Abstract: Fracture toughness is one the most important parameters for design applications and performance assessment of cemented carbides. Different from hardness, fracture toughness is commonly a property more difficult to evaluate, particularly in brittle materials. A large number of different testing methods have been introduced to evaluate toughness of hardmetals, but in general all of them have either theoretically debatable issues or important experimental difficulties. In this study, three different fracture toughness testing methodologies are investigated: three-point bending on Chevron notched specimen ("reference" baseline), Palmqvist indentation test, and Hertzian indentation method. The work is conducted in several cemented carbide grades with different microstructures, in terms of both WC grain size and Co binder content. Aiming to have a comprehensive view of fracture toughness - microstructure relationship, the mechanical study is complemented by an accurate microstructural characterization; and experimental findings are finally analyzed and discussed on the basis of two theoretical models proposed in the literature.

FRACTURE TOUGHNESS OF CEMENTED CARBIDES: TESTING METHOD AND MICROSTRUCTURAL EFFECTS

Highlights:

- Microstructural characterization is carried out using EBSD for nine different cemented carbide grades with varying grain size and cobalt content.
- Fracture toughness is determined using three different methods, and a comparison has been tried to establish between true fracture toughness (“reference”) baseline method and results obtained from two different Indentation methods.
- Microstructural parameters obtained from EBSD are correlated to basic mechanical properties with much focus on fracture toughness.
- Theoretical fracture toughness models which utilize microstructural parameter details for each grade is also utilized and compared with the true fracture toughness for a wide range of binder composition and grain size of hardmetals.

FRACTURE TOUGHNESS OF CEMENTED CARBIDES: TESTING METHOD AND MICROSTRUCTURAL EFFECTS

Abstract

Fracture toughness is one the most important parameters for design applications and performance assessment of cemented carbides. Different from hardness, fracture toughness is commonly a property more difficult to evaluate, particularly in brittle materials. A large number of different testing methods have been introduced to evaluate toughness of hardmetals, but in general all of them have either theoretically debatable issues or important experimental difficulties. In this study, three different fracture toughness testing methodologies are investigated: three-point bending on Chevron notched specimen ("reference" baseline), Palmqvist indentation test, and Hertzian indentation method. The work is conducted in several cemented carbide grades with different microstructures, in terms of both WC grain size and Co binder content. Aiming to have a comprehensive view of fracture toughness – microstructure relationship, the mechanical study is complemented by an accurate microstructural characterization; and experimental findings are finally analyzed and discussed on the basis of two theoretical models proposed in the literature.

1 Introduction

WC-Co cemented carbides, also referred to as hardmetals, exhibit an excellent combination of mechanical properties. This is the main reason for its successful implementation as tool materials in a wide range of applications: metal cutting, mining, machining and metal forming, among others [1]. Among these properties, fracture toughness is one the most important parameters for design applications and performance assessment of cemented carbides. Keeping fair toughness and maximizing hardness are prime concerns of hardmetal industry. However, different from hardness, fracture toughness is commonly a property more difficult to evaluate, particularly in brittle materials. In this regard, a large number of different testing methods have been introduced to evaluate toughness of hardmetals: Palmqvist indentation method, impact strength test on plane or notched bars, fracture mechanics protocols using either notched (Chevron or V-notch) or precracked specimens, etc. (e.g. Refs. [2-7]). In general, all of them have either theoretically debatable issues or important experimental difficulties [7,8]. This is specifically true for approaches based on conventional fracture mechanics testing, where introduction of sharp and residual stress – free cracks into specimens are required.

Within the above framework, an effort is here proposed to evaluate different fracture toughness testing methodologies where above experimental limitations are avoided: three-point bending on Chevron notched specimen (e.g. Ref. [9]) as “reference” baseline, the practical Palmqvist indentation test, and Hertzian indentation method [10]. Different from the former two approaches, the use of the latter for assessing fracture toughness of cemented carbides has been quite limited [11], even though it has similar advantages offered by the Palmqvist method compared with the more conventional testing protocols, i.e. a straightforward experimental procedure, minimal specimen preparation, and small amount of needed material needed [10]. The systematic study attempted is conducted in several cemented carbide grades with different microstructures, in terms of both WC grain size and Co binder content. Aiming to have a comprehensive view of fracture toughness – microstructure relationship, the mechanical study is complemented by an accurate estimation of single- and two-phase microstructural parameters, i.e. carbide grain size and cobalt content, as well as cobalt binder mean free path and carbide contiguity, respectively. Finally, experimental findings are analyzed and discussed on the basis of two theoretical models proposed in the literature by other authors.

2 Materials and experimental methods

2.1 Materials and microstructural characterization

Nine different cemented carbides with varying grain size and cobalt content were manufactured for the experiments. The materials were consolidated by liquid phase sintering at temperatures in the range between 1390 °C and 1470 °C following the conventional powder metallurgy route. Nominal compositional details with varying cobalt binder content and carbide grain size for each hardmetal grade studied are listed in **Table 1**. Scanning electron microscopy (SEM) micrographs for four of the investigated materials are shown in **Figure 1**.

TABLE 1

FIGURE 1

Microstructure of WC-Co cemented carbides is usually characterized in terms of both single-phase parameters: carbide phase size (d) and cobalt volume fraction (V_{Co}), as well as two-phase ones: carbide contiguity (C) and binder mean free path (λ). These parameters have great influence on the overall properties of hardmetals. Carbide grain size and contiguity were determined by SEM and electron back scattered diffraction (EBSD) with an EBSD system manufactured by HKL using their Channel 5 software. To obtain high quality patterns for the EBSD analysis the specimens were mechanically polished with diamond slurry to 1 μm , followed by ion beam etching (Ar^+) in a JEOL cross section polisher (SM-09010) with 6 kV energy and approximately 1° incident angle. EBSD mapping was performed on a Zeiss Supra 40 high resolution SEM. Optimum step size was chosen in the range 0.06 - 0.15 μm depending on the carbide grain size. The specimens were tilted 70° using a 20 kV voltage at high current mode with 60 μm aperture. After refining the data from faulty indexing, by means of wild spikes correction and noise reduction, grain size maps were constructed. Once the refined maps are obtained, the area of each WC grain can be calculated. Carbide grains may be approximated as spherical, as recommended by Stjernberg *et al.* [12]; and thus, equivalent circle diameter can be used to describe the two dimensional WC grain size. The equivalent diameter for each individual detected grain can then be used for microstructural analysis. Further details on the EBSD characterization are described elsewhere [13-15].

After obtaining orientation maps, MATLAB software was utilized to determine the number of carbide / carbide (N_{cc}) and binder / carbide boundaries (N_{bc}) per unit length. Volume fraction of binder was also

1
2
3
4 calculated using EBSD. On the basis of experimental data gathered, contiguity (C) and binder mean free
5 path (λ) were determined according to [16,17]:
6
7

$$C = \frac{2N_{cc}}{\left(2N_{cc} + N_{bc} * \sqrt{\text{Vol. \% of binder theoretical} / \text{Vol. \% obtained from EBSD}}\right)} \quad (1)$$

8
9
10
11
12
13
14 and

$$\lambda = d * \frac{V_{Co}}{(1 - V_{Co})(1 - C)} \quad (2)$$

15
16
17
18
19
20
21
22
23
24 Microstructural data for the nine hardmetal grades investigated are listed in **Table 1**.

25 26 27 28 29 **2.2 Fracture toughness**

30 31 32 **2.2.1 Chevron-notched three-point bending test**

33
34
35
36 Advantages of toughness measurement of cemented carbides through three-point bending test of
37 Chevron-notched specimens include no pre-cracking requirement and easy testing configuration. Within
38 this context, values assessed following this testing procedure will be used, for comparison purposes, as
39 “reference” baseline for further discussion on testing method and microstructural effects on fracture
40 toughness. Rectangular bars of dimensions (53x3x4 mm³), nine for each hardmetal grade, were
41 manufactured. A Chevron notch was introduced in each specimen by means of electrical discharge
42 machining. Thickness of the cutting wire was 0.15 mm. The Chevron notch angle (θ) was 90° while the
43 tip of the notch was positioned at about 1 mm below the tensile surface. Specimens were broken under
44 three-point bending, with a specimen span S of 16 mm. Tests were conducted in an Instron 8862 electro-
45 mechanical testing device, with overall load capacity of 100kN. For measurement purposes, the device
46 was instrumented with a 5 kN load cell. To be able to measure deflection of the testing sample, a LVDT
47 displacement gauge was used during the test. The stress intensity factor for a Chevron notched specimen
48 loaded in flexure under three-point bending can be expressed as [18-20]:
49
50
51
52
53
54
55
56
57

$$K_{Ic} = \frac{F_{\max} Y_{\min}^*}{B(W)^{1/2}} \quad (3)$$

58
59
60
61
62
63
64
65

1
2
3
4
5 where K_{Ic} is expressed as $MPam^{1/2}$, F_{max} is the maximum load and Y_{min}^* is a geometry factor dependent
6 on a/W [21], where a is initial crack length and W (4 mm) is the height. Finally, B (3 mm) is the
7 specimen width.
8
9

10 11 12 13 14 **2.2.2 Palmqvist Indentation toughness**

15
16
17 Palmqvist indentation toughness was determined on square shaped ($12 \times 12 \times 5$ mm³) cemented carbide
18 specimens. Ten indentations for each grade were carried out on diamond polished surfaces. A 0.75 mm
19 distance between indentations was kept in order to avoid any overlapping effects. Indentation load (P)
20 was 30 kgf, as recommended by ISO 3878 and lengths (L) of cracks starting at the corners of indentation
21 were measured by light optical microscopy at 500X magnification. Palmqvist fracture toughness was
22 assessed from Shetty et al.'s equation [22], according to:
23
24
25
26
27

$$28 \quad K_{Ic} = A\sqrt{H}\left(\frac{P}{\Sigma L}\right) \quad (3)$$

29
30
31
32
33 where H is the hardness (N/mm^2), P is the applied load (N), ΣL is the sum of crack lengths (mm), A is a
34 constant with value of 0.0028, and K_{Ic} is given as $MPam^{1/2}$. For HV_{30} values expressed in (kgf/mm^2),
35 Palmqvist fracture toughness can be calculated as:
36
37
38
39

$$40 \quad K_{Ic} = 0.15\left(\frac{HV_{30}}{\Sigma L}\right) \quad (4)$$

41 42 43 44 45 46 47 **2.2.3 Hertzian Indentation toughness**

48
49
50 Many attempts have been made to use Hertzian indentation – where a hard sphere is pressed into the flat
51 surface of a brittle substrate - to determine fracture toughness of brittle materials [23-25]. In this study,
52 early experimental limitations on the use of this technique are overcome by following the protocol
53 proposed by Warren [10] which simply requires measurement of the fracture load. It is based on a refined
54 stress intensity factor formulation for surface-breaking cracks in steep-stress gradients [26] which enables
55 estimation of the minimum loads necessary to propagate cracks by Hertzian indentation. Thus,
56 indentation tests on a flat surface of a brittle material, performed with a sphere of given radius R and
57
58
59
60
61
62
63
64
65

1
2
3
4 made of the same material, allow measurement of a definite minimum load of fracture ($P_{F\ min}$), which is
5 used for determining fracture toughness (K_{Ic}) according to:
6
7

$$8 \quad K_{Ic} = \left(\frac{E^* P_{F\ min}}{P_{FN}^{\min} R} \right)^{1/2} \quad (5)$$

9
10
11
12
13
14 where E^* is the reduced “specimen+indenter” Young modulus, and P_{FN}^{\min} is a normalized fracture load
15 necessary to propagate short plane cracks of length c , located normal to the free surface and close to the
16 contact zone of radius a .
17
18

19
20
21 At this stage, it should be highlighted that P_{FN}^{\min} is a dimensionless quantity, exclusively dependent on the
22 Poisson ratio (ν) of the material tested (P_{FN}^{\min} values for ν range relevant for this study are: 2025, 2247
23 and 2490 for ν values of 0.21, 0.22 and 0.23 respectively). On the other hand, occurrence of such fracture
24 (radial cracking) event requires propagation of pre-existing flaws. As a consequence, minimum
25 normalized lengths $(c/a)_{min}$ corresponding to surface crack depths in the 5-10 μm range are required. It
26 points out abrasion with fine SiC grits, instead of fine diamond polish, as recommended surface
27 preparation method. However, such abrasion may introduce surface residual stresses, and this effect
28 should be analysed too. Accordingly, two different surface conditions were investigated: one attained
29 through abrasion using SiC 600 grit size, and another corresponding to final polishing using 6 micron
30 diamond. After grinding and polishing, residual stress measurements were carried out using X-Ray
31 diffraction analysis [27]. Residual stresses were determined in the WC phase in both parallel and
32 transversal directions.
33
34
35
36
37
38
39
40

41
42 Regarding experimental issues, Hertzian indentation tests were conducted using spherical hardmetal
43 indenters with two different radii i.e. 1.25 mm and 2.5 mm. After indentation, specimens were inspected
44 with light optical microscope to discern cracking features at the imprint contour. Once the minimum load
45 for cracking was assessed, fracture toughness was finally calculated using equation (5). Such a procedure
46 was conducted for each surface condition and indenter radius in four selected hardmetal grades: A, C, H
47 and I.

4 **3. Results and discussion**
5
6

7
8 **3.1 Microstructural parameters obtained from EBSD and relation to basic mechanical**
9 **properties**
10

11
12 Mechanical properties of WC-Co composites are dependent on volume fraction of each phase and carbide
13 grain size. As the volume fraction of the carbide phase increases, hardness rises and fracture toughness
14 decreases. On the other hand, grades with fine carbides exhibit higher hardness and lower fracture
15 toughness than those with a coarser microstructure. The combined effect of these single-phase parameters
16 may be captured by means of two-phase microstructural parameters such as carbide contiguity and binder
17 mean free path. In general, contiguity is observed to increase as carbide content rises and carbide grain
18 size decreases. **Figure 2** shows EBSD orientation maps obtained. In such images, red and green
19 boundaries correspond to WC-Co and WC-WC interfaces respectively.
20
21
22
23

26
27 **FIGURE 2**
28
29

30
31 Microstructural characteristics, including volume fraction of binder phase, determined from EBSD
32 measurements are presented in Table 2. Values for basic mechanical properties: elastic modulus (E) and
33 Poisson's ratio (ν), determined according to ASTM E1876-01, and hardness (HV30) are also listed in
34 **Table 2**. As expected, hardness is discerned to decrease as binder mean free path rises (**Figure 3**).

47

48 **3.2 Fracture toughness - microstructure correlation**
49
50

51 Chevron-notched three-point bending test is an efficient method for fracture toughness assessment of
52 brittle cemented carbides. In this study, deflection was recorded by a linear variable differential
53 transformer (LVDT) device and a typical force-deflection curve is shown in **Figure 4**. At a critical crack
54 length, the load required to propagate the crack passes through a maximum, and such value is then used
55 for determining fracture toughness. Main advantage of this method is that it avoids any precracking
56 requirement. The values obtained by using this testing method are here used as baseline and are thus
57 referred as "reference" K_{Ic} . **Figures 5-7** display the variation of "reference" K_{Ic} as a function of
58
59
60
61
62
63
64
65

1
2
3
4 hardness, carbide contiguity and binder mean free path, respectively. The results indicate a consistent
5 decrease of fracture toughness with increasing hardness and carbide contiguity, and decreasing binder
6 mean free path.
7
8
9

10 **FIGURE 4**

11 12 13 **FIGURES 5-7**

14
15
16
17 A comparison of the fracture toughness values obtained by the different testing methods investigated is
18 shown in **Table 3**. For most of the hardmetal grades studied, a reasonably good agreement is found
19 between K_{Ic} values obtained through Chevron-notched three-point bending test and Palmqvist
20 indentation. It corresponds to a toughness range from 10 to 14 MPam^{1/2}. However, this was not the case
21 for grade H which exhibits a relatively higher toughness level.
22
23
24
25
26

27 **TABLE 3**

28
29
30
31 Depending on indenter shape, three distinct indentation modes take place in brittle materials. Ring cracks
32 and Hertzian cone cracks are formed when indenter is rounded while lateral vents or median vents are
33 formed when the indenter is sharp. For the case of cemented carbides, median vents are formed in the
34 underlying material and median vents are divided into two types: median cracks and Palmqvist cracks.
35 Schematic of Palmqvist and median cracks are mentioned in detail elsewhere [28]. Crack geometry
36 beneath indentation for grade A is shown in **Figure 8**. This was the cracking scenario discerned for most
37 of the hardmetal grades studied. It clearly follows a Palmqvist crack geometry, a necessary condition for
38 assessing fracture toughness through equation (3).
39
40
41
42
43
44

45 **FIGURE 8**

46
47
48 On the other hand, the combined effect of high binder content and relatively coarse carbides (e.g. H
49 grade) results in a relevant departure from the brittle-like nature suitable for satisfying requirements
50 implicit to application of indentation fracture mechanics [5,7]. For cemented carbide H, a well-defined
51 cracking system (with long enough fissures, as compared to indentation impression size) is not developed
52 at the corners of Vicker's indentations, even if applied load is risen up to 100 kgf. Moreover, increasing
53 the load above 30 kgf also implies a damage or failure risk for the indenter. **Figure 9** shows indentation
54 imprints and induced cracks (under same indentation load) for materials C and H, grades with similar
55 cobalt binder content but different carbide grain size. Looking at the cracking system generated in the H
56
57
58
59
60
61
62
63
64
65

1
2
3
4 grade, it is evident that some of the hypothesis assumed in developing relationships like Shetty et al.'s
5 equation, based on an approximate fracture mechanics analysis [22], are not valid for relatively tough
6 (above 14 MPam^{1/2}) hardmetals. As a consequence, toughness assessed from Shetty et al.'s equation in
7 those materials yield overestimated values.
8
9

10 11 **FIGURE 9**

12
13
14
15 Regarding toughness assessment by means of Hertzian indentation (using an indenter of radius 1.5 mm
16 and surface finish resulting from final polishing using 6 micron diamond), it seems to yield overestimated
17 values for the two fine-grained grades tested (i.e. A and D materials). On the other hand, it results in quite
18 concordant values, as compared to those measured by means of the reference Chevron-notched three-
19 point bending test, for the medium/coarse grained grades (i.e. H and I).
20
21
22

23
24
25 Aiming for a deeper study on the implementation of Hertzian indentation methodology, use of indenters
26 with different radii and surface conditions (abraded with SiC 600 grit size and polished with 6 micron
27 diamond) were tested. Ring cracks formed at the surface of grade C, at applied critical load using the 2.5
28 mm radius indenter, for the two referred surface conditions are shown in **Figure 10**. Furthermore, as
29 surface residual stresses were expected to be introduced through abrasion with SiC 600 grit size, they
30 were measured on two different surfaces, parallel and transverse directions [27]. The results obtained are
31 shown in **Table 4**. It is evident that compressive residual stresses are much higher for abraded specimens
32 than for polished ones. However, and very interesting, they are higher for the harder grades. The effect of
33 different surface treatments (and residual stresses) along with varying spherical indenter radii (r_e) on
34 fracture toughness is shown in **Table 5**. The higher toughness values determined for abraded specimens,
35 as compared to the polished ones under similar testing conditions, are intimately related to the
36 compressive residual stresses induced during surface preparation in the former.
37
38
39
40
41
42
43
44

45 **FIGURE 10**

46 **TABLE 4**

47 **TABLE 5**

48
49
50
51
52
53 In order to obtain the appropriate toughness values through Hertzian indentation using spheres with radii
54 between 1 and 5 mm, preexisting flaws of length between 5 and 10 μ m are required. Accordingly, a
55 relatively coarse surface texture is required. However, mechanical treatment of surfaces for attaining such
56 rough-like profile, usually result in relevant surface residual stresses (e.g. **Table 4**); which may then result
57 in overestimated fracture toughness values. Even if residual stresses are disregarded, an intrinsic
58
59
60
61
62
63
64
65

1
2
3
4 overestimation should also be expected, as the flaw density is not infinite in reality, and cracks will not be
5 situated at the particular position for which critical stress intensity factor is minimum. Beyond these
6 experimental limitations, it should also be highlighted the main advantage of using this method: it does
7 not require any measurement of radius of ring-crack and there is no need to determine initial crack size.
8
9

10
11 Following the above findings, from a practical view it is finally interesting to evaluate the particular
12 measurement reliability of each method as a function of a basic mechanical property such as hardness. In
13 this regard, Chevron-notched three-point bending test yields reliable fracture toughness values for a wide
14 range of cemented carbide grades with varying hardness. Concerning indentation methods, the Hertzian
15 one may be particularly recommended, as compared to Palmqvist method, as far as hardness (HV30)
16 drops below 1300. On the other hand, if HV is higher than 1300; results estimated from Shetty et al.'s
17 equation may be taken as reliable for assessment of fracture toughness.

23
24
25

26 **3.3. Theoretical considerations**

27
28
29

30 Based on different microstructural parameters and assuming deformation in cobalt binder and carbides,
31 different fracture toughness models have been proposed in the past. Using these microstructural
32 parameters, an effort is here carried out to evaluate how experimental data here gathered fit within
33 estimations extracted from two specific models.
34
35
36
37

38 **3.3.1 Godse and Gurland's model (GGM) [29]**

39
40

41 This model uses the idea of ductile fracture proposed by Rice and Johnson [30], i.e. a critical strain should
42 be exceeded for crack growth to take place. Fracture toughness obtained using this model is based on the
43 fact that crack growth resistance comes from the ductile binder (cobalt) and is valid for 10 % to 25%
44 binder volume fraction.
45
46
47
48

49 Fracture toughness K_{Ic} may be estimated from equation (9):
50
51
52
53

$$54 K_{Ic} = \sqrt{R(\lambda + d)E'\sigma_B \frac{(1 - CV_{WC})}{C_1}} \quad (9)$$

55

62
63
64
65

1
2
3
4 where C , d and V_{WC} are the contiguity, grain size and volume fraction of the carbide phase respectively;
5 λ is the binder mean free path; R is a floating parameter calculated on the basis of best fitting with
6 experimental data [29], C_1 is taken from Mcmeeking's work [31] as 0.54, E' can be calculated by using
7 equation (10) for plane stress:
8
9

$$10$$

$$11$$

$$12 \quad E' = \frac{E}{1-U^2} \quad (11)$$

$$13$$

$$14$$

15
16 and σ_B is the binder effective flow stress, calculated by using equation (12) as proposed by Sigl and
17 Fischmeister [6]:
18
19

$$20$$

$$21$$

$$22 \quad \sigma_B = 480 + \frac{1550}{\lambda} [MPa] \quad (12)$$

$$23$$

$$24$$

25

26

27 **3.2 Ravichandran's model (RM)**

28

29
30
31 Ravichandran [32] proposed evaluation of the strain energy release rate (G_C) as the sum of fracture
32 resistance of binder phase and fracture energy of carbide phase according to equation (13):
33
34

$$35$$

$$36 \quad G_C = (1-V_f)G_m + V_f\sigma_o h\chi \quad (13)$$

$$37$$

$$38$$

39
40 where G_m is the strain energy release rate of the brittle WC phase, h is similar as binder mean free path
41 (λ), V_f and σ_o are volume fraction and bulk flow stress of binder. χ is defined as the work of rupture
42 and is related to bulk flow stress of the binder as follows:
43
44

$$45$$

$$46$$

$$47 \quad \chi = \sigma_{eff} \frac{\beta}{\sigma_o} \quad (14)$$

$$48$$

$$49$$

50
51 and bulk flow stress of the binder may be further elaborated using by relating it to effective flow
52 stress σ_{eff} , according to:
53
54

$$55$$

$$56$$

$$57 \quad \frac{\sigma_{eff}}{\sigma_o} = \left[1 + \frac{2k}{3} \left(\frac{d}{2h} \right) \right] \quad (15)$$

$$58$$

$$59$$

$$60$$

$$61$$

$$62$$

$$63$$

$$64$$

$$65$$

1
2
3
4 where d is the carbide grain size and k is the maximum shear factor with a value of 0.577 .
5
6

7 As a final outcome, fracture toughness can be determined by the following relation (16):
8
9

$$K_C = \sqrt{\frac{E_C(1-\nu_m^2)(1-V_f)K_m^2}{(1-\nu_C^2)E_m} + \frac{\beta V_f E_C \sigma_{eff} h}{(1-\nu_C^2)}} \quad (16)$$

10
11
12
13
14

15 where K_C is the fracture toughness of the WC-Co composite, E_C and ν_C are elastic modulus and Poisson's
16 ratio of the composite, β is a constant with value 2, and may is defined as the ratio of critical crack tip to
17 binder thickness; K_m , E_m and ν_m are fracture toughness, elastic modulus and Poisson's ratio of the brittle
18 WC phase.

27 3.3.3. Fitting of experimental data to the models under consideration 28 29

30 A comparison between the "reference" K_{Ic} values and estimations resulting from the above theoretical
31 models are presented in **Table 6**. Both theoretical models utilize different binder flow stress and this is
32 something that needs to be further explored. For instance, RM considers a binder flow stress of 850 MPa,
33 which is lower than the binder flow stress proposed in GGM. On the other hand, GGM requires
34 modification of fitting parameters. As a result, it seems to overestimate the experimental values attained
35 in this study. RM utilizes $\beta=2$, corresponding to a critical crack tip opening displacement at fracture twice
36 the cobalt binder thickness. A slight modification of this parameter ($\beta=1.1$), indicative of an almost one-
37 to-one relationship between critical crack tip opening displacement at fracture and binder thickness yields
38 the best fitting of the experimental data. Further exploitation and adjustment may be done in order to have
39 better estimations from these models.

- Chevron-notch three-point bending test may be taken as “reference” baseline method for determining the fracture toughness for a wide range of binder composition and grain size of hardmetals. Palmqvist method gives a good approximation of toughness for brittle-like cemented carbides, but becomes invalid for grades whose “reference” toughness is higher than $14 \text{ MPam}^{1/2}$. Regarding spherical indentation, optimum indenter radius along with flat surface, free from residual stresses, are important for the determination of fracture toughness. Hertzian indentation may result in overestimated values, this discrepancy becoming significant as hardness of the hardmetal increases.
 - Current fracture toughness models overestimates the experimental “reference” fracture toughness values determined in this study. Slight modifications on fitting parameters associated with intrinsic uncertainties (binder flow stress, critical crack tip opening displacement at fracture, etc.) results in satisfactory agreement between experimental and estimated values.
