Fractures of The Pelvis:
Problems and Results of Surgical Treatment

SUMMARY

Pelvic fractures have been the domain of conservative treatment and reduction by closed methods for a long time. In the last decades advances in classification and understanding of these often very complex fractures have been made. They are now discriminated into fractures of the apophysis, acetabular fractures and fractures of the pelvic ring. By a better understanding of the functional biomechanics and the morphological changes a number of clear and valid indications for operative procedures has been worked out. Certain pelvic ring disruptions and acetabular fractures can be stabilized after open reduction and provide better functional long time results. As the surgical approach and operative technique can be rather difficult and the concept has to be fitted to the individual case it is almost impossible to give general guidelines for the surgical management.

INTRODUCTION

The pelvis as a rigid ring is made up of ilium, public rami, acetabulum, ischium and sacrum, joined by tough fibrous tissue at the symphysis and sacroiliac joints. The static force of body weight is transmitted from the vertebra over sacrum and cranial pillars of the acetabular roof to the dorsal pillars of the hip joint. The tight junction by ligaments between iliac and symphysis joints allows a rigid—however in some way elastic and very resisitant—ring construction that can only be disrupted by extreme forces.\(^{17}\)

The tradional classification of pelvic fractures has been used since 100 years\(^{15}\). Although acetabular fractures frequently occur in combination with many other pelvic fractures, they require separate treatment because the prognosis for function is worse than in other pelvic fractures. Major lesions of the pelvic ring in our opinion are disruptions of the posterior or anterior pelvic ring, whereas fractures of the pelvis involving the hip joint need separate consideration. Today we see an indication for operative treatment in instable pelvic ring fractures and acetabular fractures with dislocation.

**FRACTURES OF THE PELVIC MARGIN**

Fractures of the pelvic margin usually neither disturb the stability of the pelvic ring nor the function of the hip joint. Conservative treatment is the therapy of choice in these lesions in almost any case. There is no need for specific relief. Bed rest is required as long as is necessary to relieve pain.

In a farther sense avulsion fractures of points of muscle attachment from the ischial tuberosity or anterior superior or inferior iliac spine as well as adductor muscles from symphysis can be accounted to this type of injury. Treatment requires only bed rest with the hip in flexion. Only in younger patients with athletic ambition the operative reattachment of avulsed bone fractures of tendon insertions can be indicated in single cases, as the athletic ability otherwise may be reduced.

**FRACTURES OF THE PELVIC RING**

Pelvic ring fractures occur through direct deformation as a result of lateral or sagittal compression or through friction and rotation forces, mostly indirectly by the femoral head. A classification is senseful with a discrimination into stable and instable pelvic ring disruptions. The proposals of MÜLLER-FÄRBER and MÜLLER seem to be very useful in this context (Table 1). This classification⁶, as well as recent advances in diagnosis¹¹ and external fixation⁷.¹⁴ have led to a clear concept in surgical indications for therapy.

Isolated disruptions of the anterior pelvic ring do not need an operative stabilization because of biomechanical reasons (Type I, Table 2). In severe additional injuries like lesions of the lower urinary tract or vascular lesions (Fig. 1) however a surgical stabilization of these fractures is
Fig. 1 52 years old male patient with overrun trauma and pelvic ring fracture (Type IIa) (1a) with disruption of the symphysis and urethra (1b) and disruption of external iliac artery (1c). Before the vascular reconstruction (1d) the os pubis is stabilized with osteosynthesis plate (1e).
necessary after the operative treatment of these above mentioned injuries to avoid further disruption and further additional injuries.

If the injuring force is extremely high the posterior pelvic ring is damaged. This is always associated with the disruption of the anterior pelvic ring. In the simplest case we only see a rupture of the anterior iliosacral ligaments opening the two pelvic halves like the leaves of a door (Table 1, Type II).

By using the operative outer ventral fixation of the pelvis the lesion will heal in almost all cases with good results. A conservative treatment with longitudinal traction and a pelvic sling should no longer be considered as therapeutic measure in patients with polytrauma.

Often there are additional injuries of the lower urinary tract. If these injuries are operated upon, we prefer the stabilization in the same session using a osteosynthesis plate readapting the symphysis. In each other case we stabilize the anterior pelvic ring with an external fixateur, which minimizes the danger of infection. Usually we prefer the trapezoid-like mounting (Fig. 2)\(^6\).

Complete posterior pelvic ring fractures (Type III, Table 1) lead to major dislocations. The lateral part of the pelvis is tracted cranially with the hip joint in these cases. These dislocations are more excessive in complete ligamentous lesions of the iliosacral joint than in merely osseous lesions (for instance: fractures through the lateral mass of sacrum or os ilium), because the later ones tend to hook themselves into one another.

Conservative treatment with pelvic sling and additional supracondylous extension is no longer acceptable today. In addition the reposition results are often very unsatisficing. For a better judgement of deformations of the pelvic ring and dislocations of the iliosacral joint as well as for control purposes after reposition we demand X-ray examinations in the technique described by Pennal et al.\(^1\).

The fixation of the anterior ring alone is not sufficient in these complete pelvic ring destructions. Because of the enormous friction forces towards the two halves of pelvis the application of a fixateur externe alone is not sufficient enough. Open reduction of these fractures is recommended for sufficient stabilization ad reposition results. The disrupted iliosacral joint can be refixed by long spongiosa screws being brought into the lateral mass of sacrum through the os ilium like an ar-
throdesis (Fig. 2). However in addition the anterior pelvic ring has to be braced with a fixateur externe construction.

Thus pelvic ring fractures of Type I can be fully stressed immediately after the accident. Type II injuries need a healing period of 6 weeks and Type III injuries of 12 weeks after full load can be carried out. If the reposition is sufficient prognosis is good in these cases.

**FRACTURES OF THE ACETABULUM**

Fractures of the hip joint area need a separate consideration because they impair not only the stability of the pelvic ring but also the hip joint function. The hip joint was the last big joint being operatively reconstructed as the access to these structures is rather difficult. The complex threedimensional construction of the pelvis and the difficulties in stabilization procedures allowed only conservative treatment of fractures and luxations in the past. However after the publications of JUDET and LETOURNEL valid and senseful operative indications have been worked out in the last years.

Acetabular fractures are caused by force transmitted in the longitudinal axis of the femur to the acetebalum. They can be associated with lesions of the femoral head or of the neck of the femur. The force is transduced mainly along the dorsal and cranial pillars rather than the ventral pillar. These biomechanical aspects have to be considered in the management of those fractures. The simple discrimination into ventral and dorsal hip luxation fractures used in the past was sufficient only for conservative therapy measures.

**Diagnostics**

The most common classification of the different types of acetabular fractures is the one published by JUDET and LETOURNEL (Table 2). It respects the biomechanical aspects as well as the operative techniques. However the exact amount of the fracture can sometimes only be found during the operation. So-called Ala- and Obturator X-ray-examinations of the hip are often proposed for better exposure of the ventral pillars of hip roof and dorsal joint margin. We prefer computer-tomography, which reveals the whole amount of joint involvement and can show additional pelvic injuries.

**Operative treatment**

Reduction of acetabular fractures is one of the most complex surgical maneuvers in trauma surgery. Therefore general recommendations for routine procedures cannot be given. The most common acetabular fracture is the avulsion of the dorsal acetabular margin. The femoral head is chiseled off by force in the longitudinal axis of the femur in flexion. There is almost a luxation of some amount.

In rim fractures with posterior dislocation the blood supply to the femoral head is disrupted, and aseptic necrosis occur in approximately 50 percent of the patients. This fracture should be treated as an emergency. Reduction should be prompt. Should reduction not be done easily with gentle upward traction with the hip flexed, the femoral head may be trapped by a band of posterior capsule or by piriformis tendon. Open reduction is then necessary, and internal fixation of the rim fragment
Fig. 3 Luxation fracture of the left hip joint with avulsion of the dorsal acetabular roof (3a) in a 23 year old male patient. Immediate closed reduction with interposition of the fragment into the joint (3b, c). (3d) X-ray after operative correction.
Fig. 4 32 year old patient with avulsion of the dorsal and ventral acetabular roof (4a). Dorsal access and reconstruction with two osteosynthesis plates after removement of the major trochanter (4b).

Fig. 5 34 year old male patient with severe damage of the acetabulum with central fracture of the total acetabular roof and right pelvic bones (5a). Exposition of the hip joint from the outside and inside via ilio-inguinal access. Iliac muscle was detached from the inside and medial and minimal adductor muscle had to be detached from the outside. Stabilization with singular traction screws and reconstruction plates (5b).

should be done. The closed reduction can cause an interposition of the fragment into the joint leading to great pain. In such cases an operative reduction has to be performed as soon as possible (Fig. 3).

The way of operative approach depends on the type of fracture\(^2\). If a rim fragment is avulsed dorsocranially a posterior approach is necessary. Usually this way allows stabilization of a dorsal pillar fracture or transverse fractures also.
In all cases of avulsion of a dorsocranial rim fragment we see an absolute indication for fixation with traction screws (Fig. 4). Conservative treatment using a femur distraction will only lead to a good functional success in the very rare fractures without dislocation. To avoid posttraumatic arthrosis the hip joint must be reconstructed without any steps. An impression of the acetabular fracture margin which is rather frequent has to be perceived and should be treated by filling up the defect with autologous spongious bone transplants.

In cases of total demolition of the dorsal acetabular roof fragments are tightened with osteosynthesis plates, because only bigger pieces can be refixed with traction screws. Traumatic arthrosis frequently occurs after this injury, but the patient may have many years of useful function before this complication ensues. If the cranial acetabular roof is destroyed the dorsal standard approach has to be extended. The greater trochanter has to be chiseled off and the insertions of the medial and minimal gluteus muscle are tipped up. Thus the cranial acetabular roof can be surveyed better and iatrogenic injuries to the superior gluteal nerve may be avoided (Fig. 4).

Sometimes we need more complex operative approaches in other types of fractures. These are for instance the methods of SMITH/PETERSON or JUDET/LETOURENEL, in which the hip joint is exposed from the inner side of the pelvis. In some cases the hip joint has to be exposed from the outside and the inner side (Fig. 5). Reduction of pillar- and transverse fractures still remains difficult. Stabilization of these fractures is achieved through compression-plate-osteosynthesis or traction screws. There is no general guide line for the management of complex acetabular fractures which may need a combined dorsal and ventral operative approach. These fractures should be treated only by the experienced specialist.

**Postoperative Care**

A movement with full body weight should not be performed by the patients before 12 weeks after the operation of an acetabular fracture. Greater demolitions and persistant defects demand even longer periods of relief. However therapeutical physical mobility exercises should be started as early as possible.

The open reduction of acetabular fractures has led to better functional results. The risk of traumatic arthrosis is still very high in fractures with many fragments and in fractures with delayed operations, because often it is not possible to reconstruct the hip without any steps in these cases.

**PELVIC FRACTURES IN POLYTARUMA**

Pelvic fractures in patients with polytrauma need a special consideration. On the one hand extensive operative procedures for complex acetabular fractures with a prolonged operation time and additional blood loss may be disadvantageous for the patient. On the other hand pelvic ring fractures often lead to a severe bleeding themselves, which can only be stopped by an operative stabilization of the pelvic ring. In the own experience the stressing reconstructions of the acetabulum were not performed immediately. Sometimes a difficult general condition of the patient allowed operative reconstruction of the pelvis only several weeks after the injury. An exact reposition of the fragment could not always be achieved after that time.

In opposition to these circumstances the stabilization of the pelvic ring to seize the retroperitoneal bleeding with an external fixation is not very stressing and can be done easily.
Table 3  Pelvic ring fractures in the Department of Surgery, Bonn University between 1979 and 1988.

Table 4  Pelvic fractures in Polytrauma; Development of number of immediate operations and letality.
Whereas in the first years we decided to stabilize the pelvic ring only in cases of failure of conservative treatment, we now propose the stabilization with an external fixateur as a routine emergency procedure especially in polytraumatized patients (Table 3, 4).

In conclusion it must be stated that therapy of pelvic fractures in polytrauma often will need compromises. The older the patient the more we will renounce extended joint reconstructions and perform live saving measures only. These however may include external fixation procedures.
