Abstract

Long-term, global offline (land-only) simulations with a dynamic vegetation phenology model are used to examine the control of hydroclimate over vegetation-related quantities. First, with a control simulation, the model is shown to capture successfully (though with some bias) key observed relationships between hydroclimate and the spatial and temporal variations of phenological expression. In subsequent simulations, the model shows that: (i) the global spatial variation of seasonal phenological maxima is controlled mostly by hydroclimate, irrespective of distributions in vegetation type, (ii) the occurrence of high interannual moisture-related phenological variability in grassland areas is determined by hydroclimate rather than by the specific properties of grassland, and (iii) hydroclimatic means and variability have a corresponding impact on the spatial and temporal distributions of gross primary productivity (GPP).

40

1. Introduction

Recognition that the Earth's energy and water cycles are intrinsically entwined is longstanding (e.g., Budyko 1971). The land surface energy and water balances both feature evapotranspiration as a dominant term, and the generation of rainfall (a key component of the water cycle) has a profound effect on the heat budget of the atmosphere. The inseparability of the energy and water cycles underlies their joint treatment in numerous analyses (e.g., Trenberth et al. 2011) and the formation of international research projects addressing their linkage, such as GEWEX (the Global Energy and Water Exchanges Project, part of the World Climate Research Programme, or WCRP).

The Earth's carbon cycle is in turn intrinsically entwined with the energy and water cycles. Vegetation health (and associated carbon uptake) is affected by water availability; deserts, for example, tend not to be carbon sinks. Conversely, carbon affects the water and energy cycles; the transpiration of water from vegetation and the associated cooling of the land surface are in large part controlled by the efficiency of the vegetation's uptake of carbon dioxide (e.g., Berry et al. 2010), and the build-up of vegetation through carbon uptake has a direct impact on land surface albedo – how much of the sun's radiation is absorbed by the surface. Carbon dioxide is, of course, also a greenhouse gas. The basic connection between the surface fluxes of water, energy, and carbon is appropriately recognized in numerous studies (e.g., Leuning et al. 2004; Bowling et al. 2010), and it is a motivation for such international research projects as ILEAPS (the Integrated Land Ecosystem Atmosphere Study, another component of WRCP).

In this paper, we focus in particular on the carbon-water linkage at the land surface. A number of relevant studies in the literature have shared this focus. Using data collected at a number of flux tower sites in North America, Knapp and Smith (2001) provided a powerful,

geographically diverse analysis of the connections between the surface water and carbon cycles –

specifically, of the controls of precipitation means and variability on aboveground net primary

production (ANPP). Their results show that carbon uptake by the land surface is indeed strongly

regulated by precipitation characteristics, with maximum uptake related strongly to precipitation

amount and with the interannual variability of the uptake maximized in grassland areas, where

both precipitation variability and vegetation cover are adequately high. Remotely sensed

measurements of vegetation properties allow for an even more comprehensive and large-scale

analysis of connections between carbon and climatic variables, including precipitation (e.g.,

Fang et al. 2005, Iichi et al. 2010, Jahan and Gan 2011). In a recent global analysis, Zeng et al.

(2013) uncovered strong relationships between the interannual variations contained in a

multidecadal NDVI dataset (normalized difference vegetation index, an indicator of green leaf

area) and antecedent precipitation levels, particularly in temperate and tropical grasslands.

A modeling framework is a natural venue for studying the connections between carbon

and water. Wang and Eltahir (2000), using a simple coupled biosphere-atmosphere model,

showed how the interaction between vegetation and precipitation can lead to multiple equilibria

for vegetation state. Zeng et al. (1999) showed, again with a simple coupled model, how

vegetation-climate interactions may affect the nature of precipitation variability in the Sahel.

Puma et al. (2013) used a modeling framework to compare the impacts of meteorological

variability and phenological variability on the simulation of surface moisture and carbon fluxes.

Complex and relatively complete models of vegetation behavior, models that indeed tie together

explicitly the interactions between carbon, energy, and water fluxes at the land surface and

accordingly allow the prediction of vegetation state, are arguably the new state-of-the-art in

numerical climate modeling. Sellers et al. (1997) pointed to the explicit treatment of carbon as a

87 logical step in the evolution of land surface treatments in Earth system models; dynamic

88 vegetation models (DVMs) following this evolutionary path are already being used at major

89 climate modeling centers (e.g., Lawrence et al. 2010, Krinner et al. 2005, Boussetta et al. 2012,

90 Dunne et al. 2013).

91 An advantage of using a modeling framework for carbon-water studies is the potential for

92 doing unique analyses that isolate and illustrate the mechanisms that control the transfers of

93 water and carbon across the land surface. Carefully formulated modifications of a physical

94 process treatment or of a variable that forces it can be imposed, and the resulting impacts on

95 surface fluxes can be quantified and analyzed, thereby elucidating the role of the process

96 examined. A second important advantage of such models is their ability to provide data fields

97 that are unattainable with in situ measurement networks or even satellite-based sensors. Gross

98 primary productivity (GPP), for example, can only be measured directly at a limited number of

99 flux tower sites. A DVM, however, if driven with observations-based meteorological forcing,

100 can potentially produce estimates of GPP at high spatial and temporal resolution across the

101 globe. Such estimates would be biased relative to nature, of course, due to deficiencies in model

102 formulation and forcing data; still, if care is given to their interpretation, the estimates do have

103 scientific value.

104 Both of these advantages come into play in the present paper, in which we use the

105 dynamic phenology component of an established DVM together with the water and energy

106 balance framework of a hydrology-focused LSM to characterize, on a global scale, the controls

107 of precipitation means and variability on GPP – both on its spatial distribution and on its

108 temporal variability across the globe. The modeling system used (described in Section 2) is

109 indeed found to be effective in capturing the key hydroclimatic controls on phenology that

5

110 operate in nature (as demonstrated in Section 3). The simulated GPP distributions from the thus-

111 validated system are analyzed jointly with global precipitation data in Section 4. The model

112 experiments provide new insights into the relative impacts of precipitation means, precipitation

113 variability, and vegetation type in determining GPP distributions.

114

2. Dynamic Phenology Model

116 The dynamic phenology model used in this study is in essence a merger of the carbon

117 physics of the NCAR/DOE CLM4 dynamic vegetation model (Oleson et al. 2010) with the

118 energy and water balance formulations of the NASA Global Modeling and Assimilation Office

119 (GMAO) Catchment land surface model (LSM) (Koster et al. 2000). We provide here a brief

120 description of these two components and the technique used to merge them into a new model,

121 hereafter referred to as the Catchment-CN LSM (i.e., the Catchment LSM with carbon and

122 nitrogen physics).

123 The NCAR/DOE Community Land Model, version 4 (CLM4), represents prognostic

124 coupled energy, water, carbon, and nitrogen cycles in a framework that permits global-scale as

125 well as regional and site-level simulation. The global-scale parameterization used here includes

126 specification of sub-grid heterogeneity in plant functional type (PFT) distributions, with multiple

127 PFTs assigned fractional area coverage within each grid cell, where they compete with one

128 another for available soil moisture and mineral nitrogen resources. In this prescribed

129 biogeography mode the fractional areas occupied by individual PFTs do not change, but

130 vegetation growth, soil heterotrophic activity, carbon stocks, and other ecosystem states (such as

131 leaf area index) do vary prognostically (Thornton et al. 2009).

The GMAO Catchment land surface model is a state-of-the-art surface energy and water

budget model designed for use with global Earth system models. As with most other LSMs, the

Catchment LSM employs complex treatments of land surface flux generation, tying the

efficiency of evaporation and runoff generation to the moisture and temperature states of the land

surface, and it includes parameterizations of vegetation impacts on transpiration, canopy

interception, albedo, and surface roughness. Relatively unique to the Catchment LSM is its

treatment of the subgrid variability of soil moisture and temperature, which is explicitly tied to a

description of the topographic variability in the region modeled – in the Catchment LSM, valley

bottoms within a given grid element are explicitly modeled as being wetter, and the hilltops are

explicitly modeled as being drier. Runoff and evaporation are calculated independently in the

different hydrological regimes, using regime-specific physics.

In essence, in merging the two models, we retain the Catchment LSM's energy and water

balance calculation framework while using the NCAR/DOE CLM4 carbon balance calculations.

The approach is illustrated in Figure 1. In the original Catchment LSM (Figure 1a), the model

uses forcing from the atmosphere along with prescribed vegetation phenology (LAI and

greenness fraction) and the current values of LSM temperature and moisture prognostic variables

to compute the canopy conductance, the parameter describing the ease with which the plants

transpire water. The canopy conductance, computed separately for each hydrological regime, is

then used in each regime's energy balance and water balance calculations, which in turn provide

the fluxes of heat and moisture to the atmosphere.

Figure 1b shows the approach used by the merged system, the Catchment-CN LSM. The

atmospheric inputs are now fed first into the components of the NCAR/DOE model that update

the carbon states and compute, as a matter of course, canopy conductances that reflect an explicit

7

155 treatment of photosynthesis physics. These canopy conductances, along with the leaf area

156 indices diagnosed from the new carbon prognostic variables, are fed into the energy and water

157 balance calculations of the original Catchment LSM. The output fluxes with the merged system

158 include a net carbon flux.

159   The merger of the two models allows the Catchment-CN LSM to follow 19 distinct

160 vegetation types, a significant increase from the six independent types followed with the original

161 Catchment LSM. Furthermore, the unique character of the original Catchment LSM allows for

162 the independent monitoring of carbon variables in the different topographically-defined

163 hydrological regimes. Figure 2 describes our methodology. Each land surface element is

164 subdivided into three static carbon zones defined by topography, through analysis of the

165 distribution of the compound topographic index (Moore et al., 1993). The first zone, covering a

166 fixed 10% of the area, represents the valley bottoms; this zone tends to be generally wet. The

167 second and third zones represent the lower (drier) hillslopes and upper (even drier) hillslopes,

168 respectively. Through areal weighting, soil moisture and temperature information from the

169 dynamically-varying hydrological zones are combined for use by the carbon physics in the fixed

170 vegetation zones, as indicated in the figure. Separate sets of carbon prognostic variables are

171 followed in each vegetation zone, and thus each zone generates a different manifestation of

172 phenology. When examining the model results, we find that green vegetation indeed tends to be

173 densest in the valley bottoms.

174   Some additional modifications to the NCAR/DOE vegetation model were needed to

175 optimize its performance in the GMAO system.   To prevent some occasional singular behavior –

176 namely, the catastrophic shutdown of vegetation during cold spells and a resulting overgrowth of

177 the vegetation during the subsequent year – we replaced a particular set of vegetation types (crop

and temperate shrubs/grass) that feature a strong response to temperature stress by a mix of two different types: one that is seasonally deciduous and one that is not. Neither of the replacement types employ the temperature stress shutdown, though both respond to moisture stress; the proportion of the mix applied is defined by latitude, and the replacement is indeed limited to the latitude band 32°-42° in both hemispheres. Outside of this latitudinal band, we limit the number of coexisting PFTs in each static carbon zone to two. Also, we modified the NCAR/DOE vegetation physics to allow half of the new carbon assimilated by deciduous types to be displayed during the current year rather than in the following year, which brings certain measures of our interannually-varying phenology more in line with observations. Finally, whereas the NCAR/DOE vegetation model uses the previous year's annual mean temperature to determine certain onset triggers, we use a climatological mean temperature.

In our main ("control") application of the model, the prescribed distributions of vegetation type follow those used by the default 0.5°×0.5° version of CLM4 (Oleson et al. 2010). Vegetation phenology and carbon states, however, evolve freely. The model is run globally offline (i.e., disconnected from an atmospheric model) on high-resolution catchments (roughly 20-30 km in size) over the period 1948-2008, using the observations-based meteorological forcing of Sheffield et al. (2006); the simulation loops over this period more than 30 times to ensure spin-up and equilibration of the carbon storage reservoirs. The output data examined (phenological variables, carbon fluxes, etc.) are aggregated to 2°×2.5° for processing.

3. Evaluation Against Observations

To test the realism of the model's connections between hydroclimate and vegetation variables, we focus on two distinct aspects of global phenological expression: the global spatial

9

201 pattern of long-term phenological means and the interannual variability of phenology at a given

202 location. These are discussed in turn following a brief description of the observations.

203

204 a. Observations used

205   We examine satellite-based products of NDVI (normalized difference vegetation index)

206 and FPAR (fraction of absorbed photosynthetically active radiation), both of which increase with

207 green vegetation cover. The NDVI data is a subset of the latest version of the Global Inventory

208 and Mapping Studies, or GIMMS, data (Tucker et al. 2005). The data's native resolution is

209 semiweekly at 8 km, and the data span the period July 1981-present. For our analyses we

210 aggregate these data to a 2.5°×2.5° degree, monthly resolution for the period 1982-2010. The

211 data are derived from the Advanced Very High Resolution Radiometer (AVHRR) instrument

212 with known limitations compared to the more advanced MODIS instrument (Kaufman et al.

213 1998). However, the longer temporal coverage of GIMMS relative to MODIS (29 versus 11

214 years) and the good correspondence between their measurements (Tucker et al. 2005, Beck et al.

215 2011) makes it well suited to the analysis presented here.

216   The FPAR data are derived directly from the NDVI data using the method of Los et al.

217 (2000). The method combines the NDVI-based FPAR estimation technique of Sellers et al.

218 (1996) with that of Choudhury (1987) and Goward and Huemmrich (1992); the combination

219 provides estimates that are well behaved relative to available in-situ observations. The

220 relationship between NDVI and FPAR underlying this combined approach is monotonic but

221 nonlinear. Note that it is also somewhat vegetation dependent, so that the conversion of global

222   NDVI data to global FPAR data requires a global field of vegetation types. Thirteen years of

223   FPAR data are available, spanning the period 1997-2009.

224   As will be seen below, the sensitivities of the NDVI and FPAR data to hydroclimatic

225   variation are similar in many ways. Both are worth illustrating here. The NDVI values are

226   constructed directly from spectral reflectance measurements and thus represent a raw form of the

227   observations. While the construction of the FPAR values requires some additional assumptions

228   regarding vegetation behavior, FPAR has the distinct advantage of representing a physically

229   meaningful phenological variable, one that can be compared directly to output from the

230   Catchment-CN model.

231   The global precipitation data used here consist of monthly precipitation totals for 1979-

232   present at 2.5°×2.5° degree resolution, as produced by the Global Precipitation Climatology

233   Project as part of their Version 2 Satellite-Gauge dataset (Adler et al. 2003; see also

234   ftp://precip.gsfc.nasa.gov/pub/gpcp-v2.2/doc/V2.2_doc). Satellite-based data contributing to the

235   product, in varying capacities and over various periods and regions, include Special Sensor

236   Microwave/Imager (SSM/I) passive microwave estimates, Television-Infrared Observation

237   Satellite (TIROS) Operational Vertical Sounder (TOVS) estimates, and the Adjusted

238   Geostationary Operational Environmental Satellite (GOES) Precipitation Index (Adler et al.

239   1994). A wealth of surface rain gauges is used to adjust the multi-sensor precipitation estimates

240   over land. Hall et al. (2006) provide background on the accuracy of the GPCP product; of note is

241   the higher uncertainty of the product over mountains, deserts, high latitudes, and undeveloped

242   areas due in large part to a lower density of rain gauges.

243
244

11

245   b. Impact of hydrological variations on the mean spatial distributions of phenological variables

246   To deal with the fact that NDVI shows significant seasonal variability, with different

247   regions having different peak months for the index, we examine a quantity we will call $NDVI_{max}$.

248   We compute, at each $2.5° \times 2.5°$ grid cell, the average seasonal cycle of NDVI from the GIMMS

249   data and then identify the month for which the average NDVI is highest. $NDVI_{max}$ is set to the

250   average value for the 3-month period centered on this peak month. (Note that under this

251   definition, the values for $NDVI_{max}$ in adjacent grid cells may be taken from different 3-month

252   periods.) Figure 3a shows the global distribution of $NDVI_{max}$ as derived from the spatially

253   aggregated GIMMS data. The distribution mirrors known vegetation distributions, with large

254   values in tropical, deciduous, and boreal forests, intermediate values in grassland and shrubland

255   areas, and small values in the deserts.

256   Figure 4a shows how the spatial distribution of $NDVI_{max}$ in Figure 3a correlates with

257   various meteorological quantities. The first four bars of each panel show the square of the

258   spatial correlation (r^2, across land surface grid cells) of $NDVI_{max}$ with, respectively, annual mean

259   precipitation, the standard deviation of annual precipitation, annual mean air temperature, and

260   annual mean net radiation. (The base-10 logarithms of the precipitation quantities are in fact

261   used here. Temperature and net radiation information are derived from the full period of the

262   Sheffield et al. (2006) dataset. The outgoing longwave component of the net radiation is

263   estimated using the surface air temperature in that dataset.) The salient result from the figure is

264   the dominance of the two precipitation quantities in determining the spatial structure of NDVI.

265   Multiple regression of $NDVI_{max}$ on the mean and variability of precipitation produces an r^2 of

266   about 0.55 (fifth bar), and adding the temperature and net radiation information to the multiple

267 regression does not significantly increase the r^2 (sixth bar). These results underlie the

268 importance of hydroclimate in determining the spatial distribution of phenological maxima.

269   Figure 5a shows more directly how $NDVI_{max}$ is related to precipitation means and

270 variability. Each dot in Figure 5a corresponds to a 2.5°×2.5° land grid cell. The size and color

271 of the dot is determined by the local value of $NDVI_{max}$, as indicated by the legend. The dot's

272 abscissa is determined by the mean annual precipitation at that grid cell, and the dot's ordinate

273 refers to the interannual variability of precipitation there. (Note the logarithmic scales.) The

274 precipitation and NDVI quantities are computed over consistent time periods; for example, if a

275 grid cell's peak NDVI, as computed from the GIMMS data for 1982-2010, occurs in July, then

276 precipitation means and variances are computed from nineteen September-August yearly totals

277 starting with the total for the period September 1981-August 1982.

278   Two features of the scatter plot stand out. The first reflects an expected result: a

279 minimum average precipitation must be achieved to attain moderately high $NDVI_{max}$ levels. The

280 plot shows this minimum value to be roughly 1 mm/day; the dots to the left of this threshold

281 (which include, of course, all desert points) show low values of $NDVI_{max}$. The second, and more

282 intriguing, feature of the scatter plot is the tendency for $NDVI_{max}$ to decrease as the standard

283 deviation of precipitation increases. This feature is illustrated more clearly in Figure 5b, which

284 shows a binned version of the scatter plot data; to generate this plot, an array of boxes is overlain

285 on Figure 5a, and the $NDVI_{max}$ values for the points within each box are averaged. For a given

286 value of the mean precipitation, especially for values above 1 mm/day, $NDVI_{max}$ clearly tends to

287 decrease with increasing σ_P. This presumably reflects the reduced ability of vegetation to

288 flourish when the year-to-year supply of water is less stable.

13

289   We also examine in this context the analogous variable $FPAR_{max}$, the average value of a

290   grid cell's FPAR for the 3-month period centered on the peak FPAR month, as determined from

291   the local climatological cycle. Figure 3b shows the distribution of $FPAR_{max}$ as computed from

292   the GIMMS data. As might be expected, given that FPAR in GIMMS is derived from NDVI, the

293   spatial distributions in Figures 3a and 3b are very similar, as are the spatial correlations with the

294   meteorological forcing variables (Figure 4b). Figures 5c and 5d show the precipitation-based

295   scatter plots for the $FPAR_{max}$ values. Average water supply (mean precipitation) and water

296   supply stability (σ_P) are seen to impose dual control over $FPAR_{max}$ as well; the sensitivity of

297   FPAR to hydroclimate is indeed very similar to that of NDVI.

298   How well does the Catchment-CN model perform? The model produces diagnostics for

299   both the incident and absorbed photosynthetically active radiation; we take the ratio of these

300   quantities to produce the model's FPAR values. Figure 3c shows the global distribution of

301   simulated FPAR in the peak 3-month period; note that for a given location, this peak period may

302   differ from that for the observations. Two features of the simulated FPAR distribution stand out.

303   First, the simulated spatial patterns agree well with the observed patterns in Figure 3b.   Second,

304   there are, nonetheless, apparent biases in the simulated FPAR values, with the highest simulated

305   values being too large and the lowest being too small. Such biases presumably reflect

306   deficiencies in the model, though they may also stem partially from limitations in the forcing

307   data or in the observational FPAR values themselves. The biases must be kept in mind

308   throughout our analysis.

309   The square of the spatial correlation of simulated FPAR with meteorological forcing

310   variables (Figure 4c) agrees quite well with the corresponding values found for observed FPAR

311   (Figure 4b). The simulated r^2 values with the temperature and net radiation variables are slightly

14

312 higher, but these values are still quite low. Figure 4 shows that, in strong agreement with the

313 observations, variations in hydroclimate explain most of the FPAR variability seen in the model.

314   The agreement in spatial pattern with a presence of bias also manifests itself in the

315 precipitation-based scatter plot in Figure 5e and the corresponding binned version of the plot in

316 Figure 5f. In agreement with the observations, the model clearly shows an increase in FPAR

317 with increasing precipitation and with decreasing precipitation variability. Overall, the model,

318 though biased, does appear to simulate realistic controls of hydroclimatic variation over

319 phenological means.

320

321 c. Impact of hydrological variations on the interannual variability of phenological variables

322   As a second and somewhat independent test of the ability of the Catchment-CN model to

323 capture observed links between carbon and water variables, we examine the interannual

324 variability of vegetation phenology. Rather than examining the total variance of a variable such

325 as summertime NDVI, we focus instead on a modified quantity, one that captures the carbon-

326 water connection:

327 $$\text{Var(NDVI)}^* \;=\; \text{Var(NDVI)} \, \text{Corr}^2(\text{NDVI},P) \,, \tag{1}$$

328 where Var(NDVI) is the interannual variance of 3-month NDVI averages (again centered on the

329 peak NDVI month, based on the climatological seasonal cycle), $\text{Corr}^2(\text{NDVI},P)$ is the correlation

330 between these individual NDVI averages and the corresponding yearly precipitation totals (with

331 the end of the precipitation averaging period corresponding to the end of the 3-month NDVI

332 averaging period), and Var(NDVI)* is interpreted as the portion of the NDVI variance associated

333 with variations in moisture availability. That is, we are employing here the standard

15

interpretation of $\text{Corr}^2(\text{NDVI,P})$ as the fraction of the variance of NDVI "explained" by variations in P. Equation (1) allows us to isolate this part of NDVI variability from that associated with other sources, such as variations in radiation or nutrients as well as interference from clouds, water vapor, and aerosols (Los et al. 2000).

A few notes are required regarding the estimation of Var(NDVI)*. First, by using the annual totals for precipitation, we are assuming that a given year's precipitation represents the water available that year for growth. Of course, other averaging periods for the precipitation could have been employed (e.g., Zeng et al. 2013). The patterns in $\text{Corr}^2(\text{NDVI,P})$ obtained with these other averaging periods, however, turn out to be the same, to first order; correlation maps generated using 6-month or 9-month precipitation averages (not shown) are very similar to those generated with the annual precipitation. Note that using the annual precipitation rather than the contemporaneous 3-month precipitation has an important advantage: it reflects the fact that antecedent precipitation can provide water to vegetation growth through storage in ground reservoirs and snowpack (Milly, 1994).

Second, the observations are known to be subject to significant contamination from clouds in high latitudes and from pollution in Southeast Asia (Fensholt and Proud, 2012), the upshot being that small and artifactual negative correlations between NDVI and precipitation are often seen in these regions. These negative correlations are problematic for our analysis. We zero them out before computing $\text{Corr}^2(\text{NDVI,P})$, making the explicit assumption that any such negative correlations represent noise. Note that even on the off chance that the negative correlations are real, they would not represent the physical relationship we are after in this paper, namely, the ability of water limitations to limit vegetation growth.

16

356   Figure 6a shows the distribution of Var(NDVI)*, as computed with (1). The patterns are

357   quite interesting: the regions for which moisture-related NDVI variability is high tend to

358   coincide with the Earth's grassland regimes – in the Great Plains of the U.S., the Nordeste region

359   of Brazil, the African Sahel, the Asian steppes, and eastern and northern Australia (see Figure 7).

360   The Var(NDVI)* patterns do miss grassland areas in India and China, but as shown in Figure 7,

361   these areas are subject to extensive irrigation (Siebert et al. 2005), a supply of water not

362   accounted for in the $Corr^2$(NDVI,P) diagnostic. Figure 6 demonstrates that, aside from such

363   irrigated areas, the locations of the Earth's grassland areas can be identified reasonably well from

364   the joint analysis of NDVI and precipitation data. The same patterns, and thus the same

365   connections to grassland regimes, are seen for Var(FPAR)*, the portion of the interannual

366   variance in 3-month FPAR averages related to moisture variations.

367   The results obtained with the dynamic phenology model are remarkably similar. A

368   comparison of Figures 6b and 6c shows that the model captures very well the observed spatial

369   pattern Var(FPAR)*, though again with a bias, as indicated by the different scaling factors used

370   for the plotting.   Overall, the model successfully captures the role of hydroclimate in

371   determining the spatial distribution of interannual variability in phenology.

372

4. Model Experiments

374   Having demonstrated the Catchment-CN model's ability to capture the basic

375   hydroclimatic controls on phenology seen in the observations, we now use model experiments to

376   address key questions regarding the connections between hydroclimate and vegetation.

377

17

378   a. Influence of vegetation type on phenological variability

379   Clouding the interpretation of the Catchment-CN model's performance relative to

380   observations in Section 3 above is the possibility that its use of prescribed vegetation types is

381   somehow guaranteeing correct model behavior. Given, for example, that the observed

382   distribution of Var(FPAR)* in Figure 6b captures well the locations of the world's grasslands

383   (Figure 7), we must consider the possibility that high values of Var(FPAR)* are encouraged by

384   the unique properties of grassland and discouraged by the properties of forests and shrubs, so that

385   by imposing the observed vegetation distributions in the model, we artificially guarantee high

386   simulated values of Var(FPAR)* in the correct areas (Figure 6c). The more intriguing possibility

387   to consider, however, is that a specific hydroclimatic regime is responsible for high Var(FPAR)*

388   values, a regime for which only grasslands happen to survive. With this second possibility, the

389   vegetation type does not cause the Var(FPAR)* value; rather, the vegetation type and the

390   Var(FPAR)* value are together controlled by something else, namely, the local moments of

391   precipitation.

392   To examine this issue, we performed a repeat of the simulation described above, but with

393   a twist: grassland vegetation was imposed on all land surfaces, and no other vegetation types

394   were allowed to exist. Thus, in this experiment, vegetation type could not affect in any way the

395   simulated spatial and temporal distributions of FPAR. Note that in this experiment, grassland is

396   placed even in the driest deserts and in the wettest tropical areas; if the local climate is not

397   conducive to grassland's survival, the grass is accordingly allowed to die out.

398   Figure 8c shows the spatial distribution of Var(FPAR)* for the all-grassland simulation.

399   The plot captures, to first order, the features seen in the original model plot, supporting the

18

second possibility noted above. That is, the presence of grassland does not lead to high Var(FPAR)* values; the high values are instead indicative of a hydroclimatic regime that also happens to support grassland best. Similarly, the all-grassland simulation shows a relationship between FPAR maxima, mean precipitation, and precipitation variability (Figure 8a) that agrees to first order with that seen in the original model simulation (Figure 5f). The fact that FPAR tends to be highest in very wet conditions, for example, is not simply the result of the presence of dense forests in wet areas; the wet conditions themselves encourage the high FPAR values, and wet areas also tend to be where dense forests tend to flourish.

We repeated the simulation still again, this time after prescribing a deciduous forest vegetation type everywhere. The results, shown in Figures 8b and 8d, are essentially the same. Hydroclimatic variability, more than vegetation type, appears to dominate phenological variability – in the model and, we can infer, in nature.

b. Hydroclimate and the global carbon cycle

As noted in the introduction, a unique advantage of a model that can simulate phenology is its ability to provide information on additional, difficult to measure quantities. While carbon fluxes such as gross primary productivity (GPP), net primary productivity (NPP), and net ecosystem exchange (NEE) have been measured at various tower sites (Baldocchi 2008), directly observed global distributions of land-atmosphere carbon exchange are nonexistent. Model simulations, however, can readily provide these fields, and many examples of such simulated distributions already appear in the literature (e.g., Friedlingstein 2006). (We note that other

19

421   approaches for inferring global fields, such as machine learning algorithms that upscale from the

422   site measurements, are also available [Jung et al. 2011].)

423   Here we provide model-based estimates of the connection between carbon exchange and

424   hydroclimatic variability, focusing mainly on GPP. We first provide in Figure 9a this particular

425   model's vision of the global distribution of GPP. Because GPP is a flux rather than a

426   manifestation of vegetation state, we present it in terms of annual averages rather than for a 3-

427   month maximum period. The distributions have the expected maxima in the densely forested

428   tropics, with swaths of high values in the boreal forests of the north. Figures 9b and 9c show the

429   corresponding GPP fields from the simulations prescribing grassland and deciduous tree types,

430   respectively. The three panels show some differences but are, to first order, very similar,

431   indicating that vegetation type alone is not the main source of spatial variations in GPP; both

432   GPP and vegetation distributions are apparently controlled in tandem by something else.

433   Naturally, that "something else" is water availability. Figure 10 shows, in analogy to

434   Figure 4, the square of the spatial correlation between GPP and various meteorological forcing

435   variables. For all three simulations (control, "all grass", and "all trees"), precipitation mean and

436   variability have the dominant impact on GPP, with an r^2 of about 0.55 for the multiple regression

437   of GPP on $\log_{10}P$ and $\log_{10}\sigma_P$. Adding in the annual temperature and net radiation information

438   increases the r^2 to about 0.65. The fact that the r^2 values do not increase by much for the

439   uniform vegetation experiments suggests once again that variations in vegetation type do not by

440   themselves contribute significantly to spatial variations in GPP; the remaining unexplained

441   variance in Figure 10a presumably results from spatial variability in, for example, the seasonal

442   cycles and shorter-term temporal structure of the forcing quantities.

443   Figure 11 shows how precipitation means and variability control the spatial distribution

444 of GPP using scatter plots analogous to those shown in Figure 5. As with FPAR, GPP tends to

445 increase with increasing moisture availability (x-axis) and decreasing interannual variability (y-

446 axis), regardless of which vegetation types are assigned at the surface.

447   In contrast to Figure 5, Figure 11 uses a nonlinear scale for the shading, a scale that

448 shows the dominance of precipitation means over precipitation variability in determining GPP.

449 The impact of precipitation variability on GPP, however, is nevertheless significant. This is

450 demonstrated with a supplemental model simulation ("ClimP") in which we prescribed standard,

451 spatially varying vegetation types (as in the control simulation) but a modified precipitation

452 forcing: at each grid cell in ClimP, we scaled the precipitation forcing in each month of each year

453 so that the seasonal cycle of monthly totals for the year matched the long-term (climatological)

454 seasonal cycle. Thus, in ClimP, we artificially removed the monthly-scale year-to-year temporal

455 variability in the precipitation forcing – at each grid cell, the mean precipitation applied was

456 identical to that used in the control simulation, whereas the interannual variability of monthly

457 precipitation was, by construction, set to zero.

458   Figure 12 shows the difference between the mean annual GPP produced in ClimP and

459 that in the control simulation. Regions with large positive differences appear in the southeast

460 U.S., along the eastern coasts of South America and Australia, in the Indian subcontinent, in

461 northeastern China, and in various other regions of South America and Africa. Negative

462 differences do not appear anywhere. In effect, Figure 12 illustrates where GPP in the real world

463 would be larger if the year-to-year precipitation supply were more dependable – i.e., where the

464 interannual variability of precipitation holds down the land surface's carbon uptake. Note,

465 however, that human activities can mitigate the effects of this variability. India, southeast Asia,

21

and northeastern China in particular are known to undergo extensive irrigation (Figure 8). Because irrigation is effectively a means of providing a more dependable water supply, these particular areas may, in the real world, be capturing the larger GPP rates.

With Figure 13, we focus on the interannual variability of GPP at each grid cell rather than on the spatial distribution of its mean. Figure 13a shows the variance of annual GPP. Figure 13b shows the spatial distribution of $Corr^2(GPP,P)$, where P is the annual precipitation; that is, Figure 13b shows the fraction of the total GPP variance that is associated with, or can be "explained by", variations in annual water supply. The fractions are reasonably large across the globe, even in some areas considered to be not strongly water-stressed, such as the southeastern United States. In contrast, the fields of $Corr^2(GPP,T)$ and $Corr^2(GPP,R_{net})$, where T is the yearly-averaged temperature and R_{net} is the yearly-averaged net radiation, show significantly lower values (Figures 13c and 13d). While interannual temperature variations do have some impact on high latitude GPP variations (perhaps through their effects on snowcover duration), they have little impact anywhere else. Interannual net radiation variations appear to contribute more, especially in Africa; it is quite possible, however, that these particular "contributions" are not real and instead simply reflect known existing correlations between precipitation and net radiation there (not shown).

Together, annual precipitation, temperature, and net radiation do not explain all of the simulated GPP variability. As before, presumably a significant part of the variability stems from year-to-year variations in (for example) the sub-annual timing of the precipitation and associated variations in infiltration and runoff.

22

Figure 14 shows one final interesting result regarding the interannual variability of GPP. The shading shows Var(GPP) for a 3-month averaging period (centered, at each grid cell, around the month of maximum GPP). Overlain on the plot are black dots indicating where Var(FPAR) for 3-month averages (centered around the local monthly maximum for FPAR) exceeds a value of 0.003, an arbitrary threshold chosen for plotting convenience. The figure shows that Var(GPP) and Var(FPAR) tend not to be maximized in the same regions; Var(GPP) maxima tend to lie on the wetter sides of the Var(FPAR) maxima. The same basic result (not shown) is found for comparisons of the water-limited portions of the variances (i.e., Var(GPP)* versus Var(FPAR)*), and it is also found (not shown) for the all-grassland and all-deciduous-trees simulations, suggesting that variations in vegetation type are not responsible for such spatial offsets in the maxima. The spatial offsets are instead induced by the carbon physics built into the modeling system. Assuming these physical treatments are accurate, then similar offsets would apply to the real world's distributions of Var(GPP) and Var(FPAR). In other words, given estimates of Var(FPAR) attained, for example, through the processing of the GIMMS data, knowledge of the offsets could potentially help in the construction of an estimated spatial field of Var(GPP).

4. Summary and Discussion

Using the Catchment-CN model, a merger of the dynamic phenology components of the CLM4 dynamic vegetation model with the water and energy budget framework of the GMAO Catchment LSM, we examine the connections across the globe between hydroclimate and vegetation variables. Justification for the use of this model in such a study is provided by its demonstrated ability to reproduce observed connections between FPAR and precipitation moments (Section 3), namely, the increase in FPAR with increasing mean precipitation and

23

510   decreasing precipitation variability and the proper geographical placement of spatial maxima in

511   the global field of moisture-related FPAR variance.

512   Our model results can be summarized as follows. First, based on our supplemental

513   simulations with globally uniform vegetation type, we find that the aforementioned relationships

514   between FPAR and precipitation moments are largely independent of vegetation type; the fact

515   that trees grow in wet regimes, grass grows in drier regimes, and shrubs grow in even drier

516   regimes has only a second-order impact on the spatial distribution of FPAR and its interannual

517   variability at each location. Instead, hydroclimatic moments appear to be the dominant

518   determinants of both vegetation type and phenological expression, as represented by FPAR. Our

519   second basic result is that hydroclimatic moments provide a similarly dominant control over the

520   spatial and temporal variability of gross primary productivity (GPP), again with only a second-

521   order contribution from vegetation type.

522   Such a global scale description of GPP connections to hydroclimate is achievable with a

523   DVM but is not possible with observations, which are much more spatially and temporally

524   limited. Knapp and Smith (2001) used observations collected across eleven tower sites to show

525   that aboveground net primary production (ANPP) tends to increase with increasing annual

526   precipitation, and our global scale results (for GPP, a related variable) are consistent with this.

527   We do see some inconsistencies, however, with their study. For example, Knapp and Smith

528   (2001) find that ANPP has its maximum interannual variability in grassland areas. We find that

529   while the interannual variability of FPAR is maximized in grassland areas, the maxima for GPP

530   variability tend to be spatially offset from these FPAR variance maxima (Figure 14), slightly

531   toward the wetter (forested) side. The offset is minor, however, and the apparent inconsistency,

532   while certainly a possible result of model deficiencies, may also relate to the limited number of

24

tower sites they examined. More importantly, Knapp and Smith (2001) find that "interannual

variability in ANPP [is] not related to variability in precipitation". Results from our control

simulation (not shown) indicate that the square of the spatial correlation coefficient between

Var(GPP) and Var(P) across land points is of the order of 30%, which disagrees with their

conclusion; indeed, when we limit the calculation to values at the grid cells containing the LTER

sites they studied, the square of correlation coefficient increases. We also find a reasonably

strong relationship between the time series of GPP and precipitation (Figure 13b) at individual

locations.

While interpretations of DVM-based results must be tempered by knowledge of model

biases and limitations, DVM experiments, if properly interpreted, open the door to a wealth of

potential studies of the global carbon cycle and its interactions with the global water and energy

cycles. This paper provides one such study. Another example of note is provided by Guan et al.

(2012), who show with DVM simulations over Africa that the statistical character of

precipitation forcing (e.g., rainfall intensity) manifests itself in the GPP produced. The

advantages of using DVMs – their provision of comprehensive (and often unmeasurable) data

and their ability to be modified at will to allow the examination of the impacts of individual

physical processes – stand them in good stead for future carbon analyses. Our understanding of

global carbon-water-energy connections should continue to increase as researchers continue to

use ever-improving versions of these tools.

693   Figure 5. (a) Average GIMMS NDVI in peak NDVI season as a function of the mean

694   precipitation (x-coordinate) and the standard deviation of annual precipitation (y-

695   coordinate). Each dot represents a single land grid cell. (b) Same as (a), but with the

696   individual values in the scatter plot averaged over bins. At least 5 dots must lie within a

697   bin for the binned value to be plotted. (c) and (d): Same as (a) and (b), but for GIMSS

698   FPAR data. (e) and (f): Same as (a) and (b) , but for model-simulated FPAR data.

699   Figure 6. (a) Product of the interannual variance of GIMMS NDVI data averaged over the

700   maximum NDVI season and the square of the correlation between NDVI and annual

701   precipitation, multiplied by 1000. (b) Same, but for GIMMS FPAR data. (c) Same, but

702   for model-generated FPAR data, and with the scaling factor changed to 500.

703   Figure 7. Map of grassland locations, as derived from the distributions used in the Second Phase

704   of the Global Soil Wetness Project (Dirmeyer et al. 2006). The dots overlain on the plot

705   indicate regions for which irrigation is extensive (>10% of the land area, based on data

706   aggregated from FAO [http://www.fao.org/nr/water/aquastat/irrigationmap/index.stm]),

707   suggesting difficulty in relating observations-based FPAR values to local precipitation

708   amounts.

709   Figure 8. (a) Same as Figure 2f (average model-simulated FPAR in peak FPAR season as a

710   function of the mean precipitation and the standard deviation of annual precipitation), but

711   for the case in which the entire globe is forced to be covered by grassland. (b) Same as

712   (a), but for the "all tree" case. (c) Same as Figure 6c (product of the interannual variance

713   of model-simulated FPAR averaged over the maximum FPAR season and the square of

714   the correlation between NDVI and annual precipitation, multiplied by 500), but for case

715   where the entire globe is forced to be covered by grassland. (d) Same as (c), but for the

716   "all tree" case.

717 Figure 9. Global distribution of annual gross primary productivity (GPP, in grams C / m^2-day)

718   for: (a) the control simulation; (b) the simulation in which all land is covered with a

719   grassland vegetation type; and (c) the simulation in which all land is covered with a

720   deciduous tree vegetation type.

721 Figure 10. (a) Same as Figure 4, but for GPP (rather than NDVI or FPAR) produced in the

722   control simulation. (b) Same, but for GPP produced in the "all grass" simulation. (c)

723   Same, but for GPP produced in the "all trees" simulation.

724 Figure 11. (a) Average GPP (g Carbon / m^2-day) as a function of the mean precipitation (x-

725   coordinate) and the standard deviation of annual precipitation (y-coordinate) in the

726   control simulation, with individual land grid cell values averaged over bins. At least 5

727   dots must lie within a bin for the binned value to be plotted. (b) Same, but for the

728   simulation in which all land is covered with a grassland vegetation type. (c) Same, but

729   for the simulation in which all land is covered with a deciduous tree vegetation type.

730 Figure 12. Difference in the mean annual GPP produced in the ClimP simulation (the simulation

731   using climatological precipitation forcing) and that produced in the control simulation, in

732   units of grams carbon/m^2-day.

733 Figure 13. (a) Variance of annual GPP (in g^2 / $m^4 day^2$) as produced by the control simulation.

734   (b) $Corr^2$(GPP,P), i.e., the fraction of the GPP variance associated with interannual

735   variance in annual precipitation. (c) Same as (b), but for the fraction of the GPP

736   variance associated with interannual variations in annual temperature. (d) Same as (b),

737   but for the fraction of the GPP variance associated with variations in annual net radiation.

738 Figure 14. Interannual variance of GPP (g^2/m^4day^2) for the 3-month period centered on the

739   month for which the local GPP is climatologically largest. Overlain on the plot are black

740   dots showing where the interannual variance of 3-month FPAR is maximized.

745   Figure 1. a. Schematic of flux computations in the original Catchment LSM. b. Schematic of
746   flux computations in the merged model, Catchment-CN.

747

748

Figure 2. Schematic of independent vegetation (carbon) treatments in topographically-defined vegetation zones. Three static vegetation zones are defined, with independent carbon prognostic variables in each. W_1, W_2, and W_3 are soil moisture states in the three dynamically-varying hydrological zones (with time-varying areas AR1, AR2, and AR3); weighted averages of these states (e.g, W_{V2}, as shown in the figure) and corresponding weighed temperature states are passed down to the carbon physics calculations for the different vegetation zones. Weighted averages of vegetation zone quantities (e.g., canopy conductance) are similarly passed back to the hydrological zones.

NDVI$_{max}$ (observations)

FPAR$_{max}$ (observations)

FPAR$_{max}$ (model)
763 Figure 3. a. Distribution of average NDVI in peak NDVI season (the month for which the mean
764 seasonal cycle of NDVI is maximized along with the preceding and following months), from
765 GIMMS observations. The peak season varies with grid cell; see text for details. b. Same, but
766 for average FPAR in peak FPAR season, from GIMMS observations. c. Same, but for average
767 FPAR in peak FPAR season, from model simulation.
Figure 4. (a) Square of the spatial correlation coefficient (over land grid cells) between observed NDVI and land surface forcing variables: the logarithm of the mean annual precipitation (P), the logarithm of the standard deviation of annual precipitation (σ_P), mean annual air temperature (T), and mean annual net radiation (R_{net}). The final two bars show the square of the correlation coefficient obtained from the multiple regression of NDVI against, respectively, (i) precipitation mean and standard deviation, and (ii) all four quantities. (b) Same, but for observed FPAR. (c) Same, but for modeled FPAR.
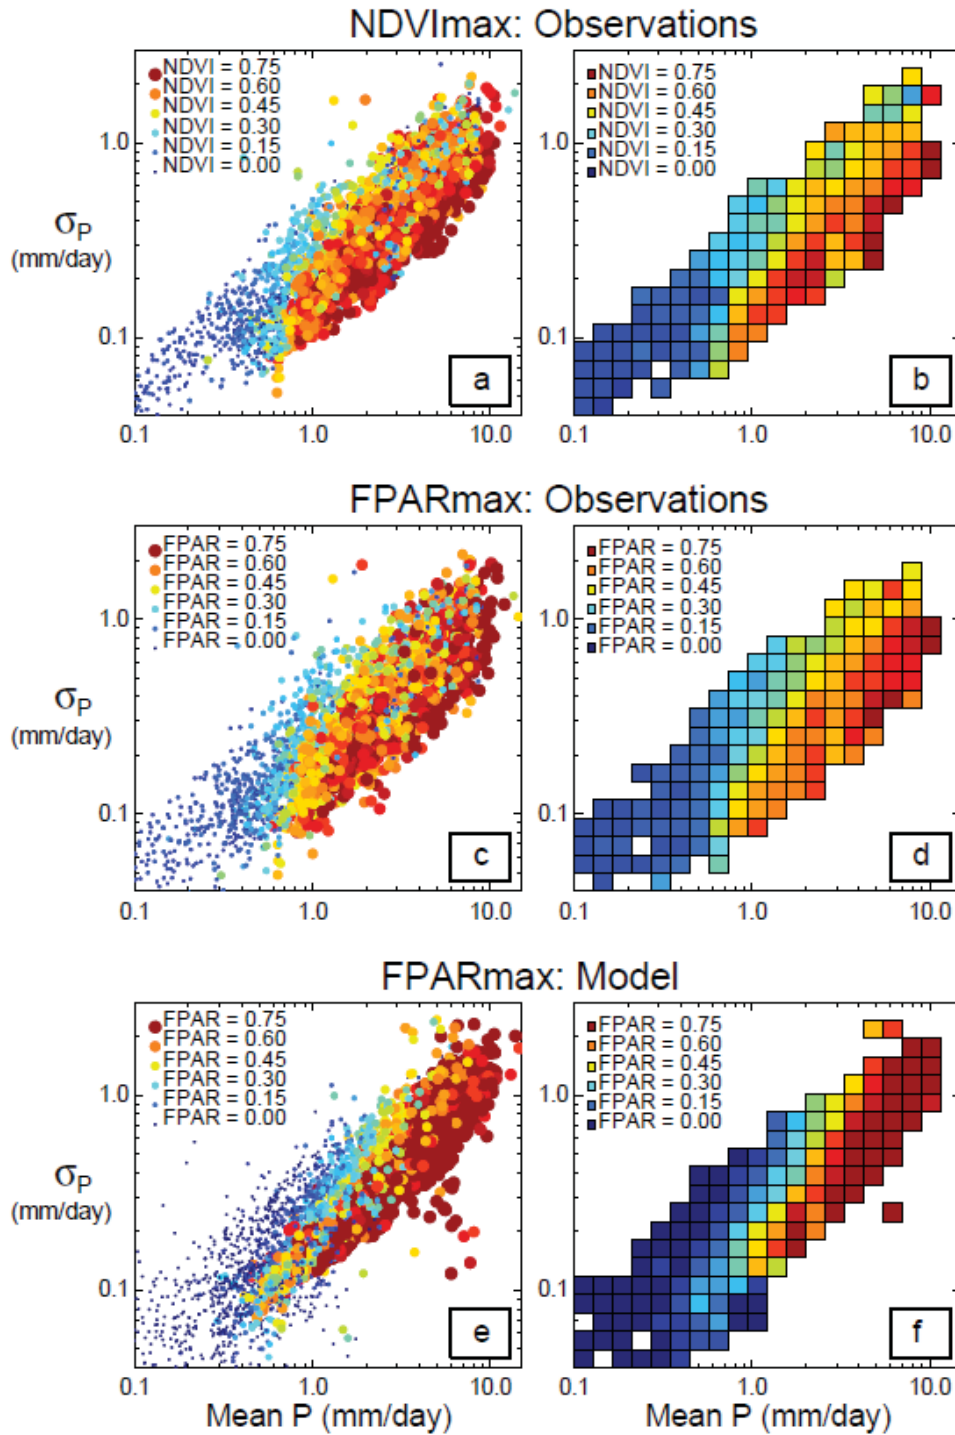

Figure 5. (a) Average GIMMS NDVI in peak NDVI season as a function of the mean precipitation (x-coordinate) and the standard deviation of annual precipitation (y-coordinate). Each dot represents a single land grid cell. (b) Same as (a), but with the individual values in the scatter plot averaged over bins. At least 5 dots must lie within a bin for the binned value to be plotted. (c) and (d): Same as (a) and (b), but for GIMSS FPAR data. (e) and (f): Same as (a) and (b), but for model-simulated FPAR data.
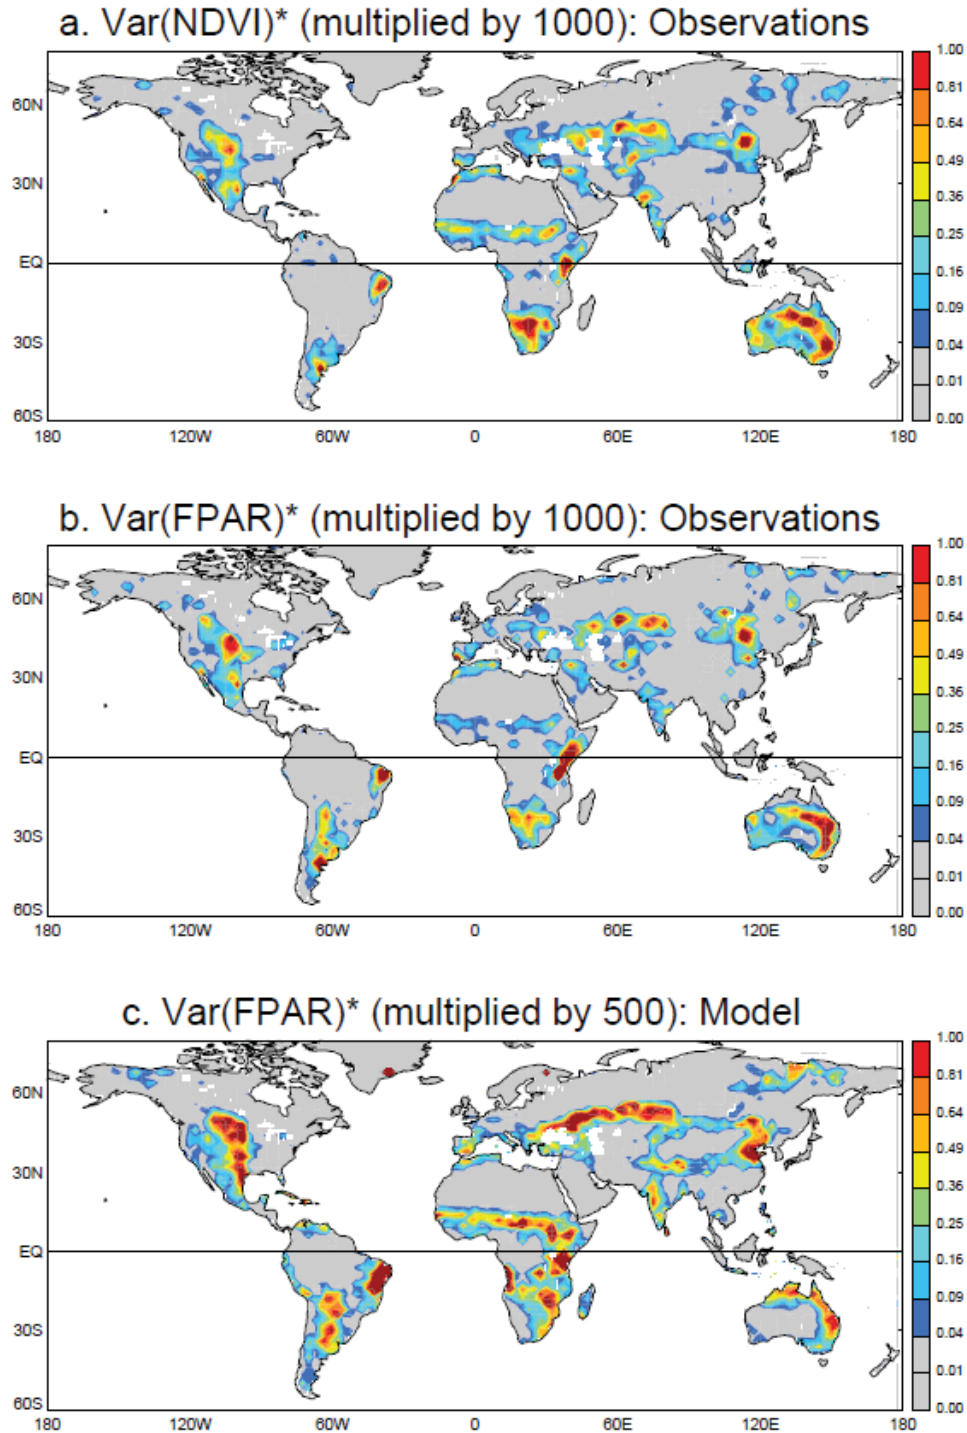

Figure 6. (a) Product of the interannual variance of GIMMS NDVI data averaged over the maximum NDVI season and the square of the correlation between NDVI and annual precipitation, multiplied by 1000. (b) Same, but for GIMMS FPAR data. (c) Same, but for model-generated FPAR data, and with the scaling factor changed to 500.
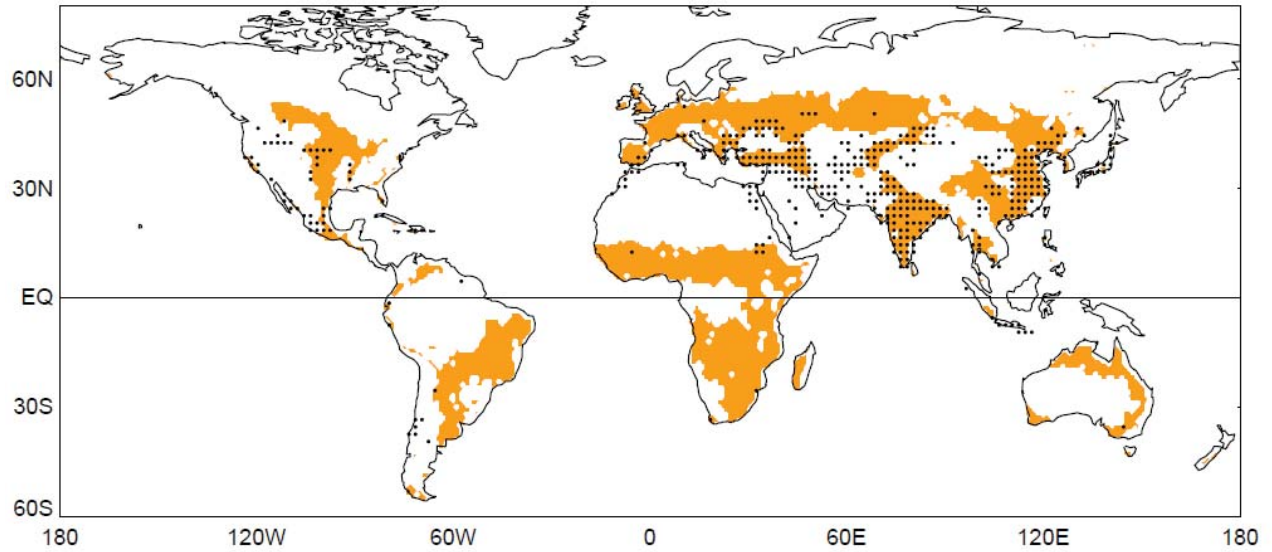

Figure 7. Map of grassland locations, as derived from the distributions used in the Second Phase of the Global Soil Wetness Project (Dirmeyer et al. 2006). The dots overlain on the plot indicate regions for which irrigation is extensive (>10% of the land area, based on data aggregated from FAO [http://www.fao.org/nr/water/aquastat/irrigationmap/index.stm]), suggesting difficulty in relating observations-based FPAR values to local precipitation amounts.

799
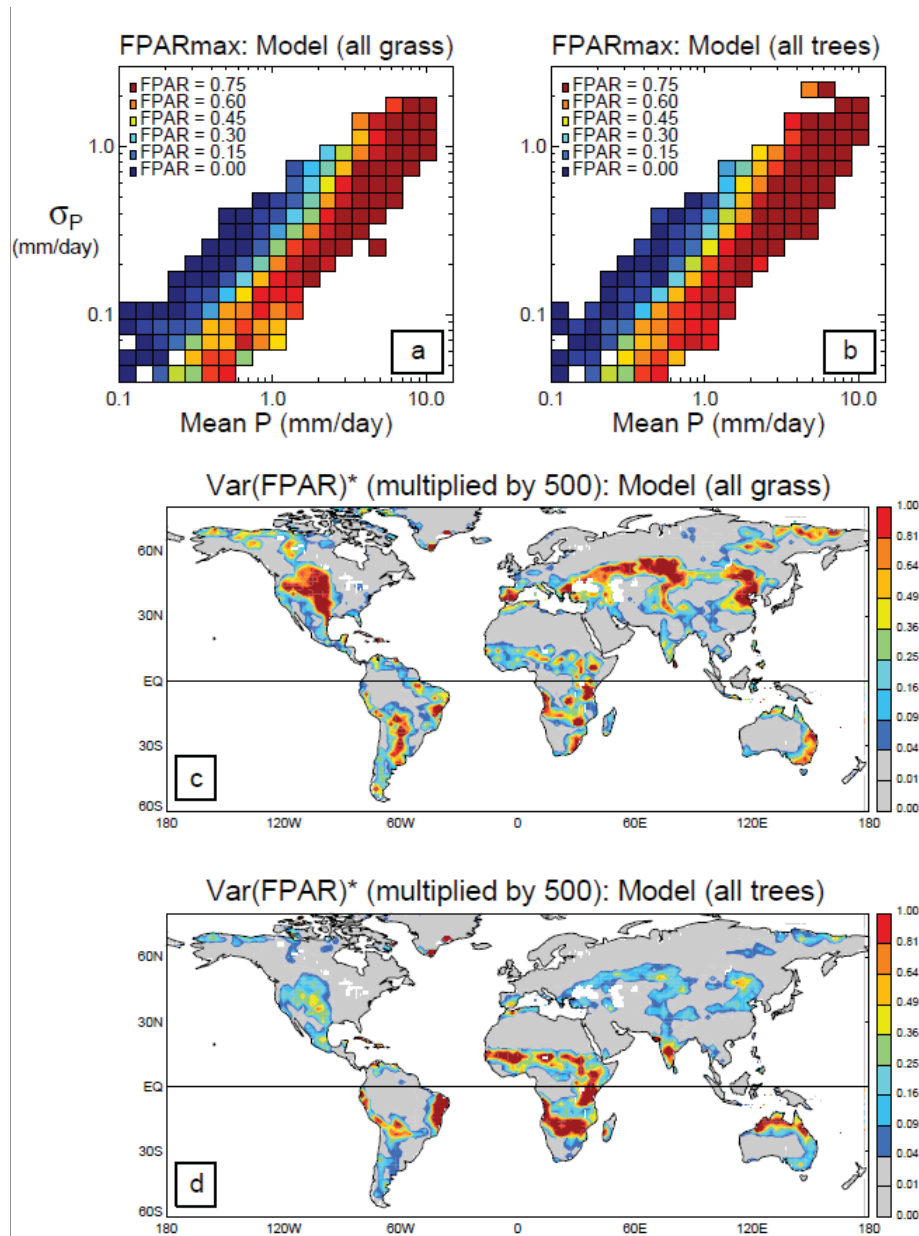

Figure 8. (a) Same as Figure 2f (average model-simulated FPAR in peak FPAR season as a
function of the mean precipitation and the standard deviation of annual precipitation), but for the
case in which the entire globe is forced to be covered by grassland. (b) Same as (a), but for the
"all tree" case. (c) Same as Figure 6c (product of the interannual variance of model-simulated
FPAR averaged over the maximum FPAR season and the square of the correlation between
NDVI and annual precipitation, multiplied by 500), but for case where the entire globe is forced
to be covered by grassland. (d) Same as (c), but for the "all tree" case.
Figure 9. Global distribution of annual gross primary productivity (GPP, in grams C / m²-day) for: (a) the control simulation; (b) the simulation in which all land is covered with a grassland vegetation type; and (c) the simulation in which all land is covered with a deciduous tree vegetation type.

812

813
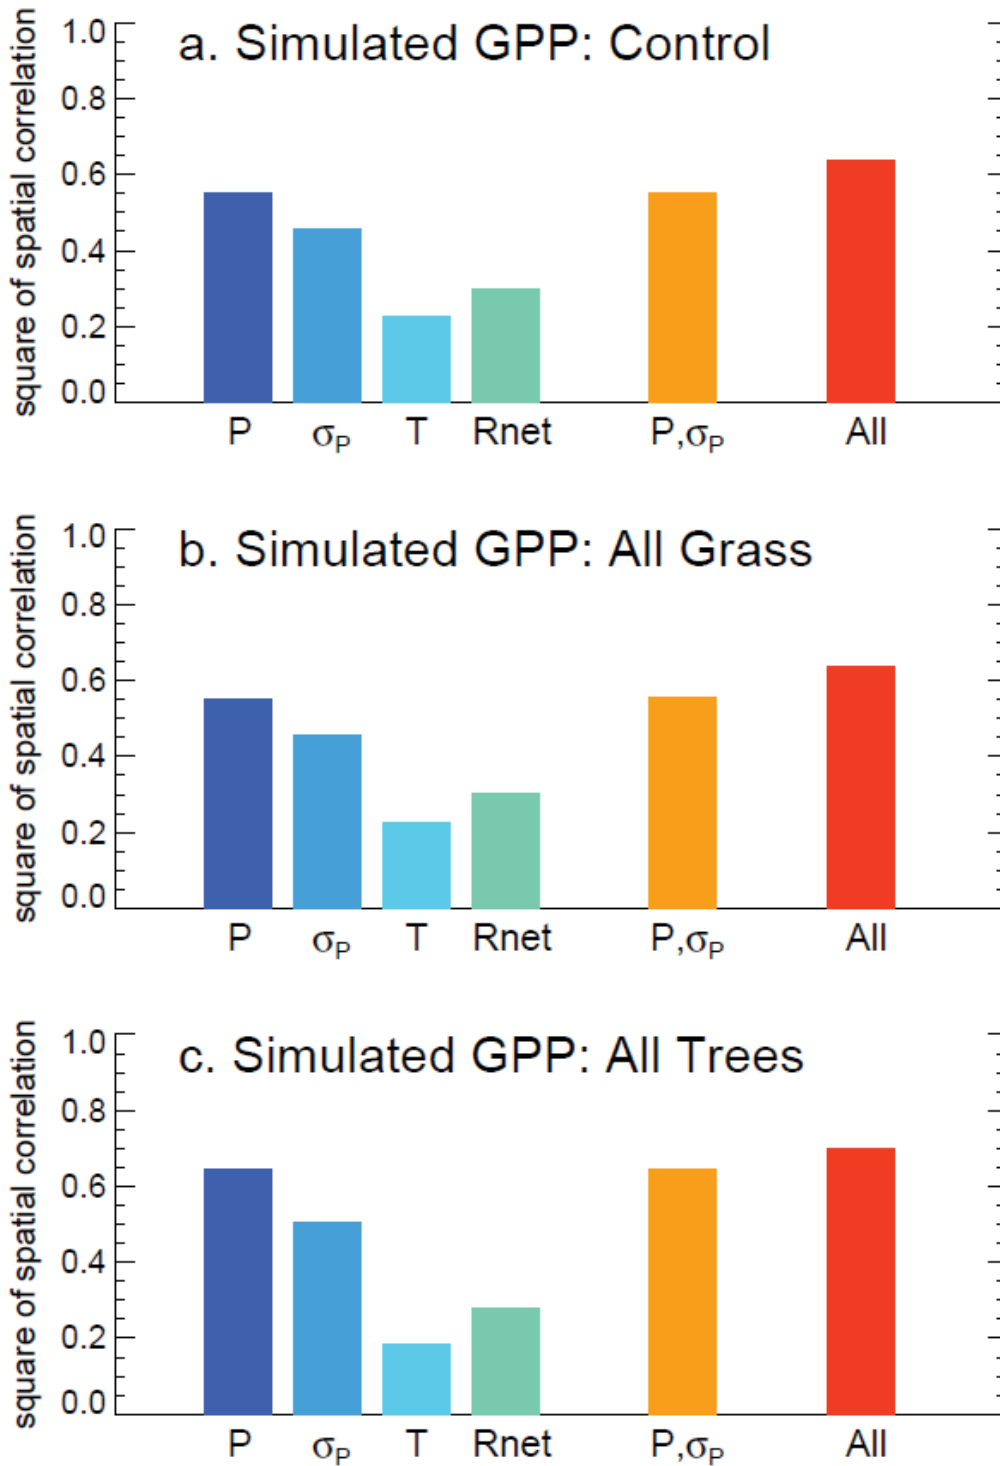

Figure 10. (a) Same as Figure 4, but for GPP (rather than NDVI or FPAR) produced in the
control simulation. (b) Same, but for GPP produced in the "all grass" simulation. (c) Same, but
for GPP produced in the "all trees" simulation.
817

Figure 11. (a) Average GPP (g Carbon / m^2-day) as a function of the mean precipitation (x-coordinate) and the standard deviation of annual precipitation (y-coordinate) in the control simulation, with individual land grid cell values averaged over bins. At least 5 dots must lie within a bin for the binned value to be plotted. (b) Same, but for the simulation in which all land is covered with a grassland vegetation type. (c) Same, but for the simulation in which all land is covered with a deciduous tree vegetation type.
