Abstract

Identification of precise bleeding sites is generally important to control haemorrhage. Nevertheless, the optimal technique to detect the bleeding sites has not yet been fully defined for patients with life-threatening postpartum haemorrhage. We describe that ultrasonographic visualisation of bleeding sites can help control postpartum haemorrhage using intrauterine balloon tamponade.

Key words

Balloon tamponade, bleeding sites, postpartum haemorrhage, ultrasonography, uterine atony
**Introduction**

Postpartum haemorrhage (PPH) is the most important cause of maternal death worldwide \(^{(1)}\). PPH is largely caused by uterine atony \(^{(1)}\). Clinical evaluation, usually in combination with ultrasound examination, identifies an underlying cause of PPH, such as uterine atony, uterine inversion, or retained products of conception. Nevertheless, intractable PPH can sometimes occur with seemingly unknown causes, and the bleeding resists conventional conservative treatments. The key to management of intractable PPH is to identify the cause of bleeding and to initiate appropriate intervention immediately. We found that intrauterine balloons could be confidently placed to control PPH by visualisation of the bleeding sites using ultrasonography.

**Case report**

A 32-year-old nulliparous woman underwent caesarean section at 37 weeks of gestation due to severe preeclampsia and breech presentation. Two hours after surgery, a boggy uterus was observed, and approximately 650 g clots were expelled
from the uterine cavity. The uterus became firm and well contracted following evacuation of all uterine contents. However, the bleeding (130 g/hour) persisted, and the accumulation of clots (430 g) in the uterine cavity recurred within two hours despite the administration of uterotonic drugs, including oxytocin (20 units), methylergonovine maleate (0.2 mg), and oral misoprostol (400 µg). Her blood pressure was 144/98 mmHg; pulse, 88 beats per minute. Laboratory data were as follows: haemoglobin 10.5 g/dl, haematocrit 32.0%, and platelet count 191x10^9/l.

Type 2 uterine bleeding (2), which seemingly presented with uterine atony, was strongly suspected from clinical manifestation. As Type 2 uterine bleeding is typified by bleeding from a disrupted artery at the upper part of the uterus (2), trans-abdominal Colour Doppler ultrasound examination (Voluson S8, convex transducer [2-5 MHz]; GE Healthcare, Milwaukee, WI) was conducted to explore bleeding sites. Active arterial bleeding was readily visualised from the posterior part of the upper uterine cavity (Figure 1). A Bakri balloon was then placed in the upper part of the uterus and was inflated with 350 mL of normal saline. An ultrasound confirmed that the surface of the balloon tightly compressed the bleeding vessel (Figure 2). Despite temporary control of bleeding (less than 30 minutes), recurrent uterine bleeding occurred due to
displacement of the intrauterine balloon towards the vagina. Consistently, active arterial bleeding was seen again using ultrasonography. Therefore, the Bakri balloon was reinserted into the uterine cavity, and each side of the uterine cervix was clamped with forceps, as previously reported (3). The balloon remained properly positioned within the uterine cavity, and the bleeding stopped. The amount of post-operative blood loss was 1300g, and a blood transfusion was not needed.

Discussion

PPH is the leading cause of maternal mortality (1). Persistent uterine bleeding with seemingly unknown causes can be classified into three types: Type 1, bleeding from a disrupted artery at the lower part of the uterus; Type 2, bleeding from a disrupted artery at the upper part of the uterus; and Type 3, bleeding due to uterine atony (2). Uterine bleeding of Type 1 and Type 2 is not stopped by uterotonic agents alone, while Type 3 is successfully controlled with uterotonic agents. Although both Types 2 and 3 have long been categorised as “uterine atony”, Type 2 bleeding, a subtype of conventional “uterine atony” in intractable PPH, cannot be resolved by the enhancement of uterine contractions alone. According most common protocols,
after use of uterotonic drugs, placement of a Bakri balloon is indicated. However, the Bakri balloon fails to control bleeding in 12.5% of PPH \(^{(4)}\), probably partially due to failure of direct compression of the bleeding site by balloon tamponade. Identification of the precise bleeding site is therefore important to manage intractable PPH. Although the sites of active bleeding can be detected on gray scale and color Doppler imaging \(^{(5,6)}\), the usefulness of ultrasound assessment of uterine bleeding sites has not been reported in the context of management of intractable PPH due to uterine atomy. The present case shows that prompt conservative intervention using a Bakri balloon in combination with ultrasonographic visualisation of bleeding sites can prevent serious PPH.
