Effective tsunami early warning for coastlines near a tsunamigenic earthquake requires notification within 5-15 minutes. We have shown recently that tsunamigenic earthquakes have an apparent rupture duration,  $T_0$ , greater than about 50 s. Here we show that  $T_0$  gives more information on tsunami importance than moment magnitude,  $M_w$ , and we introduce a procedure using seismograms recorded near an earthquake to rapidly determine if  $T_0$  is likely to exceed  $T=50$  or 100 s. We show that this “duration-exceedance” procedure can be completed within 3-10 min after the earthquake occurs, depending on station density, and that it correctly identifies most recent earthquakes which produced large or devastating tsunamis. This identification forms a complement to initial estimates of the location, depth and magnitude of an earthquake to improve the reliability of tsunami early warning, and, in some cases, may make possible such warning.

## Introduction

Effective tsunami early warning for coastlines near a tsunamigenic earthquake requires notification within 5-15 minutes after the earthquake origin time (OT). Organizations such as the Japan Meteorological Agency (JMA), the German-Indonesian tsunami early warning system (GITEWS) and the West Coast and Alaska (WCATWC), and Pacific (PTWC) Tsunami Warning Centers first identify potentially tsunamigenic earthquakes based on rapidly determined earthquake parameters such as location, depth and magnitude. JMA issues warnings for Japan about 3 min after OT for events expected to produce a tsunami with height exceeding 0.5 m. GITEWS issues warnings for Indonesia within 5 min after OT based on the earthquake parameters and corresponding, pre-calculated tsunami scenarios. WCATWC and PTWC issue regional warning notifications within about 5-10 min after OT for shallow, underwater events around North America and in the Pacific basin with moment magnitude  $M_w \geq 7.5$  [e.g., *Hirshorn et al.*, 2009].

Recently, through analysis of teleseismic,  $P$ -wave seismograms ( $30^\circ$ - $90^\circ$  great-circle distance; GCD), we have shown that an apparent rupture duration,  $T_0$ , greater than about 50 s forms a reliable indicator for tsunamigenic earthquakes [*Lomax and Michelini*, 2009; *LM2009* hereinafter]. Here we exploit this result and introduce a “duration-exceedance” procedure to rapidly determine if  $T_0$  for an earthquake is likely to exceed 50 or 100 s and thus to be a potentially tsunamigenic earthquake. This procedure does not require accurate knowledge of the earthquake location or magnitude and can be completed within 5-10 min after OT for most regions in the world.

## Tsunami importance, moment magnitude and rupture duration

We consider a reference set of 76 underwater earthquakes since 1992 with  $M_w \geq 6.6$  (Table S1). Since there is currently no uniform, physical measure of size available for most tsunamis, following *LM2009*, we define an approximate measure of tsunami importance,  $I_t$ , based on 0-

42 4 descriptive indices,  $i$ , of tsunami effects (deaths, injuries, damage, houses destroyed), and  
43 maximum water height  $h$  in meters from the NOAA/WDC Historical Tsunami Database  
44 ([http://www.ngdc.noaa.gov/hazard/tsu\\_db.shtml](http://www.ngdc.noaa.gov/hazard/tsu_db.shtml)):  $I_t = i_{\text{height}} + i_{\text{deaths}} + i_{\text{injuries}} + i_{\text{damage}} + i_{\text{houses-destroyed}}$ ,  
45 where  $i_{\text{height}} = 4, 3, 2, 1, 0$  for  $h \geq 10, 3, 0.5$  m,  $h > 0$  m,  $h = 0$  m respectively. We set  $I_t = 0$  for events  
46 not in the database, and note that  $I_t$  is approximate and unstable since it depends strongly on  
47 the available instrumentation, coastal bathymetry and population density in the event region.  
48  $I_t \geq 2$  corresponds approximately to the JMA threshold for issuing a “Tsunami Warning”; the  
49 largest or most devastating tsunamis typically have  $I_t \geq 10$ .

50 Figure 1 shows a comparison of  $I_t$  with the Global Centroid-Moment Tensor (CMT) moment-  
51 magnitude,  $M_w^{\text{CMT}}$  [Dziewonski *et al.*, 1981; Ekström *et al.*, 2005], and with  $T_0$  durations  
52 calculated from high-frequency,  $P$ -wave seismograms at teleseismic distance following the  
53 procedure of LM2009. The thresholds  $M_w^{\text{CMT}} \geq 7.5$  and  $T_0 \geq 50$  s both identify most of the  
54 events with  $I_t \geq 2$  (see also Tables 1 and S1).  $M_w^{\text{CMT}}$ , however, shows no clear relationship to  $I_t$   
55 or to event type; in contrast,  $T_0$  tends to increase for larger  $I_t$ , especially for tsunami  
56 earthquakes (type T; characterized by unusually large tsunamis and a deficiency in moment  
57 release at high frequencies, *e.g.*, Satake [2002]). We do not consider here the energy-to-  
58 moment parameter,  $\Theta$ , which is useful for identification of tsunami earthquakes [Newman and  
59 Okal, 1998], because it is not a good indicator for tsunamigenic events in general [*e.g.*,  
60 LM2009].

61 Since CMT-based  $M_w$  magnitudes are only available 30 min or later after OT, rapid magnitude  
62 estimates such as  $M_{\text{wp}}$  [Tsuboi *et al.*, 1995; Tsuboi *et al.*, 1999] are used for tsunami warning.  
63 But  $M_{\text{wp}}$  performs poorly relative to  $M_w^{\text{CMT}}$  or  $T_0$  for identifying events with  $I_t \geq 2$  (Table 1).  
64 Other rapid magnitude estimates for large earthquakes [*e.g.*, Hara, 2007;  $M_{\text{wpd}}$ , LM2009;  $m_{\text{Bc}}$ ,  
65 Bormann and Saul, 2009] may perform nearly as well as  $M_w^{\text{CMT}}$  or  $T_0$  (*e.g.*,  $M_{\text{wpd}}$  in Tables 1  
66 and S1), but are not available until about 15 min or later after OT. Thus very rapid  
67 determination of a large  $T_0$ , *e.g.*  $T_0 \geq 50$  s, would provide important complementary information  
68 to initial location, depth and magnitude estimates for early assessment of earthquake  
69 tsunamigenic potential.

## 70 Methodology for rapid rupture duration determination

71 We determine if  $T_0$  for an earthquake is likely to exceed pre-determined thresholds  $T = 50, 100$   
72 s through high-frequency (HF) analysis of vertical-component, broadband seismograms [*e.g.*,  
73 Lomax, 2005; Lomax and Michelini, 2005; Lomax *et al.*, 2007; LM2009]. We proceed as  
74 follows for each seismogram (Figure 2): 1) apply a 4-pole, 1-5 Hz Butterworth band-pass  
75 filter to form a HF trace; 2) auto-pick the  $P$  arrival time on the HF trace; 3) measure  $A_{\text{ref}}$ , the  
76 *rms* amplitude for the first 25 s after the  $P$  time on the HF trace; 4) calculate the ratio of the  
77 *rms* HF amplitude from 50-60 s after the  $P$  time with  $A_{\text{ref}}$  to obtain a station duration-  
78 exceedance level for 50 s,  $l_{50}$ , and a similar ratio for 100-120 s after  $P$  with  $A_{\text{ref}}$  to obtain  $l_{100}$ .

79 We define event duration-exceedance levels,  $L_T$ ,  $T = 50, 100$  s, as the median (50 percentile) of  
80 the station  $l_{50}, l_{100}$  values after removing the upper 10 percentile of values to avoid noisy or  
81 anomalously long HF signals. If an event exceedance level  $L_T$  is greater (less) than 1.0, then  
82  $T_0$  is likely (unlikely) to exceed  $T$  seconds. This procedure does not require an event location  
83 or magnitude, and all processing can be performed in the time domain; indeed, individual  
84 station  $l_{50}$  and  $l_{100}$  values can be calculated autonomously at each station.

## 85 Application to reference earthquakes

86 We apply the duration-exceedance procedure to the reference earthquakes using data up to 10  
87 min after OT from stations at 0-30° GCD from each event to simulate the information  
88 available in the first minutes after an earthquake occurs. The  $L_{50}$  exceedance level results are

89 tabulated in Table 1 and all event parameters and exceedance level results in Table S1; plots  
90 of the time evolution of the  $L_{50}$  calculation for two events are shown in Figure 3, and for  $L_{50}$   
91 and  $L_{100}$  for selected events in Figure S1 in the supplement.

92 A comparison of  $L_T$ ,  $T=50, 100$  s, with the  $T_0$  durations calculated from teleseismic  
93 observations (Figure 4a; Table S1) shows that, in general, the duration-exceedance level  $L_T$   
94 increases with increasing  $T_0$  and is greater than 1 for events with  $T_0>T$ . There is much scatter  
95 in these results, due primarily to the difficulty in determining cutoff points on the HF  
96 seismograms (e.g., Figure 2; LM2009), but they confirm that the rapidly available  $L_T$   
97 measures form reliable proxies for the teleseismic,  $T_0$  durations.

## 98 Discussion

99 A comparison of the  $L_{50}$  exceedance level with tsunami importance,  $I_t$ , (Figure 4b; Tables 1  
100 and S1) shows correct identification ( $L_{50}\geq 1$ ) of most events with  $I_t\geq 2$ . The miss-identified  
101 events are a shallow, offshore thrust event,  $I_t=8$ , 2003.05.21,  $M_w$ 6.8, N Algeria, and two  
102 shallow, oceanic, strike-slip events,  $I_t=13$ , 1994.11.14,  $M_w$ 7.1, Philippines and  $I_t=9$ ,  
103 2006.03.14,  $M_w$ 6.7, Seram Indonesia. All of these events are also missed using the magnitude  
104 discriminant,  $M_w\geq 7.5$ , and thus produced larger than expected tsunamis. There are 13 events  
105 with  $I_t<2$  that are falsely identified by  $L_{50}\geq 1$  values as likely tsunamigenic ( $I_t\geq 2$ ); 7 of these  
106 events have  $I_t=1$  and thus produced small tsunamis, while some may have involved under land  
107 or strike-slip rupture, or produced unobserved tsunamis. The remaining events with  $I_t<2$  are  
108 correctly identified as unlikely tsunamigenic by  $L_{50}<1$  values. For most events, the  $L_{50}$  values  
109 have stabilized within 4-6 min after OT (Figures 3 and S1).

110 The  $L_{50}$  discriminant correctly identifies 90% of tsunamigenic events with  $I_t\geq 2$ . The overall  
111 performance of the  $L_{50}$  discriminant is similar to that of  $M_w^{CMT}$ ,  $M_{wpd}$ , and teleseismic  $T_0$  (Table  
112 1), though these latter three measures are not available until at least 30, 15 and 15 min,  
113 respectively, after OT [LM2009]. In contrast, the rapidly available  $M_{wp}$  discriminant correctly  
114 identifies only 52% of tsunamigenic events with  $I_t\geq 2$ , primarily because  $M_{wp}$  underestimates  
115 the size of events with  $M_w^{CMT}>7.0-7.5$ , particularly tsunami earthquakes and other events with  
116 long rupture duration [e.g., LM2009].

117 The results for  $L_{100}$  (Figure 4; Table S1) show that  $L_{100}\geq 1$  identifies well events with longer  
118 duration,  $T_0$ , events with  $I_t\geq 10$ , and most tsunami earthquakes (type T). In contrast,  
119 1994.11.14 Philippines, 1998.07.17 Papua New Guinea, and two intraplate events (type P)  
120 with only moderately long  $T_0$  but large  $I_t$  have  $L_{100}<1$  values. For events in regions with  
121 denser station coverage, the  $L_{100}$  values have stabilized by 6-8 min after OT (Figure S1).

122 Since the station  $l_T$  exceedance values can be calculated autonomously at each station, they  
123 could aid in providing very early, local tsunami warning. For example, the first station  $l_{50}$   
124 values for the 2006 Indonesian event in Figure 3 are available only 2-4 min after OT. Single  
125  $l_T$  exceedance values must be used with care, however, as they can be biased at small  
126 epicentral distances by HF radiation effects and secondary phases, especially S.

## 127 Conclusions

128 We have shown that apparent rupture duration,  $T_0$ , provides more information on tsunami  
129 importance,  $I_t$ , than does moment magnitude and that earthquakes with a high tsunamigenic  
130 potential (e.g., possible tsunami importance  $I_t\geq 2$  or  $I_t\geq 10$ ) can be rapidly and reliably  
131 identified through a procedure that determines if  $T_0$  is likely to exceed 50 or 100 s. This  
132 identification can be performed within 5-10 min after OT for most regions using currently  
133 available seismographic stations, and probably in less than 3-5 min for regions with higher  
134 station density, such as Japan, Taiwan, Indonesia, the Mediterranean and Western North  
135 America. This identification forms a complement to initial estimates of the location, depth

136 and magnitude of an earthquake to improve the reliability of tsunami early warning, and, in  
137 some cases, may make possible such warning.

## 138 **Acknowledgements**

139 We thank Alessio Piatanesi and two reviewers for helpful comments. This work is supported  
140 by the 2008-2010 Dipartimento della Protezione Civile S3 project. We use SeisGram2K  
141 (<http://www.alomax.net/software>) for seismogram analysis and figures, GMT  
142 (<http://gmt.soest.hawaii.edu/>) and OpenOffice.org Calc for graphs. The IRIS DMC  
143 (<http://www.iris.edu>) provided access to waveforms used in this study.

 182 apparent source duration,  $T_0$ , calculated from teleseismic observations. Event labels show  
 183 event type for non interplate-thrust events with  $I_t \geq 2$  ( $T$ –tsunami earthquake;  $P$ –intraplate;  $So$ –  
 184 strike-slip oceanic,  $S$ –strike-slip continental,  $R$ –reverse-faulting ).

185 **Figure 2**

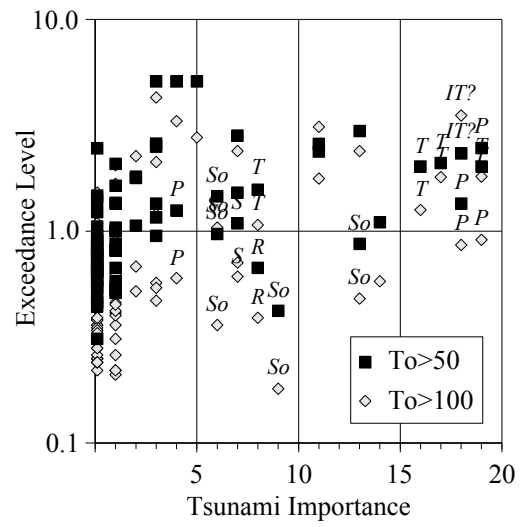

186 Raw, broadband velocity seismogram, HF seismogram and smoothed *rms* amplitude of HF  
 187 seismogram for two events: (upper 3 traces) 2006.07.17,  $M_w$ 7.7,  $T_0$ =180 s,  $I_f$ =18, Indonesia  
 188 tsunami earthquake recorded at station COCO at 11° GCD, and (lower 3 traces) 2008.04.09,  
 189  $M_w$ 7.0,  $T_0$ =23 s,  $I_f$ =0, Loyalty Islands interplate thrust recorded at station AFI at 19° GCD.  
 190 OT – origin time; P – automatic *P* pick; P to Ar, T50 and T100 – time windows (shaded) for  
 191 calculation of *rms* HF amplitude for  $A_{ref}$ ,  $l_{50}$  and  $l_{100}$ , respectively.

192 **Figure 3**

193 Evolution for 10 min after OT of the  $T_0 > 50$  s exceedance level ( $L_{50}$ ) calculation for: (upper)  
 194 2006.07.17,  $M_w 7.7$ ,  $T_0 = 180$  s,  $I_t = 18$ , Indonesia tsunami earthquake, and (lower) 2008.04.09,  
 195  $M_w 7.0$ ,  $T_0 = 23$  s,  $I_t = 0$ , Loyalty Islands interplate thrust. Blue lines show  $P$ -arrival times for  
 196 each station; red, yellow or green horizontal bars show the station exceedance levels,  $l_{50}$ ,  
 197 starting at its first reported time (about 60 s after the corresponding  $P$  time). Histogram  
 198 shows  $l_{50}$  values at 600s; the median (50 percentile) and bounds (20 and 80 percentile),  
 199 respectively, for  $L_{50}$  are indicated by solid and dotted white lines on the main plot and as a  
 200 colored diamond and error bar. Red indicates  $l_{50}$  (or  $L_{50}$ )  $\geq 1$  (likely that  $T_0 > 50$  s and  $I_t \geq 2$ );  
 201 yellow indicates  $0.7 \leq l_{50}$  (or  $L_{50}) < 1$  (possible that  $T_0 > 50$  s and  $I_t \geq 2$ ); green indicates  $l_{50}$  (or  
 202  $L_{50}) \leq 0.7$  (unlikely that  $T_0 > 50$  s or  $I_t \geq 2$ ). For both events the  $L_{50}$  values have stabilized by 4-6  
 203 min after OT. For real-time monitoring, comprehensive information about exceedance level  
 204 could be provided by a time-sliding display similar to the above.
