INTRODUCTION

There are three purposes in preprocessing from a pass of raw satellite range measurements:

- a) Correcting system errors for raw SLR data and forming observational files;
- b) Fitting a smoothing function to the range residuals from the predicted orbit, rejecting noises and outliers then estimating accurate for this pass;
- c) Forming QL, FL and NP data files.

The second term is very important for data preprocess, because the smoothing function will have effect on quality of NP data.

The smoothing function we used is simply a polynomial in time. Generally, the least squares (LS) estimation is used to solve the parameters of polynomial. But, the LS estimation is not a robust estimation. Sometime, there are a large number of noises in raw SLR data, especially those passes are in daylight, the solution of the LS estimation will converge to false values.

In this paper, M-estimator, one kind of robust estimator has been used in SLR data preprocessing. It has been shown that the M-estimator has 50% or more breakdown point ϵ^* . The breakdown point means that, when the probability of noises ϵ increases to ϵ^* , this method will fail.

M-ESTIMATOR

The linear equation is written:

$$y_i = X_i^T \theta + e_i \quad (1)$$

where

y_i are observations

θ is the vector of parameters to be estimated
 X_i is the vector of coefficients
 e_i are random errors.

The M-estimator, called Maximum Likelihood Type Estimator, is such an estimator which makes the following objective function minimum:

$$\sum_{i=1}^N F((y_i - X_i^T \hat{\theta})/\sigma) = \min. \quad (2)$$

$\hat{\theta}$ are values estimated for θ

σ^2 is variance

$F(\cdot)$ is an even function

Different objective functions have different M-estimator. In this paper we used Hampel estimator, here

$$F(r_i) = \begin{cases} -\frac{1}{2} r_i^2 & |r_i| \leq \lambda_0 \sigma \\ \lambda_0 \sigma (|r_i| - \frac{1}{2} \lambda_0 \sigma) & \lambda_0 \sigma < |r_i| \leq \lambda_1 \sigma \\ \frac{\lambda_0}{\lambda_2 - \lambda_1} (\lambda_2 \sigma |r_i| - \frac{1}{2} r_i^2) & \lambda_1 \sigma < |r_i| \leq \lambda_2 \sigma \\ -\frac{\lambda_1}{\lambda_2 - \lambda_1} \frac{\lambda_0}{2} \sigma^2 - \frac{1}{2} \lambda_0^2 \sigma^2 & |r_i| > \lambda_2 \sigma \\ \lambda_0 (\lambda_2 + \lambda_1 - \lambda_0) \sigma^2 / 2 & |r_i| > \lambda_2 \sigma \end{cases} \quad (3)$$

$$r_i = y_i - X_i^T \hat{\theta}$$

$$\lambda_0 = 3, \lambda_1 = 4, \lambda_2 = 6.$$

Equation (2) can be rewritten as:

$$\sum_{i=1}^N X_i \Psi((y_i - X_i^T \hat{\theta})/\sigma) = 0 \quad (4)$$

where

$$\Psi(\cdot) = F'(\cdot).$$

Then

$$\hat{\theta} = \left[\sum_{i=1}^N X_i W_i X_i^T \right]^{-1} \left[\sum_{i=1}^N X_i W_i y_i \right] \quad (5)$$

and

$$W_i = \Psi(r_i/\sigma) / (r_i/\sigma). \quad (6)$$

From (3) we have

$$W(r_i/\sigma) = \begin{cases} 1 & |r_i| \leq \lambda_0 \sigma \\ \lambda_0 \sigma / |r_i| & \lambda_0 \sigma < |r_i| \leq \lambda_1 \sigma \\ \lambda_0 (\lambda_2 \sigma - |r_i|) / (\lambda_2 - \lambda_1) |r_i| & \lambda_1 \sigma < |r_i| \leq \lambda_2 \sigma \\ 0 & |r_i| > \lambda_2 \sigma \end{cases} \quad (7)$$

and

$$\hat{\sigma}^2 = \frac{1}{N-p} \sum_{i=1}^N r_i^2 \quad (8)$$

p is number of the paramaters estimated.

When given the starting values θ_0 and σ_0 , we can solve $\hat{\theta}$ by (5), (6) and (7). The solution is then iterated between (5) and (8), until convergence of the object function.

$$|U^{j+1} - U^j| / U^j < 10^{-3}$$

here

$$U = \sum_{i=1}^N F\{(y_i - X_i^T \hat{\theta}) / \sigma\}$$

j is the times of the iteration.

PROCEDURES

The predicted and observed ranges is R_c and R_o at each instant of observation T . After atmospheric correction, center of mass correction and delay calibration, we have the following range residual equation:

$$\begin{aligned} y_i &= \Delta R_i \\ &= a + b \dot{\rho}_i + e_i \end{aligned} \quad (9)$$

Where a , b are range bias and time bias.

$\dot{\rho}$ is the variability of range.

Reference show a method of caculation which have 50% breakdown point.

a) If total observation data points are N , which are divided into n subgroups equally and every subgroup includes four data points, as:

$$\begin{array}{cccc} y_1 & y_{n+1} & y_{2n+1} & y_{3n+1} \\ y_2 & y_{n+2} & y_{2n+2} & y_{3n+2} \\ \dots & \dots & \dots & \dots \end{array}$$

$$\begin{array}{cccc}
y_k & y_{n+k} & y_{2n+k} & y_{3n+k} \\
\cdots & \cdots & \cdots & \cdots \\
y_n & y_{n+n} & y_{2n+n} & y_{3n+n}
\end{array}$$

$$n=N/4.$$

When noise numbers in raw observation data are less than $N/2$, there must be a subgroup in which contains one noise point at most.

b) For the linear model as (9), we can find the linear estimated value of \hat{b}_k for any subgroup k :

$$\hat{b}_k = \sum_{i=1}^4 \beta_i y_i \quad (10)$$

If \hat{b}_k is no-bias, we have:

$$\left. \begin{array}{l}
\sum_{i=1}^4 \beta_i = 0 \\
\sum_{i=1}^4 \beta_i \dot{\rho}_i = 1
\end{array} \right\} \quad (11)$$

and

$$\sum_{i=1}^4 \frac{1}{\delta_i} \beta_i^2 = \min$$

where

$$\delta_2 = \delta_3 = 1$$

$$\delta_1 = \frac{T_2}{2T_1 + T_2} C \quad (C \text{ is a constant to be selected})$$

$$\delta_4 = \frac{T_2}{2T_3 + T_2} C$$

$$T_i = \dot{\rho}_{i+1} - \dot{\rho}_i \quad (i=1, 2, 3)$$

By solving equations (11), we get:

$$\beta_i = \delta_i \lambda \tau_i \quad (i=1, 2, 3, 4)$$

where

$$\lambda = 1 / \sum_{i=1}^4 \delta_i \tau_i^2$$

$$\tau_i = \dot{\rho}_i - \dot{\rho}_0$$

$$\dot{\rho}_0 = \sum_{i=1}^4 \delta_i \dot{\rho}_i / \sum_{i=1}^4 \delta_i$$

$$C = \max \left[\frac{T_2 + T_3}{T_1 + T_2 + T_3}, \frac{T_1 + T_2}{T_1 + T_2 + T_3} \right]$$

Thus, the residuals of k -subgroup are

$$r_{kl} = y_{kl} - \dot{b}_k \dot{\rho}_{kl} \quad (l=1, 2, 3, 4)$$

c) For each subgroup, the largest and smallest values of r_{kl} are rejected. And we can get the initial values a_{k0} , b_{k0} from remained two data points through follows:

$$y_{kl} = a_{k0} + b_{k0} \dot{\rho}_{kl} \quad (j=1, 2)$$

d) Then calculation the object function of M-estimate used all observations for every subgroups:

$$U_k = \sum_{i=1}^N F\{y_i - a_{k0} - b_{k0} \dot{\rho}_i\} \quad (k=1, 2, \dots, n)$$

where $F(\cdot)$ can be taken from (3), and the initial value of σ can be arbitrarily given, for example 0.5 meters.

e) Select the minimum value from U_k ($k=1, 2, \dots, n$). Suppose $k=m$, that is

$$U_m = \min.$$

Then a_{m0} and b_{m0} those are taken from m -subgroup, can be used as the initial values a_0, b_0 . It is sure that the a_0 and b_0 are taken from 'good' observation points.

f) Then we can get

$$r_i = y_i - a_0 - b_0 \dot{\rho}_i \quad (i=1, 2, \dots, N)$$

$$\sigma_0^2 = \frac{1}{N-2} \sum_{i=1}^N r_i^2$$

Because a_0, b_0 are obtained by two data points, they have just lower accuracy. From (5) to (8) and iterated until convergence, the accurate results a, b can be get as above.

g) After correcting range bias and time bias, we can get a polynomial in time as following:

$$\begin{aligned} \Delta \rho'_i &= y_i - a - b \dot{\rho}_i \\ &= a_0 + a_1 t_i + a_2 t_i^2 + a_3 t_i^3 + \dots \end{aligned}$$

Using M-estimator, the parameters of polynomial $a_0, a_1, a_2, a_3, \dots$ can be solved.

CONCLUSION AND DISCUSSION

Comparing with the LS estimator, M-estimator has its advantage as follows:

a) It can be preprocess observation data that contain a large amount of noises, for example , a pass for LAGEOS in daytime are shown in fig 1, (12/20/1991 8:45 UT). In this pass rate of noise is up to 70%.

b) At same accuracy, the order of polynomial fitting is only 4 using M-estimator, while the order is up to 6-8 or more with LS estimator. Seeing table 1.

c) Noise mixed at the parts near the both ends of the curve can be detected and deleted.

Besides, comparison with the method of screen-processin and LS estimator, one third time is saved with M-estimator.
