Scope of Research

The research activities in this subdivision cover structural studies and molecular motion analyses of highly organized polymer materials in the different states by high-resolution solid-state NMR, electron microscopy, X-ray diffractometry, and so on, in order to develop high-performance and high-functionality polymer materials such as organic electron luminiscence devices and different molecular hybrid materials. The structure formation process of bacterial cellulose is also characterized in detail and environmentally friendly cellulonic nanohybrid materials are examined to develop in different stages of the biosynthesis.

Effects of Added Electrolytes on the Phase Separation Behavior in Aqueous Suspensions of Bacterial Cellulose Nanocrystals and on the Magnetic Alignment of the Chiral Nematic Phase

Effective utilization of cellulose as nano-materials is an important subject to create a sustainable society for the 21st century. Bacterial cellulose (BC) is produced by a gram-negative bacterium called *Gluconacetobacter xylinus* cultured in an aqueous medium containing carbon and nitrogen sources. The phase separation behavior in water suspensions has been studied for BC nanocrystals prepared by hydrolysis of BC with 60 wt% sulfuric acid at 51 °C for 1 h. The suspensions separated into the upper isotropic and lower chiral nematic phases above 0.42 wt% of BC nanocrystals. The shape and size distributions of BC nanocrystals in both the phases were determined by transmission electron microscopy (TEM) and atomic force microscopy (AFM). The average size of the BC nanocrystals in the isotropic phase was 8.5 nm × 40 nm × 800 nm and the aspect ratio was 44. On the other hand, the average size of the BC nanocrystals in the chiral nematic phase was 9.8 nm × 54 nm × 1670 nm and the aspect ratio was 73. The surface charge densities were 0.051 and 0.055 e·nm⁻² for the isotropic and chiral nematic phases, respectively.

The effects of added NaCl (0–5.0 mM) on the phase separation behavior of the aqueous suspensions were investigated for a fixed total cellulose concentration of 3 wt% as shown in Figure 1. The volume fraction of the chiral nematic phase had a minimum value at an NaCl concentration of ca. 1.0 mM. At NaCl concentrations ranging from 2.0 to 5.0 mM, the suspensions did not separate into two phases, but became entirely liquid crystalline, yet not chiral nematic. Figure 2 shows optical polarization micrographs of the anisotropic phase with the addition of NaCl. The size of the ordered domains in the anisotropic phase decreased with an increase in the NaCl concentration from 0 to 2.75 mM. At 2.75 mM, only tactoids were observed in the entire region. At 5.0 mM, chiral nematic domains were no longer observed. The chiral nematic pitch decreased with increasing concentration of added NaCl, reached a minimum value at approximately 0.75 mM, and then increased sharply with the NaCl concentration up to 2.0 mM.

The effects of added sodium chloride on the magnetic alignment of the chiral nematic phase of the suspensions are shown in Figure 3. Under a magnetic field of 9T at 20 °C for 24 h, the helical axis of the chiral nematic phase of the suspensions without NaCl aligned parallel to the applied field. At 0.75 mM the helical axis of the chiral nematic phase aligned almost parallel to the applied field. However, the added NaCl mole than 1.0 mM prevented the helical axis of the chiral nematic regions from aligning parallel to the field.
