Abstract

To understand deep groundwater flow systems and their interaction with CO₂ emanated from magma at depth in a volcanic edifice, deep groundwater samples were collected from hot spring wells in the Aso volcanic area for hydrogen, oxygen and carbon isotope analyses and measurements of the stable carbon isotope ratios and concentrations of dissolved inorganic carbon (DIC). Relations between the stable carbon isotope ratio ($\delta^{13}\text{C}_{\text{DIC}}$) and DIC concentrations of the sampled waters show that magma-derived CO₂ mixed into the deep groundwater. Furthermore, groundwaters of deeper areas, except samples from fumarolic areas, show higher $\delta^{13}\text{C}_{\text{DIC}}$ values. The waters' stable hydrogen and oxygen isotope ratios (δD and $\delta^{18}\text{O}$) reflect the meteoric-water origin of that region's deep groundwater. A negative correlation was found between the altitude of the well bottom and the altitude of groundwater recharge as calculated using the equation of the recharge water line and δD value. This applies especially in the Aso-dani area, where deeper groundwater correlates with higher recharge. Groundwater recharged at high altitude has higher $\delta^{13}\text{C}_{\text{DIC}}$ of than groundwater recharged at low altitude, strongly suggesting that magmatic CO₂ is present to a much greater degree in deeper groundwater. These results indicate that magmatic CO₂ mixes into deeper groundwater flowing nearer the magma conduit or chamber.

30 **1. Introduction**

31 Stable carbon isotope studies of groundwater systems at some volcanoes have
32 revealed that deeply derived CO₂ mixes into groundwater that contains CO₂ derived from
33 soils (Chiodini et al., 2000; Ohsawa et al., 2002; Evans et al., 2002; Caliro et al., 2005).
34 These studies, using datasets of stable carbon isotope ratios and concentrations of
35 dissolved inorganic carbon (DIC), present a robust approaches to determine whether or
36 not magmatic CO₂ is dissolved by groundwater. In addition, it is possible to determine
37 recharge elevations of groundwaters using stable hydrogen and oxygen isotopes based on
38 isotopic altitude effects of precipitation (Yasuhara et al., 1993; Kazahaya et al., 1999;
39 Nakamura et al., 2002; Yasuhara et al., 2002). Using this technique, it is possible to
40 investigate groundwater movement in volcanic edifices. Both of these isotopic methods
41 are powerful tools for investigating the groundwater hydrology of volcanoes.

42 It is expected that the combined use of these two methods, as first demonstrated at
43 Kuju volcano by Yamada et al. (2005), will be effective to deepen our understanding of
44 the input of magmatic CO₂ into volcano groundwater flow systems. Although Yamada et
45 al. (2005) studied shallow groundwater flow systems forming cold carbonic springs and
46 bicarbonate-type hot spring, deep groundwater flow systems and their interaction with
47 CO₂ from deep-seated magma requires analysis of groundwater from deep wells drilled
48 into the volcanic edifice. As new hot springs for bathing have been developed by deep

49 drilling in Japan, including at Aso volcano, we have investigated the interaction between
50 magmata CO₂ and deep groundwater using hot spring wells at Aso volcano.

51 In this paper, we first present results of the isotope and DIC analyses of hot spring
52 waters, and then assess these results to determine the importance of magmatic CO₂ in
53 deep groundwater in the vicinity of Aso volcano. Results suggest a latent mixing process
54 of magmatic CO₂ into the deep groundwater flow system at Aso volcano.

55

56 **2. Site description and Methods**

57 Aso volcano is an active volcano in Kyushu Island, southwest Japan. This volcano is
58 characterized by a large caldera, extending 18 km east-west and 25 km north-south,
59 where a central cone is located (Fig. 1). The caldera floor is divided into north and south
60 parts called Aso-dani (Aso Valley) and Nango-dani (Nango Valley) respectively. As
61 Aso-dani is covered with lake sediment (Tanaka, 2000), the Aso-dani landform is much
62 flatter than that of Nango-dani, implying a simple stratified structure of the groundwater
63 flow system at the Aso-dani area. Two large rivers, called Kurokawa and Shirakawa,
64 respectively flow on the lowest part of caldera floors at Aso-dani and Nango-dani. Those
65 rivers, which meet within the caldera, flow out from the caldera at the western rim of the
66 caldera.

67 Surface geothermal activities of Aso volcano are only observed on the central cones.
68 One type of activity is characterized by volcanic gas discharge from a hot, highly acidic
69 crater lake at the first crater of Mt. Naka-dake (e.g. Saito et al., 2008); the other is
70 characterized by fumarolic gas discharges originated from hydrothermal systems at
71 Yuno-tani and Tarutama areas on the western slope of Mt. Eboshi-dake (NEDO, 1989)
72 (Fig. 1). Many natural hot springs in and around those areas are recognized as
73 steam-heated hot springs and have been used from antiquity. Recently, many “hot springs”

74 aside from those in the Uchinomaki area (AHL02–AHL05 in Fig. 1) have been developed
75 for bathing by drilling to about 1000 m deep. Although proprietary chemical data of
76 major dissolved constituents of hot spring waters from *Onsen-bunsekisho* (data tables of
77 hot springs' water quality that must be kept by Japanese law), formation processes of the
78 hot spring waters, including their relation to magmatic emanation, have not been
79 investigated at Aso volcano.

80 Hot spring water samples from 23 wells of variable depth were collected to produce
81 datasets of concentrations and stable carbon isotope compositions of dissolved inorganic
82 carbon (DIC and $\delta^{13}\text{C}$, respectively), stable isotopic composition of water (δD and $\delta^{18}\text{O}$)
83 and of concentrations major ions (Na, K, Mg, Ca, Cl, SO_4 and HCO_3). Cold spring waters
84 were also collected to determine the relation between δD and recharge elevation of hot
85 spring waters following the method described by Kazahaya and Yasuhara (1994). The
86 samples for water isotope analysis were collected in a glass vial to avoid water
87 evaporation. The samples collected in a CO_2 gas-tight bottle, were stored in a refrigerator
88 at 5°C until chemical and isotopic analyses were undertaken. Water temperature and pH
89 were measured in the field. All sampling locations are presented in Fig. 1.

90 Major ions (Na, K, Mg, Ca, Cl and SO_4) were determined by ion-chromatography
91 (DX-120, Dionex) and HCO_3 by acid titration. The concentrations of DIC were

92 determined using a CO₂-gas electrode (CE-2041; DKK–TOA Corp.) with an ion meter
93 (IM-22P; DKK–TOA Corp.) after all the carbonate species in the sample water (9 ml)
94 were converted into CO₂(aq) by the addition of 1 ml of 10% sulfuric acid. The water
95 samples for measurement of δ¹³C were injected into a glass vial containing phosphoric
96 acid and filled with helium gas. The generated CO₂ gas in the vial was transferred to a
97 mass spectrometer (Delta-Plus; Thermo Finnigan) through pre-treatment equipment of
98 carbon stable isotope of DIC (Gas Bench II; Thermo Finnigan). The obtained δ¹³C is
99 shown using δ notation as ‰-deviation from the value of Vienna-Peedee Belemnite
100 (V-PDB). The oxygen and the hydrogen isotope ratios (δD and δ¹⁸O) of the water samples
101 were determined using a mass spectrometer (Geo 20-20 model installed at the Stable
102 Isotope Laboratory of IGNS, New Zealand) with the zinc reduction method and CO₂
103 equilibration method. The obtained δD and δ¹⁸O are shown using δ notation
104 as ‰-deviation from the value of SMOW. The analytical precisions are ±0.5mg/l for
105 major ions, ±0.3mmol/l for DIC, ±0.2‰ for δ¹³C, ±1.0‰ for δD and ±0.1‰ for δ¹⁸O,
106 respectively. All analytical results are presented in Table 1.

107

108 **3. Results and Discussion**

109 3.1. Dissolved inorganic carbon

110 The relationship between $\delta^{13}\text{C}$ and DIC are shown in Fig. 2. The two lines in Fig. 2
111 show theoretical mixing curves calculated considering the dissolution of magmatic CO_2
112 by a groundwater which initially contained only biogenic soil CO_2 . Although the actual
113 mixing process could be more complex, we estimated the simple theoretical mixing
114 curves because the influence of the isotopic fractionation is so small that we can neglect it
115 because of the following reasons: (1) the all saturation indexes for the calcite were less
116 than 1 (Table 1; SI is calculated by use of the chemical and physical data of the water),
117 implying no precipitation of calcite, or precipitation at a very low rate when the saturation
118 index exceeds the value of 1 (Dandurand et al., 1982; Alessandro et al., 2007): (2) we
119 were careful to sample waters degassing. The equation used to compute these theoretical
120 curves is the following:

121

122
$$\delta^{13} C_g = \frac{C_0 \times (\delta^{13} C_0 - \delta^{13} C_{in})}{C_g} + \delta^{13} C_{in} \quad (1)$$

123

124 where C_0 and C_g represent DIC concentrations of the initial value and the value after
125 mixing respectively, and where $\delta^{13}\text{C}_0$, $\delta^{13}\text{C}_{in}$, and $\delta^{13}\text{C}_g$ denote the stable carbon isotope

126 ratio of the initial value, the value of input gas, and the value after mixing respectively.
127 Here, the $\delta^{13}\text{C}$ value of a fumarolic CO_2 discharged from Tarutama area (-5‰ ; NEDO,
128 1989) was used for $\delta^{13}\text{C}_{\text{in}}$ as magmatic gas, and for $\delta^{13}\text{C}_0$ and C_0 consistent with
129 groundwater values in equilibrium with soil CO_2 , (-30‰, 0.1 mmol/L) and (-30‰, 1
130 mmol/L) were used. The -30‰ is the lowest value of cold spring water in this area (CS01).
131 Almost all data points are shown on these mixing lines or the enclosed area between the
132 two lines. Ohsawa et al. (2002) suggested using the same kind of $\delta^{13}\text{C}_{\text{DIC}}$ versus DIC
133 concentration diagram that magmatic CO_2 mixes into soil CO_2 dissolved groundwaters
134 having variable DIC concentrations in Unzen volcano, Japan. Chiodini et al. (2000)
135 presented a similar interpretation using a $\delta^{13}\text{C}_{\text{DIC}}$ versus DIC diagram for central
136 Apennine Italy. Consequently, the results obtained in this study demonstrate that all hot
137 spring waters in Aso volcano are contaminated by magmatic CO_2 to varying degrees.

138 The mixing relation showed on Fig. 2 provides an effective index for expressing the
139 degree of magmatic CO_2 mixing because $\delta^{13}\text{C}_{\text{DIC}}$ value increases with the amounts of
140 mixed magmatic CO_2 . In other words, $\delta^{13}\text{C}_{\text{DIC}}$ of hot spring water will be higher if it is
141 contaminated by more magmatic CO_2 . Figure 3 presents relations between $\delta^{13}\text{C}_{\text{DIC}}$ of hot
142 spring waters and altitudes of hot spring well bottoms, for the Aso-dani area (A), the
143 Nango-dani area (B), and the whole area (C). The data plot of Aso-dani area (Fig. 3A)

144 portrays a clear increase in $\delta^{13}\text{C}_{\text{DIC}}$ value with decreasing altitude of the well bottom,
145 although the data plots of Nango-dani area (Fig. 3B) show no such clear tendency.
146 However, as depicted in Fig. 3C, some plots of the Nango-dani area agree in the tendency
147 of that of Aso-dani area. This tendency suggests a groundwater system forming in which
148 more magmatic CO_2 mixes in the deeper groundwater (Fig. 3C). Five samples, hatched in
149 fig 3c. (NHC01, NHC02, NHC06, NHL02, and NHL04 in Fig. 1), show a different
150 behavior. With the exception of NHL02, topographic catchment areas of these hot spring
151 waters include Yunotani and Tarutama fumarolic areas. As described above, these areas
152 are active geothermal areas with fumarolic gas discharges and natural hot springs of
153 steam-heated type. The fumarolic gases in these areas include a magmatic gas component
154 (Ohsawa et al., 1997). It can therefore be inferred that magmatic CO_2 rises near the
155 surface around these areas. Hence hot spring waters that do not show the typical
156 correlation between $\delta^{13}\text{C}$ and the altitude of the well bottom, as described above, are
157 produced by near surface mixing of ascending magmatic CO_2 and shallow groundwater.
158 This “exceptional” mixing process is linked with the well known formation mechanism
159 of volcanic hot spring water of bicarbonate type. This study has shed light on a formation
160 mechanism of hot spring water in the volcanic edifice different from well known
161 processes. Regarding the formation process of the NHL02 hot spring water, we cannot

162 reach a definite answer because of insufficient data.

163

164 3.2. Water isotopes

165 The δD and $\delta^{18}O$ values of groundwater samples vary from -62.2‰ to -44.2‰ and
166 -9.2‰ to -7.2‰, respectively. Results are shown on the δD versus $\delta^{18}O$ diagram with the
167 field of andesitic magmatic steam (Giggenbach, 1992) and the meteoric water line ($\delta D =$
168 $8\delta^{18}O + 10$; Craig, 1961) (Fig. 4). All data of groundwater samples are lie along the
169 meteoric water line, indicating that hot spring waters are derived almost entirely from
170 meteoric water, and that magmatic steam does not mix with groundwater.

171 In the case where groundwater originates from meteoric water, the recharge altitude
172 of that groundwater can be estimated using the recharge water line: a relation between δD
173 values and mean recharge altitude in the studied area (e.g., Yasuhara et al., 1993;
174 Kazahaya and Yasuhara, 1994; Nakamura et al., 2002; Yasuhara et al., 2002). In this study,
175 four cold spring water samples (CS01–CS04) were used to determine the local
176 recharge-water line. The recharge-water line of Aso volcano is determined as $H = -56.4$
177 $\delta D - 2063$, where H expresses the recharge altitude. The obtained relation is presented in
178 Fig. 5. The vertical bars associated with data points show the topographic recharge
179 altitude of each cold spring.

180 The relation between the δD data of hot spring waters and altitudes of hot spring well
181 bottoms is presented in Fig. 5. A slight positive tendency of the relation is apparent, which
182 suggests that hot spring water recharged at high altitude flows deeper than that at low
183 altitude. To clarifying this, we examined the relation between the altitudes of well
184 bottoms and the recharge altitudes of hot spring waters, dividing them into four groups
185 according to their location: central cones at Aso-dani side, central cones at Nago-dani
186 side, Aso-dani to caldera rim, and Nago-dani to caldera rim. As depicted in Fig. 6,
187 negative correlations were found between the altitudes of well bottoms and the recharge
188 altitudes of hot spring waters in every area, although correlation levels differed among
189 areas. Furthermore, it can be inferred from the correlation line's slopes that the
190 groundwater flow systems forming hot spring waters in Aso-dani areas (central cones at
191 Aso-dani side and Asodani to caldera rim) are more strongly layered than those in
192 Nago-dani areas (central cones at Nago-dani side and Nago-dani to caldera rim). The
193 systematic relations of recharge altitude and flow depth of hot spring waters in Aso-dani
194 areas are consistent with the general conceptualization of deep groundwater flow systems
195 (Ward and Robinson, 1990): the higher elevation at which the groundwater is recharged,
196 the deeper the groundwater flows. In contrast, in Nago-dani areas, the deep
197 groundwaters that are recharged at several altitudes tend to come together into an almost

198 identical aquifer.

199

200 **4. Conclusions**

201 In section 3.1 we have shown that at Aso volcano, deeper groundwater has a stronger
202 interaction with magmatic CO₂, except in the vicinity of the Yunotani and Tarutama areas.

203 On the other hand, in section 3.2, it was shown that deeper groundwater was recharged at
204 higher altitude. This relation is evident in Aso-dani areas of the northern part of Aso

205 caldera, which is not inconsistent with the groundwater circulation in the stratified

206 volcanic deposits (see section 2.). Combining the results obtained from the inspection of

207 carbon and water isotopes are evident that the $\delta^{13}\text{C}_{\text{DIC}}$ of groundwater recharged at high

208 altitude is more positive than that at low altitude (Fig. 7). Figure 7 presents the good

209 relations between recharge altitude and flow depth of hot spring waters for the Aso-dani

210 areas (central cones at Aso-dani side and Asodani to caldera rim). As clearly shown in Fig.

211 7, the $\delta^{13}\text{C}_{\text{DIC}}$ of groundwater recharged at high altitude is more positive than that

212 infiltrating at low altitude, suggesting a significant contribution of magmatic CO₂ for

213 such deeper groundwater.

214 From a simple geometrical consideration of a layered groundwater flow system in

215 volcanic edifice, it is readily understood that groundwater recharged at the highest

216 altitude flows much nearer the magma conduit or chamber than those recharged at low
217 altitudes (Fig. 8). Consequently, the much deeper groundwaters in Aso-dani areas are
218 thought to be affected strongly by mixing of magmatic CO₂. For that reason, results of our
219 study suggest that magmatic CO₂ was mixed into the volcano groundwater flow system at
220 Aso volcano. This mechanism differs from the well known mixing process on the
221 formation of bicarbonate type hot spring waters observed in the vicinity of the Yunotani
222 and Tarutama areas (see section 3.1.).

223 It is reasonable to believe that deep groundwaters are influenced by the magmatic
224 emanation at the central cone side of Aso-dani area, although it is not easy to understand
225 why such a system is apparent at Uchinomaki area at the northern end of Asodani to the
226 caldera rim far from the central cones (AHL02–AHL05 in Fig. 1). For clarification of this
227 point, further geophysical explorations in and around the central cones (e.g., Tsutsui and
228 Sudo, 2004; Hase et al., 2005; Kanda et al., 2008) are necessary.

Figure 1

Map showing sampling locations at Aso volcano, Japan. Sampling points of hot springs are shown as diamond, triangle, square, and circle symbols, respectively, on the central cone side of Kurokawa River, caldera limb side of Kurokawa River, central cone side of Shirakawa River, and caldera limb side of Shirakawa River. Hexagonal symbols denote cold spring sampling sites.

Figure 2

Concentrations of dissolved inorganic carbon (DIC) versus $\delta^{13}\text{C}_{\text{DIC}}$. Two lines represent theoretical curves calculated by adding magmatic CO_2 to initial groundwater dissolved soil CO_2 . For details, see the text.

Figure 3

Relation between $\delta^{13}\text{C}_{\text{DIC}}$ values and altitude of the well bottom of hot springs. (A), (B), and (C) respectively show data of the Aso-dani area, the Nango-dani area, and the whole area.

Figure 4

The δD - $\delta^{18}\text{O}$ plots of study-area groundwater. The diagonally shaded box shows ranges of δD and $\delta^{18}\text{O}$ values of andesitic magmatic steam (Giggenbach, 1992). The solid line

expresses the meteoric water line: $\delta D = 8 \delta^{18}O + 10$ (Craig, 1961).

Figure 5

The δD value versus altitude of the well bottom. The solid line shows the recharge-water line ($H = -56.4\delta D - 2063$, where H expresses the recharge elevation) as estimated using data of four cold springs.

Figure 6

Relations between the well bottom altitude and recharge altitude as calculated using the equation of recharge-water line and δD value. Regression lines and correlation factors are shown on each diagram.

Figure 7

Relation between $\delta^{13}C_{DIC}$ values and recharge altitude as calculated using the equation of recharge-water line and δD value in Aso-dani. Solid and broken lines respectively show the regression lines of the central cone side samples and caldera limb side samples.

Figure 8

Conceptual image of groundwater flow and inflow of magmatic CO_2 for groundwaters in Aso volcano at the Aso-dani central cone side. Magmatic CO_2 escaped from the magma conduit or chamber to volcanic edifice mixes into groundwater recharged at the high altitude area of the central volcanic cone and flowing through in the proximity of the

magma conduit.
