The interest in gonio-apparent pigments (metallic, pearlescent, interference, or diffractive) has increased in the last few years, especially for applications in the automotive industry. In order to assure a proper characterization of colors with gonio-apparent pigments, commercial devices have appeared to characterize the color in different geometries, which are called multi-angle spectrophotometers. Since the gonio-apparent pigments and multi-angle instruments are relatively new, no studies exist regarding the instrumental-based procedure followed in the industry, and if the results provided are in agreement with the observer perception.

Consequently, the main objective of this study was to examine the correlation of the instrumental color differences with visual assessments.

The instrumental color difference was calculated with the color difference

1
2 formula AUDI2000 (specific for this sector) between pairs of similar
3
4 samples of three types of coated panels (solid, metallic and pearlescent).
5
6 The values measured by a tele-spectroradiometer in a directional lighting
7
8 booth and the colorimetric values obtained by means of a multi-angle
9
10 spectrophotometer BYK-mac were considered for this purpose. Additionally,
11
12 a visual experiment was conducted to quantify the color difference by using
13
14 the gray scale method.
15
16

17
18 The results revealed that an acceptable instrumental correlation existed
19
20 despite the visual and the instrumental correlation being worse. In
21
22 particular, it was checked that observers accepted a larger number of color
23
24 pairs, that is, the visual color difference was smaller than the tolerance
25
26 demanded by the industry (derived from AUDI2000).

36 1. Introduction

37
38 The interest in gonio-apparent pigments applied in many industries (cosmetics, inks, etc.)
39
40 continues increasing day by day, especially in the automotive sector. This sector has undergone
41
42 many changes and updates in the last years [1, 2], from employing only paints without visual effect
43
44 to use many of them containing gonio-apparent pigments providing new and attractive visual
45
46 effects by combining variable color and texture according to irradiation and viewing directions.
47
48
49
50

51
52
53
54
55 Goniochromatism is a change in any or all attributes of color of a specimen on change in angular
56
57 illuminating-viewing conditions but without change in light source or observer [3]. This happens
58
59
60

1 when the material that is under evaluation includes gonio-apparent pigments. Therefore, it is
2 possible to classify materials into three types according to the pigment recipe and its colorimetric
3 behavior: [4, 5, 6]: solid, metallic and pearlescent or interference coatings (Figure 1, Right). The
4 solid color only includes scattering pigments, and hence, the perceived color does not show
5 significant changes due to the variation of the direction of lighting and/or detection. The metallic
6 coating includes metallic pigments that provide a color shift mainly in lightness. The pearlescent
7 coating includes in its recipe pearlescent pigments (even solid pigments) that provide a color shift
8 mainly due to a hue and a chroma change.

11
12
13
14
15
16
17
18
19
20
21
22
23

24 Currently, in the automotive sector, color quality of automotive coatings with gonio-apparent
25 pigments is performed by characterizing the color under different measurement geometries [5, 7-
26 10]. For this, commercial devices, called multi-angle spectrophotometers, are able to characterize
27 the color in different geometries, such as BYK-mac, or X-Rite MA98, which satisfy ASTM and DIN
28 standards [11-14].
29
30
31
32
33
34
35

36 Although multi-angle spectrophotometers are commonly used in the automotive industry, there
37 are few studies focused on the correlation between instrumental measurements and visual
38 assessments by using rightly directional lighting booths [15-17]. In other words, there are not
39 studies to check if the procedure followed in the industry, mainly based on instrumental measures
40 of a multi-angle spectrophotometer, would match the decision that an observer would give [18].
41 Therefore, the conventional approach using a diffuse lighting booth and an integrating sphere
42 spectroradiometer is not valid for gonio-apparent colors, so it is necessary to use a commercial
43 directional lighting booth such as the gonio-vision box from Merck or the byko-spectra effect
44 cabinet from BYK-Gardner.

1
2 The purpose of this work is to study the correlation of the visual and instrumental assessment of
3
4 the color differences between pairs of similar samples. The instrumental measurements were made
5
6 with two different measurement devices: BYK-mac multi-angle spectrophotometer and PR-650
7
8 tele-spectroradiometer. In addition, a psychophysical experiment that included a directional
9
10 lighting booth was designed to obtain the visual assessments in order to quantify the color
11
12 difference by the comparison with a standard gray scale for color differences.

18 19 **2. Materials and Methods**

20
21
22 A total set of 60 pairs of different samples from solid, metallic and pearlescent pigments were
23
24 selected (Fig. 1 Left). For this work knowing previously the pigment formulation of this panels was
25
26 not important, though it could be interested in other future studies, because we only focused in the
27
28 optical and colorimetric behavior, not structural (pigments type, size, shape, etc.). Figure 1a Left
29
30 shows the a^*b^* and L^*C^* chromatic diagrams with the representation of the 20 solid color pairs.
31
32 The different colors indicate the different measurement geometries, and the different symbol, circle
33
34 and square, the two color samples of one color pairs. Figure 1b Left shows the representation at
35
36 both chromatic diagrams for the metallic color pairs. And finally, Figure 1c Left shows the
37
38 pearlescent color pairs. In this figure it can be seen, the color gamut associated with the selected
39
40 color samples and the behavior of each kind of pigment, solid, metallic and pearlescent.
41
42
43
44
45
46
47
48
49

50 The color differences between pairs of samples were calculated by the color difference formula (1)
51
52 AUDI2000 [19, 20], based on the CIELAB color space. This color difference formula was developed
53
54 by and is used by AUDI, without being endorsed by any standardization body till now, with the
55
56
57
58
59
60

main purpose to manage the color tolerances varying depending on the specific application, paint batch acceptance, color matching for add-on parts in the car body, refinish, etc.

AUDI2000 color difference formula was especially designed for materials with gonio-apparent pigments; then, it considers the changes that these materials show depending on the angle of illumination and observation (flop) as follows:

$$\Delta E_{\gamma} = \sqrt{\left(\frac{\Delta L_{\gamma}}{s_{\Delta L, \gamma} g_{\Delta L}}\right)^2 + \left(\frac{\Delta C_{\gamma}}{s_{\Delta C, \gamma} g_{\Delta C}}\right)^2 + \left(\frac{\Delta H_{\gamma}}{s_{\Delta H, \gamma} g_{\Delta H}}\right)^2} \quad (1)$$

$$s_{\Delta L \gamma_i} = \left(\frac{|L_{\gamma_i}^* - L_{\gamma_{i+1}}^*|}{\gamma_{i+1} - \gamma_i}\right)^{2/3} + 0.002 \cdot C_{45}^* + 0.33 \quad (2)$$

$$= s_{\Delta L \gamma_i, Flop} + s_{\Delta L \gamma_i, Solid} + 0.33 \quad (3)$$

$$s_{\Delta C \gamma_i} = 1.478 \cdot \left(\frac{|C_{\gamma_i}^* - C_{\gamma_{i+1}}^*|}{\gamma_{i+1} - \gamma_i}\right) + 0.014 \cdot C_{45}^* + 0.27 \quad (4)$$

$$= s_{\Delta C \gamma_i, Flop} + s_{\Delta C \gamma_i, Solid} + 0.27 \quad (5)$$

$$s_{\Delta H \gamma_i} = 0.800 \cdot \left(\frac{|C_{\gamma_i}^* - C_{\gamma_{i+1}}^*|}{\gamma_{i+1} - \gamma_i}\right) + 0.004 \cdot C_{45}^* + 0.30 \quad (6)$$

$$= s_{\Delta H \gamma_i, Flop} + s_{\Delta H \gamma_i, Solid} + 0.30 \quad (7)$$

Where “s” are the weighting functions and “g” are the parametric factors for each term, lightness, chroma and hue, and γ is referred to the measurement geometry, with $\gamma_i \in \{15^\circ, \dots, 110^\circ\}$. To obtain a weighting for the measurement angle of 110° we use half the value of the flop term from the 75° angle. For the negative effect angle -15° we specified to use the weighting for the 15° angle multiplied by a factor 1.2. [20].

In this study, the instrumental evaluation is carried out using two different strategies. On one hand, the color difference was calculated by using the measurement data performed by the commercial multi-angle spectrophotometer BYK-mac. This is a device that measures the samples by contact in six different geometries. This methodology is called “direct measurement”, and it is the usual procedure in the automotive sector.

On the other hand, a system consisting of the tele-spectroradiometer PR-650, and the directional lighting booth, the byko-effect spectra cabinet (from BYK-Gardner) [21], were used to obtain the real spectral color stimulus and the corresponding colorimetric values of all samples without contact, never used in the automotive sector, in spite of having directional lighting booths in this sector. The main advantage of this indirect system is that it collects exactly what the observer would perceive, the PR-650 has a telecentric lens, with a measuring area of 1 deg and the distance to the spot area was about 55 cm. For this reason, this methodology was called “(true) visual simulation”. Moreover, a reference white placed at the same position as the samples was measured with the spectroradiometer to allow transformations to CIELAB color space by means of the

1 absolute XYZ values (in cd/m^2), enabling us to apply absolute colorimetry into relative colorimetry,
2 as it is usual in color appearance models [22]. The byko-effect cabinet was selected due to the fact
3 that it allowed measuring the same geometries of illumination / observation that the BYK-mac. It
4 is important to mention that the luminaire of the byko-effect spectra cabinet is a not a good D65
5 simulator, if not it is closer to a D50 simulator [23, 24]. We referred to both methodologies as direct
6 measurement and visual simulation; however, it is important to point out that both arise from
7 different instruments. But, obviously, the method described above can be applied to other
8 directional lighting booths, with or not the same nominal geometries common with other multi-
9 angle spectrophotometers.

23
24
25
26

27 The measurement geometries used were fixed by the multi-angle spectrophotometer and the
28 lighting booth: 45as-15, 45as15, 45as25, 45as45, 45as75, and 45as110, written following ASTM
29 standards (Figure 2). These measurement geometries can be rewritten by following the CIE
30 nomenclature [25] as: $45^\circ\text{x}:-60^\circ$, $45^\circ\text{x}:-30^\circ$, $45^\circ\text{x}:-20^\circ$, $45^\circ\text{x}:0^\circ$, $45^\circ\text{x}:30^\circ$ and $45^\circ\text{x}:65^\circ$, respectively.
31
32
33
34
35
36 The illumination angle was constant for all the measurement geometries.
37
38
39
40
41

42 For the visual evaluation, a psychophysical experiment was conducted by using a gray chart of the
43 Society of Dyers and Colourists [26] for qualifying the color difference perceived in the byko-spectra
44 effect cabinet (Figure 3 Left). The gray chart used consisted of nine neutral gray chips pairs, which
45 are ordered in increasing color-difference. The grey scale was measured both with the BYK-mac for
46 the experiment called “direct measurement”, and with the PR650 for “visual simulation”
47 experiment. To obtain true values for the calibrated visual assessment, that is, the visual color
48 difference ΔV which is the subjective answer provided by the observers from the visual
49 assessments, a transformation had to be done to values that related to the color-differences
50
51
52
53
54
55
56
57
58
59
60

1
2 calculated from the instrumental measurements of the grey scale. The CIELAB color-difference
3
4 (ΔE^*_{ab}) was selected for this purpose as it is traditionally used for this transformation [27]. The grey
5
6 pairs were measured at each angle, following the same methodology applied in the previous work
7
8 [19], and a fourth polynomial fitting was found to be the best to adjust the values in the scale color-
9
10 differences obtained through instrumental measurements for each of these observation angles
11
12 (Figure 3 Right). Thanks to this adjustment, the visual color difference (ΔV) for a given angle can
13
14 be interpolated and directly related to ΔE^*_{ab} . For this experiment, 10 observers were included (5
15
16 men and 5 women) with normal color vision. In each 30-min session, the observer performed 120
17
18 evaluations, having a total of 1080 evaluations done in 9 sessions (3 repetitions in each session).
19
20 The color pairs and the different measurement geometries were randomly presented to the
21
22 observers. Before each session, the observer spent 3 minutes to adapt to the illuminance level and
23
24 cabinet environment. The observer's task was to quantify the color difference in the test pair by
25
26 comparing with the color differences shown in the several gray pairs (Figure 3 Left).
27
28
29
30
31
32
33
34
35

36 The STRESS index (standardized residual sum of squares) was used to evaluate the performance
37
38 of the color difference formula with respect to the visual assessments obtained [28, 29]. As a
39
40 consequence, the lower the STRESS values, the better the correlation. In addition, the STRESS
41
42 index was used not only to estimate the color difference performance but also to know how reliable
43
44 the results were by determining the intra- and inter- observer variability [30].
45
46
47
48
49
50

51 The intra-observer variability refers to the differences between the results obtained when the same
52
53 observer reported more than once on the same issue. It was measured by the STRESS index,
54
55 calculated from 3 repetitions for each observer at the same experiment. The inter-observer
56
57 variability refers to the differences between the results produced by different observers. It was also
58
59
60

1
2 calculated by means of the STRESS index, considering the total average of the 10 observers and
3
4 the mean value of 3 replicates of each observer.
5
6
7
8

9 10 **3. Results**

11
12
13 The psychophysical assessments and the instrumental data allowed determining the instrumental
14
15 and visual correlation regarding the experiment executed.
16
17

18 19 *Observer Variability*

20
21 The average intra-observer variability obtained in this experiment was 23.65 STRESS units and
22
23 the average inter-observer variability was 28.25 STRESS units. Although there were two observers
24
25 who showed high intra-variability, the calculated values were good compared with previous studies
26
27 [19, 31].
28
29
30
31

32 33 *Instrumental Correlation*

34
35 Before analyzing the visual and instrumental correlation, an instrumental correlation between the
36
37 two measurement methodologies (direct measurement and visual simulation) was done. The
38
39 AUDI2000 color difference ($\Delta E_{\text{AUDI2000}}$) was calculated by considering the measurements from the
40
41 BYK-mac multi-angle spectrophotometer, fixating the D65 illuminant, and the measurement from
42
43 the PR-650 tele-spectroradiometer from the true spectral stimuli, that is, the combination of the
44
45 true lamp into the booth and the spectral reflectance of the panel for this measurement geometry.
46
47
48 Next, a correlation of these instrumental data (BYK-mac and PR-650) was performed by using a
49
50 graphical analysis in which the values of $\Delta E_{\text{AUDI2000}}$ obtained in the different conditions were
51
52 compared.
53
54
55
56
57
58
59
60

1
2 Ideally, a linear correlation of slope close to 1 in $\Delta E_{\text{AUDI2000}}$ values was expected. These values were
3
4 generated with both measuring instruments for each of the measurement geometries. In these
5
6 conditions a pair of panels would exhibit similar color differences by using the BYK-mac multi-
7
8 angle spectrophotometer ($\Delta E_{\text{BYK-mac}}$) and by using the PR-650 tele-spectroradiometer and the
9
10 cabinet (ΔE_{PR650}) even though they were analyzed with the BYK-mac and the tele-
11
12 spectroradiometer PR-650 plus the lightning booth, respectively. In addition, the correlation would
13
14 be linear in spite the fact that the method that involves the tele-spectroradimeter and the lightning
15
16 booth contains higher variability in the position/direction of the instrument, orientation of panels,
17
18 and the spectral quality of the daylight D65 simulation installed into the lighting booth.
19
20
21
22
23
24
25
26

27 Plots in Figure 4 show the correlations in terms of the color differences ($\Delta E_{\text{PR-650}}$ and $\Delta E_{\text{BYC-mac}}$) for
28
29 the 60 color pairs classified by measurement geometry. There was a good correlation between both
30
31 instruments and methods, although it was not perfect. The differences found might be due to
32
33 several factors. Firstly, the fact that the light source (fluorescent lamp) was not the same. Firstly,
34
35 although using the BYK-mac the reference illuminant is the D65, the light source of the byko
36
37 lighting booth, both belonging to the same company, is closer to the D50 illuminant [30, 31].
38
39 Secondly, the illumination / observation conditions may be slightly altered between various
40
41 measurements, and this is especially relevant in goniochromatic samples where color strongly
42
43 depends on the measurement configuration.
44
45
46
47
48
49
50

51 It is worth to point out that the correlation between both methodologies was poorer for the
52
53 geometry 45as-15. Whilst the 45as-15 and 45as15 geometries were equally close to the specular
54
55 direction, the geometry of 45as-15 was experimentally the most conflicting, since in this direction
56
57 the intensity of the reflected light was higher than in other more distant specular geometries. In
58
59
60

1
2 general, a great spreading was found for the geometries 45as-15 and 45as110. Moreover, some
3
4 color pairs did not follow a linear behavior as expected. As these measurement geometries are the
5
6 extreme ones in both instrumental configurations, this could be the reason why a worse correlation is
7
8 found, specifically due to some opto-mechanical design problems for applying tele-
9
10 spectroradiometry on a tilted scene. However, for 45as25, 45as45 and 45as75 geometries which
11
12 progressively move away from the specular peak, the intensity of the reflected light decreased the
13
14 goniometric effects, there was less spreading in characterizing the samples and the color
15
16 difference results matched for both procedures.
17
18
19
20
21

22 *Visual and Instrumental Correlation*

23
24 The next step was the evaluation of the visual and instrumental correlation. As it was mentioned
25
26 before, the correlation was evaluated by the STRESS index. Therefore, this index was calculated
27
28 for both instrumental color differences (BYK-mac and PR-650) by considering the visual differences
29
30 obtained from the psychophysical experiment. In Figure 5, a histogram is shown for the STRESS
31
32 values calculated for both color differences and measurement geometry. As it can be seen, the
33
34 results were very similar for both color differences. The STRESS average for all geometries was of
35
36 39.78 and 40.87 units for BYK-mac and PR-650 data, respectively. This result was already
37
38 expected as the correlation between both instruments was acceptable as previously shown.
39
40
41
42
43
44
45
46

47 A set of color-pairs was identified having high deviations between the visual assessment and
48
49 instrumental measurement, even for both methodologies. These are types of samples that would
50
51 cause problems in the industry. Therefore the multi-angle spectrophotometer would not accept the
52
53 color pair as a good color matching, but an observer would.
54
55
56
57
58
59
60

1
2 Furthermore, color-pairs that generated conflicts, i.e. the response of the instrument was different
3
4 from the observer's decision, were identified and selected. Therefore, a new analysis was done in
5
6 order to show for each color-pair, the correlation of both processes, instrumental and visual
7
8 evaluation, in each measurement geometry. This analysis consisted of doing a representation
9
10 (Figure 6) by denoting with zones the criteria established by the AUDI color tolerances. In this
11
12 way, it was easy to visualize if the samples presented acceptable color differences or not.
13
14

15
16 Based on the AUDI tolerance criteria, all samples with $\Delta E > 1.7$ units would be placed within the
17
18 red zone and would be considered as different; samples with color differences between 1.4 and 1.7
19
20 would be at the yellow zone, where samples should be studied with other visual tests to establish if
21
22 they pass or not; finally, the green area would contain samples with $\Delta E < 1.4$, which could be
23
24 considered almost indistinguishable.
25
26
27

28
29
30
31 Once the most troubled samples were identified and analyzed, 3 pairs of characteristic samples
32
33 were selected to be shown in Figure 6. In this case, measurement data from the BYK-mac was used
34
35 as it is the most common instrument used in the automotive industry.
36
37
38

39
40
41 Figure 6a shows the color differences for all the measurement geometries for a solid sample. As it
42
43 can be noticed, there was a good correlation between visual and instrumental assessments, which
44
45 means that for both methodologies the color difference of the color pair was indistinguishable
46
47 (green region). This situation should be the real one, where the information provided by the
48
49 instrumental analysis and visual evaluation would be equivalent.
50
51

52
53 Figures 6b and 6c show an opposite situation. These examples correspond to pearlescent and
54
55 metallic samples, respectively. In the pearlescent sample, the color-pair was accepted by the BYK-
56
57 mac (for all the measurement geometries) but rejected by the average observer. On the contrary,
58
59
60

1
2 for the metallic sample the average observer accepted the color-pair as a good color matching or
3
4 approval, whereas the color difference calculated from the BYK-mac measurements was big
5
6 enough to consider the color-pair as not good or fail. Therefore, it would be interesting for car
7
8 makers and coating providers to know what type of automotive colors or recipes (by hues, flops,
9
10 etc.) are prone to be associated with the cases shown in these figures.
11
12
13
14
15
16

17 It is important to mention that with the PR-650 data, results were similar to those obtained using
18
19 the BYK-mac, since in the majority of samples, pairs were accepted by observers, but rejected by
20
21 the instrument, as for the BYK-mac.
22
23
24
25
26

27 4. Conclusions

28
29
30 The correlation between visual and instrumental evaluation was performed with a set of
31
32 automotive samples. Two instrumental evaluations were conducted, a direct measurement with
33
34 the BYK-mac multi-angle spectrophotometer, and a visual simulation with the PR-650 tele-
35
36 spectroradiometer and the byko-effect lighting cabinet, with the same measurement geometries
37
38 setup than in the BYK-mac. The visual evaluation was conducted by a conventional psychophysical
39
40 experiment where observers quantified the color difference in color pairs by using the gray scale
41
42 method. The observer variability showed that the observer responses were consistent enough.
43
44
45
46
47
48
49

50 Firstly, a comparison between both instrumental evaluations was done. The results exhibited an
51
52 acceptable correspondence between both methodologies. Nevertheless, a slightly measurement
53
54 mismatch that could be due to the illuminant – light source differences or different geometries
55
56 configurations was found.
57
58
59
60

1
2
3
4 Secondly, the study of the visual and instrumental correlation was carried out. The performance of
5
6 the AUDI2000 color difference with the visual assessments done by observers was evaluated by the
7
8 STRESS index. The results revealed that it would be possible to obtain a better performance by
9
10 improving the color difference formula since the observer variability was lower than the
11
12 performance of the color difference. A detailed analysis was done for each color pair. A number of
13
14 color pairs were identified to have instrumentally color differences far away from visual color
15
16 differences. It was determined that the general tendency was that observers gave lower color
17
18 difference values than those provided by the devices. This implies that observers accepted a larger
19
20 number of valid color pairs compared with those accepted by the devices, despite being "experts" in
21
22 color, although not color automotive engineers. Therefore, it could be concluded that there was not
23
24 a perfect correlation between instrumental and visual evaluation and that it would be interesting
25
26 to analyze which parameters can influence, and how, in this correlation failure related with
27
28 commercial color devices typically used in the automotive sector. One approach would be to
29
30 improve the AUDI2000 color difference formula or to propose a new one in order to obtain a better
31
32 performance. Taking into account that the observer variability was lower than the performance of
33
34 the color difference, it would be possible to improve the AUDI2000 color difference formula to find a
35
36 better correlation with visual evaluations. Other strategies, even combining with the first
37
38 approach, would be to use a better D65 simulator, a more powerful lamp for a higher level of
39
40 illumination, better lighting uniformity, or even use a specified gray card with smaller steps to
41
42 compare directional level colors. This experiment should also be done with professional colorists of
43
44 the automotive industry and with normal observers (with no experience in colorimetry), to see
45
46 whether the level of experience affects ΔV . Therefore, this justifies that it is necessary to apply both
47
48 methodologies, visual and instrumental evaluation, to avoid this kind of discrepancies. Otherwise,

working hardly in the improvement of directional lighting booths, using better D65 simulators and high illuminance levels, either based on current fluorescent lamps or new solid-state lighting sources as LEDs, OLEDs, etc.

In conclusion, the new main contributions of this paper is the use of tele-spectroradiometry for testing the visual and instrumental correlation in automotive coatings at the realistic way, showing that this instrumental technique for measuring the true spectral stimuli is necessary to understand and manage doubtful color pairs for the final color matching/approval. And it can be applied to new experiments and studies crossing structural (formulation, pigment size, etc.) and colorimetric data.

Acknowledgments

The authors are grateful to EMRP for funding the project “Multidimensional Reflectometry for Industry”. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union. We would like to thank the Ministry of Economy and Competitiveness for the coordinated project “New developments in visual optics, vision and color technology” (DPI2011-30090-C02). Francisco Javier Burgos would also like to thank the Autonomous Government of Catalonia for his pre-doctoral fellowship grant and Omar Gómez to the Ministry of Economy and Competitiveness for his pre-doctoral fellowship (FPI BES-2012-053080).
