a 4-tuple \( S = (C, \leq, \text{Ad}, \text{Impl}) \) where:

1. \( C \) is a finite set of class names.
2. \( \leq \) is a partial order on \( C \) representing a class hierarchy. If \( c' \leq c \), then we say that \( c' \) is a subclass of \( c \) and \( c \) is a superclass of \( c' \). We assume that the class hierarchy is a forest on \( C \), that is, for all \( c_1, c_2, c \in C \), the following condition is satisfied:
   
   If \( c \leq c_1 \) and \( c \leq c_2 \), then \( c_1 \leq c_2 \) or \( c_2 \leq c_1 \).
3. \( \text{Ad} : C \times \text{Attr} \rightarrow C \) is a partial function representing attribute declarations, where \( \text{Attr} \) is a finite set of attribute names. By \( \text{Ad}(c, a) = c' \), we mean that the value of attribute \( a \) of an object of \( c \) must be an object of \( c' \) or its subclass.
4. \( \text{Impl} : C \times \text{Meth} \rightarrow S \) is a partial function representing method implementations, where \( \text{Meth} \) is a finite set of method names and \( S \) is a set of well-formed sequence of sentences defined below.

A sentence is an expression which has one of the following forms:

1. \( y := y' \),
2. \( y := \text{self} \),
3. \( y := \text{self}.a \),
4. \( y := m(y') \),
5. \( y := \text{return}(y') \),
6. \( \mathcal{I} \).

where \( y, y' \) are variables, \( a \) is an attribute name, \( m \) is a method name, and \( \text{self} \) is a reserved word that denotes the object on which a method is invoked (or, to which a message is sent). Let \( s_1; s_2; \ldots; s_n = \alpha \) be a sequence of sentences. We say that \( \alpha \) is well-formed when the following two conditions hold:

- No undefined variable is referred to. That is, for each \( s_i \) \((1 \leq i \leq n)\), if \( s_i \) is one of \( y := y', \ y := m(y'), \ \text{self}.a := y', \ \text{return}(y') \), then there exists a sentence \( s_j \) \((j < i)\) that must be one of \( y' := y'', \ y' := \text{self}, \ y' := \text{self}.a', \ y' := m(y'') \) \((y'' \text{ is a variable, } a' \text{ is an attribute, and } m' \text{ is a method})\).
- Only the last sentence \( s_n \) must have the form \( \text{return}(y') \) for some variable \( y' \). Thus the other sentences \( s_1, s_2, \ldots, s_{n-1} \) must be of types 1 to 5.

Without loss of generality, we often omit temporary variables for readability. For example, we write \( y := m(\text{self}.a') \) instead of \( "y' := \text{self}.a; y' := m(y')" \), where \( y' \) is a temporary variable.

The method dependence graph [1] \( G = (V, E) \) of \( S \) is defined as follows:

- \( V \) is the set of all the method names in \( S \); and
- An edge from \( m \) to \( m' \) is in \( E \) if and only if there is some \( c \) such that \( m \) appears in \( \text{Impl}(c, m') \).

If the method dependence graph of \( S \) is acyclic, then we say that \( S \) is recursion-free.

Lastly, we define the description size of \( S \), denoted \( |S| \), as follows:

\[
|S| = |C| + (\text{the number of attributes}) + (\text{the number of attribute declarations given by } \text{Ad}) + (\text{the number of methods}) + (\text{the total number of sentences given by } \text{Impl}).
\]

2.2 Semantics of Database Schemas

Let \( S = (C, \leq, \text{Ad}, \text{Impl}) \) be a database schema. The inherited implementation of method \( m \) at class \( c \), denoted \( \text{Impl}^*(c, m) \), is defined as \( \text{Impl}(c', m) \) such that \( c' \) is the smallest superclass of \( c \) (with respect to the partial order \( \leq \)) at which an implementation of \( m \) exists, that is, if \( \text{Impl}(c', m) \) is defined and \( c \leq c' \), then it must hold that \( c' \leq c'' \). If such an implementation does not exist, then \( \text{Impl}^*(c, m) \) is undefined. Similarly, the inherited attribute declaration of attribute \( a \) at class \( c \), denoted \( \text{Ad}^*(c, a) \), is defined as \( \text{Ad}(c', a) = c' \) such that \( c' \) is the smallest superclass of \( c \) at which an attribute declaration of \( a \) exists. If such an attribute declaration does not exist, then \( \text{Ad}^*(c, a) \) is undefined. A database instance of \( S \) is a pair \( I = (\nu, \mu) \), where:

1. To each \( c \in C \), \( \nu \) assigns a disjoint, finite set, denoted \( \nu(c) \). Each \( o \in \nu(c) \) is called an object of class \( c \).
2. To each object \( o \in \nu(c) \) and each attribute \( a \in A \) such that \( \text{Ad}(a, c) = c', \mu \) assigns an object, denoted \( \mu(o, a) \), that is called the value of attribute \( a \) (or simply \( a \)-value) of \( o \). If \( \text{Ad}(a, c) = c' \), then \( \mu(o, a) \) must belong to \( \nu(c') \) for some \( c' \) \((c' \leq c')\).

Hereafter, we denote \( \mu(o, a) \) by \( o.a \). If every object \( o \) in \( I \) satisfies

\[
o.a_1 a_2 \ldots a_n \neq o
\]

for any sequence of attributes \( a_1, a_2, \ldots, a_n \), then \( I \) is said to be acyclic.

The operational semantics of a database schema \( S \) under a given database instance \( I \) is formally defined by using a method execution tree [2]. Here, we do not repeat the formal definition. Instead, we briefly explain its intuitive meaning. As stated before, \( \text{self} \) represents the object on which a method is invoked; it is called a self object.

1. The meaning of a sentence \( y := y' \) is obvious.
2. \( y := \text{self} \) means that the self object is assigned to variable \( y \).
3. \( y := \text{self}.a \) means that the \( a \)-value of the self object is assigned to \( y \).
4. If the control reaches a sentence \( y := m(y') \), then method \( m \) is invoked on the object assigned to \( y' \) (or, message \( m \) is sent to the object assigned to \( y' \)) and the "returned value" is assigned to \( y \). Assume that an object \( o \) of a class \( c \) is assigned to \( y' \). If \( \text{Impl}^*(c, m) = \alpha \), then \( o \) is bound to "self" in \( \alpha \), \( \alpha \) is executed, and the returned value is assigned to \( y \). If \( \text{Impl}^*(c, m) \) is undefined, then a run-time error occurs.
5. Consider a sentence \( \mathit{0}.a := y' \), and let \( o \) be the object assigned to \( y' \) when the control reaches this sentence. Assume that \( Ad^*(c, a) = c' \in C \). If \( o \) is an object of a class \( c'' \) and \( c' \leq c'' \), then the value of attribute \( a \) of the self object becomes \( o \). Otherwise, a run-time type error occurs.

2.3 Consistency of Database Schemas

Let \( S \) be a database schema, and \( I \) be a database instance of \( S \). We say that \( I \) is consistent under \( S \) when the following condition holds:

Let \( m \) be an arbitrary method of \( S \) and \( o \in \nu(c) \) be an arbitrary object in \( I \). If \( \text{Impl}^*(c, m) \) is defined, then no type errors occur during the execution of \( m \) on \( o \).

If \( I \) is not consistent under \( S \), then we say that \( I \) is inconsistent under \( S \).

3 Basic Techniques

In this section, we present some basic techniques which are used in the following sections. Throughout this section, \( C, \leq \), and \( Ad \) are defined as follows:

- \( C = \{c, c_1, c_2\} \);
- \( \leq \) is the reflexive closure of \( \{(c_1, c), (c_2, c)\} \) (i.e., \( c \) is a superclass of both \( c_1 \) and \( c_2 \), see Fig. 1(a)); and
- \( Ad \) is shown in Fig. 1(b).

Let \( o \) be an object of class \( c_0 \). Each attribute \( a \in \{a_1, a_2, a'_1, a'_2\} \) of \( o \) represents a Boolean value: \( a \) represents true if \( o.a = o \), and false otherwise. Note that \( o.a \) always represents false because of the declaration \( Ad(c_0, a) = c_1 \).

First, we define a method \( \text{nor}[a_1, a_2] \) as shown in Fig. 2, which calculates NOR of \( o.a_1 \) and \( o.a_2 \). Since any Boolean operator can be represented by NORs, we can construct a method which calculates any given Boolean formula by using \( \text{nor}[a_1, a_2] \). Formally, we have the following lemma:

Lemma 1: Let \( o \) be an object of class \( c_0 \). Let \( o' \) denote the object returned by the execution of method \( \text{nor}[a_1, a_2] \) on \( o \). Then, the following equation holds:

\[
\begin{align*}
o' &= \left\{ \begin{array}{ll} o & \text{if } o.a_1 \neq o \text{ and } o.a_2 \neq o, \\
o.a & \text{otherwise}. \end{array} \right.
\end{align*}
\]

Proof: Consider how \( o.a' \) changes during the execution of \( \text{nor}[a_1, a_2] \). First, \( o.a' \) is set to \( o \). By the second line of \( (c, \text{nor}[a_1, a_2]) \), \( o.a' \) is set to \( o.a_1 \) if \( o.a_1 = o \), and unchanged otherwise. Similarly, by the third line, \( o.a' \) is set to \( o.a_2 \) if \( o.a_2 = o \), and unchanged otherwise. Therefore, \( o.a' \) is set to \( o.a_1 \) if \( o.a_1 = o \) or \( o.a_2 = o \), and unchanged (i.e., \( o.a' = o \)) otherwise.

Next, consider a database instance of this schema shown in Fig. 3. By invoking a method \( \text{copy}[a_1, a_2] \) (Fig. 4) on an object \( o_i \) in the “\( o.a \)-chain,” the Boolean value represented by \( o_j.a_1 \) is copied to \( o_{j+1}.a_2 \) (\( = o_j.a_{\Rightarrow-}a_2 \)). Formally, we have the following lemma:

Lemma 2: Let \( o_j \) be an object of class \( c_0 \). After the execution of method \( \text{copy}[a_1, a_2] \) on \( o_j \), the following equation holds:

\[
o_{j+1}.a_2 = \begin{cases} o_{j+1} & (\text{if } o_j.a_1 = o_j), \\
o_{j+1}.a_{\Rightarrow-}a_2 & (\text{otherwise}). \end{cases}
\]

Proof: An easy observation proves this lemma.

Lastly, see again Fig. 3. Suppose that a method \( m_0 \) returns \( o.a_\Rightarrow \) when \( m_0 \) is invoked on \( o \). Define method \( m_i \) (\( 1 \leq i \leq n \)) as shown in Fig. 5. It is easy to see that \( m_n \) sequentially invokes \( m_0 \) on \( 2^n \) objects in the “\( o.a \)-chain” (see Fig. 6). Note that \( m_i \) (\( 1 \leq i \leq n \)) can be constructed in polynomial time of \( n \).

4 Recursion-Free Schemas

Definition 1: Problem \( RF/AC \) is to determine whether there exists an inconsistent acyclic instance under a given
Fig. 5: Method which sequentially invokes method $m_0$ on $2^n$ objects.

\text{return} (\text{self} \Rightarrow).
\end{array}
\]

Fig. 6: Invocation of $m_n$ on $o_1$.

We show that $RF/AC$ is NEXPTIME-complete.

**Lemma 3:** $RF/AC$ is in NEXPTIME.

**Proof:** Since $S$ is recursion-free, execution of any method in $S$ always terminates and the number of objects traversed during the execution is bounded by $|S|^{|S|}$. Therefore, to solve $RF/AC$, nondeterministically guess an instance of size $|S|^{|S|} = 2^{|S|} \log^{|S|}$ which causes a type error.

To show that $RF/AC$ is NEXPTIME-hard, we reduce any language in NEXPTIME to $RF/AC$. To do this, for a given input string $x$ of a fixed $2^n$-time bounded nondeterministic Turing machine $M$, we construct, in polynomial time of $|x|$, a schema $S_{M,x}$ such that there is an acyclic instance that is inconsistent under $S_{M,x}$ if and only if $M$ accepts $x$. First, we define a nondeterministic Turing machine and an instantaneous description.

**Definition 2:** A nondeterministic Turing machine $M$ is a triple $(Q, \Sigma, \delta)$, where

- $Q$ is a finite set of states. $Q$ has three special states: the initial state $q_0$, the accepting state $q_{\text{yes}}$, and the rejecting state $q_{\text{no}}$;
- $\Sigma$ is a finite set of symbols. $\Sigma$ has two special symbols: the blank symbol $B$ and the first symbol $\triangleright$. The first symbol is always placed at the leftmost cell of the tape; and
- $\delta$ is a function which maps $(Q - \{q_0, q_{\text{yes}}, q_{\text{no}}\}) \times \Sigma$ to the power set of $Q \times \Sigma \times \{<, ->, =, \}$. $\delta$ must satisfy the following conditions:
  - For each pair $(q, \sigma)$ in $(Q - \{q_0, q_{\text{yes}}, q_{\text{no}}\}) \times \Sigma$, $|\delta(q, \sigma)|$ (the number of possible nondeterministic choices) is at most two. Assume that the elements of each $\delta(q, \sigma)$ are identified by 0 and 1; and
  - If $(q', \sigma, d) \in \delta(q, \triangleright)$, then $\sigma = \triangleright$ and $d = ->$. Therefore, the tape head never falls off the left end of the tape.

**Definition 3:** An instantaneous description (ID) $I$ of $M$ is a finite sequence $(q_1, \sigma_1), \ldots, (q_k, \sigma_k)$, where $q_i \in Q \cup \{\perp\}$ and $\sigma_i \in \Sigma$. It is required that exactly one $q_i$ is in $Q$ (i denotes the head position). The $i$-th pair $(q_i, \sigma_i)$ of an ID $I$ is denoted by $I[i]$. The transition relation $\vdash_{M}$ over the set of IDs are defined as usual. Let $I_j$ denote an ID after $j$-step transition of $M$.

Let $M = (Q, \Sigma, \delta)$ be a $2^{O(n)}$-time bounded nondeterministic Turing machine. Let $x \in (\Sigma - \{B, \triangleright\})^*$ be an input string for $M$. Let $n = |x|$ and $N = 2^{O(n)}$. Let $K = \lceil\log(|Q| + 1)\rceil + \lceil\log(|\Sigma|)\rceil$. For $M$ and $x$, define $C$, $c_0$, and $Ad$ of $S_{M,x}$ as follows:

- $C = \{c_0, c_{10}, c_{11}, c_{10}, c_{11}\}$;
- $c_0 \leq c_1 \leq c_2 \leq c$, and
- $Ad$ is shown in Fig. 8. Strictly speaking, some more temporary attributes are necessary to store intermediate result of calculation.

An example of an acyclic database instance of $S_{M,x}$ is shown in Fig. 9. Note that any "$a_{\triangleright}$-chain" in any acyclic database instance terminates in an object of class $q_i$. Objects $o_1, \ldots, o_{2N}$ in Fig. 9 are used as working space for simulating $M$: $I_j[I]$ is "stored" in object $o_{i+j}$ (see Fig. 10). The class which each object $o_j$ belongs to represents the nondeterministic choice at $j$-th step of $M$; Class $c_0$ represents choice 0 and $c_1$ does choice 1.

In what follows, we show that there is an inconsistent acyclic instance under $S_{M,x}$ if $M$ accepts $x$. Let $T$ be an acyclic instance with an $a_{\triangleright}$-chain whose length $k$ is greater than $2N$ (e.g., instance shown in Fig. 9). Let $o_i$ ($1 \leq i \leq k$) be the $i$-th object in the $a_{\triangleright}$-chain.

Define method TM as shown in Fig. 11. Suppose that TM is invoked on $o_1$. The behavior of TM is as follows:
1. Initialize the first $2N = 2p(n)+1$ objects (line 1 of $(c_0, \text{TM})$ of Fig. 11). More precisely, for each $i$ ($1 \leq i \leq 2N$), $I_0[i]$ is stored in $a_1, a_2, \ldots, a_{K-1}$ by binary encoding.

2. Rewrite the ID stored in the working space $N (= 2p(n))$ times (line 2). This phase is explained in detail below.

3. Check whether the accepting state $q_{\text{yes}}$ is in the last ID, i.e., in objects $a_{K}, \ldots, a_{2N}$ (line 3). The returned value of accept is an object of class $c_0$ (or its subclass) if $q_{\text{yes}}$ is in the last ID. Otherwise, an object of class $c_1$ is returned. Method accept can be easily constructed by using methods $\text{nor}(a_1, a_2)$, $\text{copy}(a_1, a_2)$ and $m_n$ stated in Sect. 3.

4. Invoke test on the returned value of accept (line 4).

Since method test is defined only for class $c_1$, that will cause a type error if $q_{\text{yes}}$ is in the last ID. That is, $Z$ is inconsistent under $S_{M,x}$ if $M$ accepts $x$.

Now define methods $\text{step}_0, \ldots, \text{step}_p(n)$ as shown in Fig. 12. Consider the $j$-th step of $M$. Each $I_{j-1}[i]$ ($1 \leq i \leq N$) is stored in object $a_{j+i-1}$ (see Fig. 13(a)), and method $\text{step}_0$ is invoked on $a_j$. By method choice (Fig. 12), the nondeterministic choice $c_{h_j} \in \{0, 1\}$ at the $j$-th step, which is given by the class which $a_j$ belongs to, is stored in $a_j.a_{h_j}$. Then, method $\text{copy}_0$ (Fig. 12) is invoked on each $a_{j+i-1}$ ($1 \leq i \leq N$). The underlined part (the first line of $(c_0, \text{TM})$) is macro notation. All of them can be expanded when $M$ and $x$ are reduced to

$$ S_{M,x}.$$ After the invocations of $\text{copy}_0$, each object $a_{i+j}$ ($1 \leq i \leq N$) has $I_{j-1}[i-1], I_{j-1}[i], I_{j-1}[i+1]$, and $c_{h_j}$ (see Fig. 13(b)). Lastly, method delta$_0$ is invoked on each object $a_{i+j}$ ($1 \leq i \leq N$) to obtain $I_{j}[i]$, which is to be stored in $a_1, \ldots, a_K$ (see Fig. 13(c)). Method delta$_0$ can be constructed in constant time with respect to $n$ by using $\text{nor}(a_1, a_2)$ stated in Sect. 3.

Conversely, we show that there is an inconsistent acyclic instance under $S_{M,x}$ only if $M$ accepts $x$. The whole of $S_{M,x}$ can be easily constructed so that a type error can occur only at the fourth line of $(c_0, \text{TM})$. And it is also easy to see that $q_{\text{yes}}$ is stored in some of the objects
Theorem 1: $RF/AC$ is NEXPTIME-complete. □

Let $RF$ be the problem of determining whether there exists an inconsistent instance under a given recursion-free schema $S$. By slightly modifying the construction of $S_{M,x}$, we have the following theorem:

Theorem 2: $RF$ is NEXPTIME-complete. □

5 Arbitrary Schemas, Acyclic Instances

Definition 4: Problem $AC$ is to determine whether there exists an inconsistent acyclic instance under a given schema $S$.

We prove that $AC$ is undecidable by showing a reduction from any recursively enumerable language to $AC$. To do this, for a given input string $x$ of a fixed Turing machine $M$, we construct a schema $S'_{M,x}$ such that an acyclic instance is inconsistent under $S'_{M,x}$ if and only if $M$ accepts $x$.

Let $M = (Q, \Sigma, \delta)$ be a deterministic Turing machine, i.e., for each pair $(q, \sigma) \in (Q - \{q_0, q_{yes}, q_{no}\}) \times \Sigma$, $\delta(q, \sigma)$ is at most one. Let $x \in (\Sigma - \{B, \bot\})^{*}$ be an input string for $M$. Let $K = \lceil \log(|Q| + 1) \rceil + \lceil \log(|\Sigma|) \rceil$. For $M$ and $x$, define $C, \leq$, and $Ad$ to be the same as $S_{M,x}$ in Sect. 4.

Let us construct TM' which simulates $M$ on $x$. Since recursion is allowed now, we modify init.\_ws0, step0, etc. in Sect. 4 so that they recursively traverse the $a_{\Rightarrow}$-chain until it reaches object $o_{k}$ of class $c_{0}$. Therefore, init.\_ws1, step1, etc. are not necessary. Moreover, it is unknown when $M$ stops in advance. A tentative solution would be as follows:

\[(c_{01}, TM'):
    y := init.\_ws0(self);
    y := step'&accept&test(self);
    return(self).
\]

\[(c_{01}, step'& accept& test) :
    y := step0(self);
    y := accept(self);
    y := test(y);
    y := step'&test(self,a_{\Rightarrow});
    return(self).
\]

However, this does not work since step'&accept&test may invoke on an object in an $a_{\Rightarrow}$-chain which is not initialized. Hence, it is possible that there is an acyclic instance that is inconsistent under $S'_{M,x}$ even if $M$ does not accept $x$.

Instead, we define TM' and step' as shown in Fig. 14. Classes $c_{0}$ and $c_{1}$ represent the choice whether rewriting the ID is continued or not. To explain this more precisely, consider the situation that TM' is invoked on $o_{1}$ in Fig. 9. All the objects in the $a_{\Rightarrow}$-chain are initialized by method init.\_ws0. Then step' is invoked on $o_{1}$. If $o_{1}$ is of class $c_{0}$, then the ID stored in the $a_{\Rightarrow}$-chain is rewritten and step' is recursively invoked on $o_{2}$. This recursive invocation is repeated until some object $o_{j}$ of class $c_{0}$ or $c_{1}$ is encountered. That is, if $o_{2} \in r(c_{0})$ for each $j (1 \leq j \leq k')$ and $o_{k'} \in r(c_{0}) \cup r(c_{1})$, then TM' simulates $M$ up to $k'$ steps.

Fig. 14: Methods $TM'$ and step'.

By an easy observation, we have the following theorem:

Theorem 3: $AC$ is undecidable. □

Consider executing TM' on a cyclic database instance. Since all the attributes except $a_{\Rightarrow}$ are initialized by init.\_ws0, we can focus on the case that $a_{\Rightarrow}$ forms a cycle. In this case, TM' does not terminate. More precisely, init.\_ws0 is invoked infinitely many times without type error. Therefore, we have the following known result [2]:

Theorem 4: The problem of determining whether there exists an inconsistent instance under a given schema $S$ is undecidable. □

6 Conclusions

Theorems 1 and 2 mean that there are no algorithms to solve $RF/AC$ or $RF$ better than the obvious algorithm stated in Lemma 3. On the other hand, as stated in Sect. 1, these problems for method schemas are solvable in polynomial time (recall that method schemas do not update database instances). It is interesting to find a subclass of update schemas for which type consistency problems are solvable more efficiently than NEXPTIME.
