TECHNICAL MEMORANDUM NO. 203.

SPEED LIMITS OF AIRCRAFT.*

## Introduction.

"Flight means landing" says Siegert: But flight also means speed. It is all the more difficult to reconcile the structural contradiction between great speed and good landing ability, because the requirements have not yet been firmly established and can only be determined with reference to the manner of landing and the nature of the landing field.

This paper is therefore restricted to the question of attainable speed limits and attacks the problem from different angles. A theoretical limit of the maximum speed is obtained from consid621 mad erations of air resistance above 1000 km per hour. According to the present state of engine technics, half of the above is to be regarded as the upper limit. The maximum speed, thus far attained by an airplane, is 341 km ( 212 miles ) per hour, which is already quite near the technical limit. The landing speed, according to tests on models with ordinary wing sections, ranges from 53 km ( 33 miles) to 75 km ( 47 miles ) per hour, but is still somewhat smaller for actual airplanes.

The actual relation between speed and landing ability is given by statistics of airplanes in dimensionless presentation. The limits are not related according to any rigid law, but a low land-

* Paper read by Dr. E. Everling, June 18, 1922, befcre the W.G.L. (Scientific Society for Aviation).
ing speed must be obtained at the expense of aerodyramic efficiency.

The selection of suitable wing sections for increasjing the maximum speed is facilitated by a new and especially simple abacus, which enables the computation of a series of relations. In particular, it gives from the wing load and the load per $H P$, the power coefficient, i.e. the D/L ratio divided by the square root of the lift coefficient ( $D / \mathrm{L}^{3 \ell^{2}}$ ) and hence the point on the lift curve at which the flight is made. The landing speed must be taken into consideration in determining the wing load.

Ordinary wing sections give, even with low wing loading, quite high landing speeds. "Air brakes" and reversible propellers reduce, it is true, the size of landing field required, but not the landing speed. Adjustable wings are of very little advantage and folding wings add but little to the maximum speed.

Lachmann's slotted wings, which have been tested by Handley Page on an airplane and by a model in the Göttingen aerodynamic laboratory, seem to be the most promising.

The goal of flight technics, namely, ability to land on a small field, requires quite different means. Perhaps the helicopter is destined to help. Light engines are essential, however.

SPEED LIMITS OF AIRPLANES.
(Lecture by Dr. E. Everling)

## 1. Importance of Large Speed Range.

"Flight means landing" says Siegert, in connection with Baumann's lecture on the economics of air traffic.* The need of being able to compete with other means of transportation, even with inconveniently located airports and against strong winds,** occasions the claims that "Flight means speed."

One of the greatest problems of airplane construction is to reconcile the contradiction between grest speed and good landing ability. Efforts have been made to solve it by ordinary technical means and with special devices.

In giving here, at the request of the W.G.L. (Wissens chaftlische Gesellschaft für Luftfahrt), information concerning this work, I am obliged to refrain from any exhaustive treatment of the all too plentiful literature in this field.

I would much rather indicate the present status of the problem, after mentioning the numerical speed limits, by showing statistically what has hitherto been accomplished, what practical limits must be opposed to the theoretical limits, how suitable wing sections for high speeds may be selected, what has been done in the matter of improving the landing speed and what still remains to be done.

* A. Baumann, "Die Kosten der Luftreise," Z.F.M., April 15, 1921, p.98. N.f.L. 21/7, 29 (Nachriohten für Luftfahrer, 1921, No.7, item 29).
** E. Everling, "Der Einfluss des Windes im Luftverkehr," Naturwissenschaften, May 28, 1920, pp. 418-423; "Der Einfluss des Windes auf die Transportleistung," Z.F.M., Feb. 15, 1922, p. 40.

## 2. Maximum Speed:

a) Limit according to the theory of flow.- From the efficiency formula of unaccelerated horizontal flight, the propeller efficiency

$$
\begin{equation*}
75 \eta \mathbb{N}=W \frac{V}{3.6}=G \in \frac{V}{3.6} \tag{1}
\end{equation*}
$$

follows for the velocity $v$ (in $\mathrm{km} / \mathrm{hr}$; or $\mathrm{v} / 3.6$ in $\mathrm{m} / \mathrm{sec}$ )

$$
\begin{equation*}
v=270 \frac{\eta}{\epsilon} \frac{N}{G} \tag{2}
\end{equation*}
$$

in which: $G$ denotes the flight weight in $k g ;$
N (HP) or 75 N (kgn/sec) the HP of the engine, hence G/N (kg/HP) the load per HP;
$\eta$ propeller efficiency, about 0.67 or $2 / 3$, hence
$\eta \mathrm{N}(\mathrm{HP})$ or $75 \eta \mathrm{~N}(\mathrm{~kg} / \mathrm{sec})$ the propeller output and
$75 \eta \mathrm{~N} / \mathrm{G}(\mathrm{m} / \mathrm{s})$ the vertical velocity,*
$\epsilon$ the drag-lift ratio (Gleitzahl), the ratio of the drag to the weight $G(\mathrm{~kg}) .{ }^{* *}$

Hence, speed of airplane $(\mathrm{m} / \mathrm{sec})=$ vertical velocity divided by the drag-lift ratio,
or, flight speed ( $\mathrm{km} / \mathrm{hr}$ ) bears the same relation to $270 \mathrm{~km} / \mathrm{hr}$, as the quotient of efficiency divided by the drag-lift ratio to the load per HP.

In order to obtain a pure theoretical upper limit for the

[^0]$\frac{\eta}{\varepsilon}=2.57$; hence $\epsilon \approx \frac{0.7}{2.57}=0.27=\frac{1}{3.7}$.
ilight speed, we write $\eta=1$, since the maximum propeller efficiency at high speeds ciosely approximates this value. For the load per $H P$, values are known up to $2.43 \mathrm{~kg} / \mathrm{HP}$. Here let $G / \mathrm{N}=2 \mathrm{~kg} /$ HP be adopted as the minimum value. There follows for the maximum speed
\[

$$
\begin{equation*}
v_{g}=\frac{135}{\epsilon_{k}} \tag{3}
\end{equation*}
$$

\]

For the minimum value of the drag-lift ratio $\epsilon_{k}$, under the assumption that neither parasite drag nor wing-section drag, but only the marginal drag of the wing is present, we obtain*

$$
\begin{equation*}
\epsilon_{k}^{\prime}=\frac{G}{F q} \frac{\lambda}{\bar{\pi}}=c A \frac{\lambda}{\bar{\pi}} \tag{4}
\end{equation*}
$$

in which $F=$ wing area in $\mathrm{m}^{\mathrm{B}}, \mathrm{q}=$ dynamic pressure of the wind in $\mathrm{kg} / \mathrm{m}^{2}$ and $\lambda=$ aspect ratio of wing (mean chord to span $b$, or wing area $F$ to $b^{2}$ ). The abstract lift coefficient $c A$ is the ratio of the lift $A$ or weight $G$ to the pressure on the wing surface. **

For the aspect ratio $\lambda=1: 10=0.1$ we would therefore have, as the maximum speed,

$$
v_{g}=\frac{135}{c A} \frac{\pi}{0.1}=\frac{4240}{c A} \mathrm{~km} / \mathrm{h}
$$

* According to L. Prandtl, "Tragflachenauftrieb und -widerstand in der Theorie," Jahrbuch der W.G. L. $z_{\text {19 }}$ 1920, p. 49, equation 2, we have, for the marginal drag, $W_{\Gamma}=A^{z} / \pi b^{2} q$ and hence, for the drag-lift ratio, $\epsilon_{I}=W_{I} / A=A / H b^{8} q$. The drag-lift ratio, in consequence of the marginal drag, is therefore, the lift divided by the dynamic pressure on the circle with the span as the radius. From this follows equation 4.
** The symbol cA is substantiated rather than $c_{a}$. E. Everling, "Luftkrafte und Beiwerte," Z.F.M. Dec. 15, 1921, p. 340, par. 3. Equation 6 leads moreover to the expression $\epsilon / \mathrm{cA}$, while later

$$
\frac{\epsilon}{\sqrt{c \bar{A}}} \text { or } \frac{\epsilon}{\sqrt[4]{C \bar{A}}} \text { will appear. }
$$

a value, which, for sufficiently small lift coefficients, can grow into infinite, though fabulous, wing loads, near the ground,* on. acount of equation 7),

$$
\begin{equation*}
\frac{G}{F}=c A q=\frac{c A}{16} v_{g}^{2}=\frac{4240}{16} \nabla_{g}=265 \mathrm{v}_{\mathrm{g}} \mathrm{~kg} / \mathrm{m}^{2} \tag{8}
\end{equation*}
$$

Hence no upper limit can be obtained** in this manner, even by solving equation 8 according to $\mathrm{V}_{\mathrm{g}}$.

Useful results came from the assumption that only the parasite drag of a fuselage for passengers and power plant exists. If the cross-section of this fuselage $f$ is called its coefficient of drag (ratio of drag $W$ to dynamic pressure $q$ on $f$ ), $c W_{f}=0.05$ and we have, for the flight performance,

$$
\begin{equation*}
75 \eta N=W \frac{v}{3.6}=c \mathbb{W}_{\mathrm{f}} \frac{\mathrm{f}}{16}\left(\frac{\mathrm{v}}{3.6}\right)^{3} \tag{9}
\end{equation*}
$$

Since a 1000 HP engine can be easily brought within one sq.m. of front surface area, $\mathrm{N} / \mathrm{f}=1000 \mathrm{HP} / \mathrm{m}^{2}$ is not too favorable and may therefore

$$
\begin{gather*}
v_{g}=3.6 \sqrt[3]{75 \eta \frac{16}{c W_{f}} \frac{N}{f}}=3.6 \sqrt[3]{75 \times 1.00 \frac{16}{0.05} \frac{N}{f}}= \\
=103.8 \sqrt[3]{\frac{N}{f}}=1038 \mathrm{~km} / \mathrm{h}=288 \mathrm{~m} / \mathrm{s} \tag{10}
\end{gather*}
$$

be regarded as a sort of upper limit.
*Air density designated by $0.125 \mathrm{~kg}^{2} / \mathrm{m}^{4}$, hence half the air density $=1 / 16 \mathrm{~kg}^{2} / \mathrm{m}^{4}$.
** This is comprehensible, if we remember that the parabola of the marginal drag, in Lilienthal's lift curve has the axis of the lift coefficient at the zero point for tangent. On the other hand, L. Prandtl, in Luftfahrt, May, 1921, p.83, gives a formula for the minimum power of airplanes for a desired speed without deduction. This equation, which follows from our equation 1 by solving according to $N$ and introducing $W$ according to equation 5, occasioned the remarks in the paragraph in small type. It could not be simply inverted, because it was sought to determine the speed limit for any horsepower.
b) Limits according to techinical considerations. - While theoretical considerations seek to outline the field of possible limits zocording to physical laws, technical considerations give limits, which, in the present status of engine construction, carnot be exceeded.

Rateau* takes

$$
\begin{align*}
& r_{1}=0.75 \\
& \frac{G}{\mathbb{N}}=3.5 \mathrm{~kg} / \mathrm{HP} \text { and } \\
& \epsilon=\frac{1}{8}=0.125, \text { hence } \\
& \frac{\eta}{\epsilon}=0.75 \times 8=6.0 \tag{12}
\end{align*}
$$

a value which, so far as I know, has only been exceeded by one airplane.** There follows, for the maximum speed according to equation 2 ,

$$
\begin{equation*}
v_{g}=270 \frac{6.0}{3.5}=463 \mathrm{~km} / \mathrm{h}=129 \mathrm{~m} / \mathrm{s} \tag{12}
\end{equation*}
$$

Near the ground, this corresponds to $129^{2} / 16=1030 \mathrm{~kg} / \mathrm{m}^{2}$ dynamic pressure, hence about $500 \mathrm{~kg} / \mathrm{m}^{2}$ wing load, or about onetenth of the usual crossmsectional area and about six times the maximum value at that time.** Although this maximum wing load occurs on the same airplane, which, on account of its favorable flow characteristics, has a better drag-lift ratio than here

* A. Rateau, "Sur les plus grandes distances franchissables par les avions et les plus grandes vitesses realisables" (Maximum flight distances and speeds), Comptes Rendus, Feb. 16, 1920, pp. 364-370; Z.F.M. July 15, 1920, p. 196.
** For the 1000 HP Staaken monoplane, $\eta / \varepsilon>7$ (See table 2, No. 38). Fing load is $G / F=80 \mathrm{~kg} / \mathrm{m}^{2}$; load per $H P$ is high, $G / \mathbb{N}=$ 8.5 kg .
a.dopted, it is nevertheless to ot expected that, $\pi i t h a$ still greater wing load, the parasite drag will preponderate and accordircty reduce $T / \epsilon$ of equation 11 , and hence also the maximum speci, to a value estimated at 4. On the other hand, the load per H3 can be reduced. If it is set, as above, at $G / N=2 \mathrm{~kg} / \mathrm{HP}$, we have

$$
\begin{equation*}
v_{g}=270 \quad \frac{4.0}{2.0}=540 \mathrm{~km} / \mathrm{h}=150 \mathrm{~m} / \mathrm{s} \tag{13}
\end{equation*}
$$

which would be about the upper limit in the present state of the science.
c) Speed records. - In omparison with these commotations, What has actually been attained?

1. The speed record* stands at
2. Offeicial speed record**:

| $341 \mathrm{~km} / \mathrm{h}$ | or | $25 \mathrm{~m} / \mathrm{s}$ |  |  |
| :---: | :---: | :---: | :---: | :---: |
| 330 | $\prime \prime$ | $"$ | 92 | $\prime \prime$ |
| 463 | $\prime \prime$ | $"$ | 127 | $\prime \prime$ |
| 540 | $\prime$ | $"$ | 150 | $\prime \prime$ |
| 1038 | $\prime \prime$ | $"$ | 288 | $" 1$ |

We are therefore not so very distant from the technically possible limit of the maximum speed, having attained $3 / 4$ of Rateau's maximum value or $2 / 3$ of our value, and will in fact probably get no higher, because the drag-lift ratio of racers is poor. Contrary to the general opinion, we would emphasize the fact that,

* Speed record of the Englishman, James, on a Vars Bamel racer of the Gloucestershire Aviation Company, with a 450 HP Napier Lion engine at Mattlesham, Dec., 1921, the average speed for the whole distance being $316 \mathrm{~km} / \mathrm{hr}$ or $88 \mathrm{~m} / \mathrm{s}$. Source: N.f.L. 22/2;4 (Nachrichten fur Luftfahrer, 1922, No. 2, item 4); Luftweg, Jan. 24, 192む.
** From the FAI official record of Sadi Lecointe on a 300 HP Nieuport Delage, Sept. 26, 1921. Source NfL, 22/9, 2, last line of table.
in the future, it will be the provinoe and duty or aerodynamice in increase the naximum speed.
d) Egsujts. - The econoraical and practical aspects of carrying and landing ability set: however, a far lower limit to the meximum speed, than thet technically posstble. A greater carrys.ng capacity increases the load per HP and consequentiny reduces the speed, so long as the engines are not lighter or more economical, in like meacure. The endeavor after a lower landing speed ieads to the choice of wing aections with a poorer drag-lift ratio (D/L).

## 3. Lo íding Sneed.

Here aercdynamics rust help. The landing speed linits mast be first calculated and compared with the landing speed alreacy attajned.
a) Minimum speed limit with model, The flight speed is at the minimum $v_{k}(\mathrm{~km} / \mathrm{n})$, when the lift ccefficient attains its maximurn value for $c A_{g}$, hence near the ground* according to the definition of $c A$, equation 4 or 8 ,

$$
\begin{equation*}
\mathrm{v}_{\mathrm{k}}=14,4 \sqrt{\frac{\mathrm{G}}{\mathrm{~F}}} \frac{1}{\sqrt{\mathrm{CAg}^{2}}} \tag{14}
\end{equation*}
$$

hence proporticnal to the square root of the wing load $G / F\left(\mathrm{~kg} / \mathrm{m}^{2}\right)$ and of the reciprocal of the maximum lift coefficient $c A_{g}$.

Table 1 contains several measurements, obtainea with models, of especially large lift coefficients, with notation of source. **.

* Air density deasigrated by $0.125 \mathrm{~kg}^{x} / \mathrm{m}^{4}$, nence ha?f the air density $=1 / 16 \mathrm{~kg}^{2} / \mathrm{m}^{14}$.
** Max Munk und Erich Huckel, "Der Profilwidejetand von Pragute. eln, " Technis che Berichte, Aug. 1, 1918, pp. 45i-461, especiailiy p. 458 , column $B_{0}$.

Also the quantity $I / \sqrt{c A_{g}}$, which gives the landing speed for the model, when multiplied by $14.4 \sqrt{G / F}$, hence, for example, for the wing loads $25,36,49,64,81$ and $100 \mathrm{~kg} / \mathrm{m}^{2}$ multiplied by $72,86.4,100.8,115.2,139.6$ and 144 respectively, (the minimum drag coefficient $c w k$ being added).

The maximum value of table 1 for ordinary wing sections ( $\mathrm{c}_{\mathrm{g}} \mathrm{g}=1.805$ ) gives for ving loads of 25 and $49 \mathrm{~kg} / \mathrm{m}^{2}, 54$ and $75 \mathrm{~km} / \mathrm{hr}$, respectively. Any diminution of the wing load is made at the expense of speed and works according to the square root of G/F.
b) Influence of scale of model. - Results obtained with models cannot be transferred directly to full-sized airplanes. The Reynolds number is generally greater in flight than in the wind tunnel and hence the flow conditions are changed. Moreover, the shape of actual wings does not correspond to the cross-section of the model. Lastly, good wind tunnels are not so turbulent as the atmosphere.

Experiments with models therefore give too small a maximum lift. For not too thick wing sections, the lift is directly proportional to Reynolds number. For very large angles of attack the flow shifts, as shown both by experiments with models* and during flighto ** The increase in lift for a large airnlane, in

* L. Prandtl, C. Wieselsberger und A. Betz, "Ergebnisse der Aerodynamischen Versuchsarstalt zu GÖttingen, "Reprot I, Ohap. IV, 2, "Der Einfluss des Kennwertes auf die Luftkräfte von Trägfiugeli" pp. 54-62; 21so N.f.L. 22/8, 14.

See N.f.L. $22 / 9,13, " c A_{g_{1}}=2.34$ beim Flugzeug, gegen 2.07 beim Modelin; iv. f. L. 22/7, 21, "Auftrieb beim Fiugzeurversuch Tie beim llodell"; IV.f. $\mathrm{L} .221 / 51,30$ (the same for Fok D VII) and 21/20, 34, "Stromung schlagt bei grossen Flugzeugen erst mit hoherem Anstellwinkeln um"; $20 / 7,4$, "c Ag beim grossen Flugzeug noher."
comparison with the model, is estimated et about 0.05.
c) Influence of nearness of ground. - For the same value (0.05), the maximum lift may be considered greater, when the airplane is near the ground. According to experiments with models* and during flight,** the lift increases, in harmony with computation, as much as $10 \%$ of its value in free air. If we, accordingly, call the lift coefficient of an airplane near the ground $10 \%$ greater than that of a model, we obtain, according to equation $14,5 \%$ smaller landing speeds.
d) Observed landing speeds. - In comparing computations on the basis of wind tunnel experiments, the $c A_{g}$ values are therefore increased by 0.1 and also, on account of the influence of the ground, the minimum speeds measured in free air are diminished by about 0.05 in the transition to landing speeds.

On the other hand, $\exists$ contrary wind has $\exists$ much greater effect on experiments at low speeds than $3 t$ maximum and mean flight speeds. The experimental values of landing speeds are therefore much too favorable. Horeover, the gliding before landing is no permanent condition.*** Thereby mechanical energy is also destroyed. But in the last instant before landing, if one does not plunge into the ground, he must pass through the angle of attack of maximum lift. These tendencies offset one another partially, so that observation

and computation agree quite well here.

## 4. Speed Limits of Actusl Airclanes.

What relation do the facts bear to these speed limits? Table 2 gives airplane speed statistics whic may be considered as reliable.
a) Scope of statistics. -* More than half the accumulated material had to be eliminated at the outset, because the sources seemed unreliable or the computation gave impossible coefficients. Of the 43 selected data, one or the other may still be incorrect, but it cannot vitiate the result, since it does not fall outside the field of the others.

On the other hand, useful data may have escaped our notice. I would be especially grateful for any such data for supplementing table 2.
b) Method of presentation. - In order to be able to compare the speed limits of widely differing airplanes, not these themselves but abstract members were assembled (See Fig. 1, and table 2) The airplanes are arranged according to increasing landing speed (in a few cases computed by subtraction of 0.05 of the value from the minimum speed) and for the same landing speed according to the decreasing maximum speed.

There were computed and set down the abstract values

$$
\begin{equation*}
\frac{v_{k}}{3.6 \times 4} \sqrt{\frac{F}{G}}=\frac{v_{k}}{14.4}: \sqrt{\frac{G}{F}}=\frac{1.05}{\sqrt{6 A_{g}}}=\text { Landing } \text { coefficient } \tag{15}
\end{equation*}
$$

$$
\begin{equation*}
\frac{\mathrm{v}_{\mathrm{g}}}{3.6 \times 75} \quad \frac{\mathrm{G}}{\mathrm{~N}}=\frac{\mathrm{v}_{\mathrm{g}}}{270} \frac{\mathrm{G}}{\mathrm{~N}}=\frac{\eta}{\varepsilon \mathrm{F}}=\text { Speed coefficient } \tag{16}
\end{equation*}
$$

[^1]Equation 15 follows from equation 14. The quantity 1.05 on the right side refers to the lift increase of the airplane near the ground in comparison with the result obtained from the model. Equation 15 is derived from equation $2 . \epsilon F$ is the drag-lift ratio for the angie of flight.

Fig. I shows, as the second division on the horizontal axis, the value $c A$; on the vertical axis, the value

$$
\frac{1}{\epsilon}=\frac{A}{W}=\frac{C A}{C W} \text { for } \eta=0.70
$$

The bundle of lines from the zero point correspond to like values of the expression

$$
\begin{equation*}
\frac{v_{g}}{v_{K}} \frac{4}{75} \frac{G}{N} \sqrt{\frac{G}{F}}=\frac{\eta}{1.1} \frac{\epsilon F}{c A_{g}}=\frac{\eta}{1.05} \times F \sqrt{\frac{c A_{F}}{c A_{g}}} \tag{17}
\end{equation*}
$$

according to which

$$
\begin{equation*}
\kappa=\frac{\epsilon}{\sqrt{C A}}=\frac{c W}{c^{1 \cdot 5}} \tag{18}
\end{equation*}
$$

an important value for flight with constant propeller efficiency,* for which we propose the term "Flugzahl" (power coefficient**). In fact, it gives the momentary flight condition. If we write both equations 15 and 16 for the flight speed $V F$, we will have instead of equation 17
*First probably by Racul J. Hofmann, "Der Flug in grossen Höhen, " 2 FFM , 0 ct . 11,1913 , pp. 255-256, especially equation 3.
**Mostly the less convenient value $1 / \mathrm{k}^{2}=\mathrm{A} / \mathrm{cW}^{2}$ is used and of ten termed "Steigzahl" (coefficient of climb). The question however does not concern climbing, as shown by equation 19, but flight and the deduction (descending speed!) in climb computations. H. V. Sanden ("Die Bedeutung von $\mathrm{Ca}^{3} / \mathrm{CW}^{2}{ }^{\prime \prime}$ T B IIT, 1918, pp. 330-i) - recommends instead, with reference to change of eificicecy with speed, $c A^{\frac{2.5}{5}} / \mathrm{c} \mathbb{W}^{3}$, which gives

$$
\begin{equation*}
\kappa=\frac{C W}{C A^{2 \cdot 25}}=\frac{\epsilon}{\sqrt[4]{C A}} \tag{19}
\end{equation*}
$$

$$
\begin{equation*}
\frac{4}{75 \eta} \frac{G}{N} \sqrt{\frac{G}{F}}=\kappa \tag{20}
\end{equation*}
$$

c) Results - Limit curves.- The points for the varicus airplanes generally lie in a bunch, so that it is impossible to draw any curve through them.

Especially high and aerodynamically favorable are the two German traffic airplanes, the Staaken monoplane and the Sablatnig $P_{3}$. The folding-wing airplane of Gastambide - Levasseur presents the best landing characteristics (even aside from its increased. wing area), if we may trust the data, though the reasons are not apparent. The old English biplanes of 1912 lie rather far to the right. The poorest of all is a heavily loaded Curtiss boat seaplane, though it makes a better showing with a smaller weight. Of two otherwise similar Curtiss airplanes, the biplane is aerodynamically better than the triplane, though both land equally well. The limiting of the group of points to the left and top by a curve (dash line in Fig. 1) is rather bold, since airplanes with alleged good landing ability were eliminated as doubtrul, though the inclination of the curve shows that a lirge $c A_{g}$ can only be obtained at the expense of otherwise good flow characteristics.
d) Estimation of the speed range.- Even when neither the group of points nor the boundary curve shows any legitimate connection, there must nevertheless be some order of ranking airplanes according to their speed.

Fig. 1 gives curves which run parallel or nearly parallel to the boundary line. They are not quite accurzely enough deter-
mined. They correspond to the ratio of the landirg coefficient to the speed coefficient, in that they pass through the zero point and intersect the boundary curve rether bluntly, but show, hovever, that this ratio cannot exceed a certair magnitude of the indivicual values.

Practice demands, independently of the naximum steed, a $\dot{d e f}$ inite landing speed, which cannot be exceeded, if the airplane is to be capable of being used on the landing placea provided. For sift airplanes, however, better landing places can be provided at greater intervals. For racing purposes, a good starting track is sufficient.

Evidently, the different viewpoints lend themselves just as poorly to any computation formula or to a set of curves of like speed values, as is possible for the matual estimation of carrying capacity and speed. In contests, we must proceed more or less arbitrarily, according to practical experience and requirements or $3 l l o w$ the contestant the choice of various determining factors.

## 5. Increasing the Maximum Speed.

The problem is to increase the maximum speed without increasing the landing speed, or still better, to reduce the latter at the same time.
a) Abacus for lift curve ("Polar"). - According to equation 3 the speed for 2 given flight condition is obtained from the vertical velocity and the drag-lift ratio. The argle of attack follows,

The line and the parabola from the zero point, which just touch the lift ourve, give the best drag-ift ratio and the smailest power coefficient. All other straight lines and curves have two points of intersection with the lift curves.

The lift curve must be shifted sidewise with its zero point, as far as the $c \mathbb{W}$ value of the abacus, which corresponds to the parasite drag of the airplanecwith reference to the wings.
b) Determination of diag-lift ratio, power coefficient and maximum speed. -* The abacus in Fig. 2 solves graphically equations 20 and 2. We first find the drag-lift ratio and power coefficient, for any angle of attack, from the straight lines or parabolas passing through the corresponding point of the lift curve (values read on the middle scale).

In practice, it is better to find the angle of attack and speed of an actual airplane, i.e. for a given load per $H P$ (upper horizontal line, lower scale). A straight line through the proper points of the scales intersects the middle scale at the point of the desired coefficient of power. The intersection of the corresponding parabola with the lift curve gives the angle of attack, coefficient of lift and coefficient of drag. A line through the zero point and this polar point enables the reading of the draglift ratio on the middle scale. If this is combined with the value of the load per HP (upper horizontal line, iower scale), the flight speed is intersected on the oblique line (lower scale). For any ratio. given load per HP , it is inversely proportional to the drag-lift/
c) Choice of wing section. - For a given lift curve, the wing

[^2]load and load per HP should be so chosen for the maximum speed that the power coefficient curve gill pass through the contact point of a tangent to the lift curve from the zero point, thus enabling flight with the best draeg-lift ratio. Ther the inclination of this tangent is decisive between two wing sections.

If, however, the power coefficient is fixed, the lift curve, which intersects the parabola farthest to the left, gives the maximum speed.

The graphic selection is so convenient that it seems useless to seek for mathematical solutions (such as replacing the lift curve by a parabola), so long as the shape of the wing section cannot be connected analytically inith the course of the lift curve.*
d) Choice of wing load. - From Fig. 2 it follows that a high maximum speed must be obtained through high wing loading. On the contrary, landing requires a small wing load. Here it is generally more difficult to give the correct value, in proportion as the requirements for the speed limits are not well established. Pröll** gave, for the maximum speed and for the landing speed and also for gliding, curves and computation methods, which clearly explain the process of landing. Our abacus could also serve the same purpose.

The power coefficient parabola through the zero point on the
*Mention, should, however, be made of a graphic-mathematical process for choosing a wing section, N.f.L. 22/11, 28, Edward P. Warner, "The choice of wing sections for airplanes," N.A. C.A., Technical Note Nio. 73, November, 1921.
$* * A$. Proll, "Uber die Wahl der Flächenbelastung mit besonderer Rücksicht auf den Landungsvorgang," ZFM, Oct. 31, 1920 pp . 277-28].
lift curve gives, with the load per $H P$, the most favorable wing load for the maximum speed. If the wing area differs much from the first assumption, the parasite drag must sometimes be corrected by shifting the lift curve correspondingly and correcting the calculation. If the lift curve is drawn on transparent paper and laid. over the abacus, this is easily done.

## 6. Reducing the Landing Speed.

Though the maximum speed, without regard to economy, may be quite easily increased, the landing speed limit, by ordinary means, has been reached. Most wing sections with high lift have a large drag (See table 1). Over $c A_{g}=1.81$ has not been obtained.* Search has therefore been made for special devices for reducing the speed just before coming in contact with the ground.
a) Air brakes and reversible propellers.- Just as in taxying on the ground, the use of devices, such as air brakes** and reversible propellers, for increasing the parasite drag while still in the air, enables the shortening of the requisite landing distance.***

The landing speed, i.e. the speed at the instant of touching the ground, and hence the danger of upsetting, can be lessened, *C. Wieselsberger remarked that the maximum lift evidently depends largely on the vortex condition of the air stream and next on the exactness of the model. **"Luftbremsen fur. Flugzeuge" (Air brakes for airplanes), ZFM, Jan. 31, 1920, p. 30. ***Report of H. Glauert "Über das Landen von Flugzeugen" (Landing of airplanes), N.f.L. 21/47, 38.
however, not by increasing the drag but only by increasing the lift. Hence, retarding devices do not enter into our problem, but rather lifting devices.
b) Shifting the wing section. - By increasing the camber,* best by a simultaneous lowering of both the leading and the trailing edge,** the wing load* may be increased up to $35 \%$ for the same landing speed,*** but the increase in the weight of the wings and the weight of the warping mechanism* and the shifting of the center of pressure**** nullifies these advantages. Flexible rios are structurally difficult and unsafe,* but enable nearly as great improvement.***

We have no reliable data on the actual weight and speed relations of airplanes with adjustable wing section. We must therefore await the results of technical investigation, without being too sanguine.
c) Increasing the wing area.- On account of the marginal drag, folding wings of maximum span and small area are better for swift flight and hence in landing they should be extended forward and backward, instead of laterally.***** The weight of the wings
*Views of W. H. Sayers, N.f.L. 21/29, 21. Also remarks of C. R. Fairey, (Fairey seaplanes with a wing load of $60 \mathrm{~kg} / \mathrm{m}^{2}$ have successfully alighted on water, due to their wing flaps ("Frofilklappen."):
**"Luftbremsen für Flugzeuge" (Air brakes for airplanes), ZFM, Jan. 31, 1920, p. 30.
***H. Hermann, "Verstellprofile" (Flexible wing sections), ZFM, May 31, 1921, pp.147-154, especially Figs. $4 \& 5$, tables $4 \& 9$, Parker wing section with flexible ribs.
****Report of H. Glauert, "Uber das Landen von Flugzeugen" (Landing of airplanes), N.f.L. 21/47, 38.
*****Gastambide-Levasseur biplane (Table 2, No.1), N.f.L, 21/27, 38. The upper wing is made twice as broad ( 3.28 instead of 1.6 m. ) thereby increasing its area from $32 \mathrm{~m}^{2}$ to $52 \mathrm{~m} .^{*}$, or 1.6 -fold.
is, however, more than half again as great* as that of adjustable wing sections, and hence the chances of success are poorer.

The landing speed is affected in like degree (equation 14) by the lift coefficient and by the wing load. While a greater maximum lift unfits a wing section for swift flight, the maximum speed is only slightly increased by employing folding wings and for small powers it is even decreased. This was done by Lupberger** under the here fairly justified assumption that the parasite drag is independent of the wing area.*** This follows also from the abacus (Fig. 2), though not just the same as Lupberger's approximation. The power coefficient varies as the square root of the wing load, though the corresponding drag-lift ratio, on account of the flexure of the lift curve, varies much less, even when the lift curve is shifted toward the left, for a small wing load, in order to make allowance for the relatively small drag coefficient.

Folding wings must be rejected, chiefly because the 1.8 -fold increase of area, technically a very difficult task, only reduces the landing speed one-fourth, not to mention the increase in weight.
*Views of W. H. Sayers, N.f.L. 21/29, 21. Also remarks of C. R. "Fairey (Fairey seaplanes with a wing load of $60 \mathrm{~kg} / \mathrm{m}^{2}$ have successfully alighted on water, due to their wing flaps "Profilklappen").
**E. Lupberger, "Über den Einfluss der Flügelabmessungen auf die Fluggeschwindigkeit," 2FM, Nov. 15, 1921, pp. 316-318.
***With the drag area $f\left(\mathrm{~m}^{\frac{2}{2}}\right)$ and the parasite drag coefficient $c \mathbb{W}_{\mathrm{f}}$, Lupberger makes $\mathrm{f} \subset \mathbb{W}_{\mathrm{f}}=1.2 \mathrm{~m}^{2}$. We must therefore make $c W_{S}=\frac{1.2}{F}$. Moreover, Lupberger considers the wing section drag as constant, hence the lift curves as parabolas.
d) Slotted wings. -* Lachmann's invention, which, independently of him, Handley Page tested, both on a model and on a finil-sized airplane, offers the best prospects (Table 1, Nos. 7-10). The maximum value $c A_{g}=3.92$, corresronds, for 25 and $49 \mathrm{~kg} / \mathrm{m}^{2}$ ring load to the respective landing speeds 35 and $51 \mathrm{~km} / \mathrm{hr}$, with respect to the size of the airplane and the nearness to the ground, 35 and $48 \mathrm{~km} / \mathrm{hr}$. For the maximum value of the German measurements, the figures are $c A_{g}=2.19, v_{k}=49$ and $68 \mathrm{~km} / \mathrm{hr}$ and 46 and 65 $\mathrm{km} / \mathrm{hr}$, respectively.

We must await the confirmation of the high value of the English measurements and information as to how much the result was affected (presumably favorably) by the turbulence, which is not always present; as to how far it is possible to retain the good qualities of the wing with closed slots, to combine rigidity, light weight and reliability in multiple slotted wings, with their many shutters; and to admit of an angle of attack of $45^{\circ}$, without excessively heavy landing gear and complicated wing controls.

## 7. Future Development.

However promising these means for increasing the speed range may seem to the hopeful inventors, we must not forget that, at best, the ground must be encountered, in landing, at the maximum speed of our street vehicles, if the airclane is suited in other respects for air traffic.
*N. f. L. 21/25, 33-35. C. Wieselsberger, "Untersuchungen uber Handley Page Flügel" (Mitteilungen der Aerodynamischen Versuchsanstalt zu Gồttingen, III Foige, No. 3), 2FM, June 15, 1321, pp. 161164; G. Lachmann, "Das unterteilte Flächenprofil," idem, pp. 164-169.

The goal lies, however, much nearer - and yet, at the same . time, very far. "To fly safely and efficiently means to land on the spot." None of our roads leads there. Shall not the helicopter give us the solution? And here aerodynemics turns again to engine constructors with the demand for light and reliable engines.

[^0]:    * Georg König ("Indiziertes Steigvermögen statt Leistuvgsbelastung, Z.F.M., Aug. 31, 1920, pp. 236-237) calls the 75-fold inverse value of the load per HP "indiziertes Steigvermögen" (indicated climbing ability) and, multiplied by efficiency and degree of utilization, "effective Steigvermögen" (effective climbing ability). Our expression "Hubgeschwindigkeit" (vertical velocity) is shorter, more German, and emphasizes "velocity."
    ** See Table 2, No. 39, Curtiss biplane from the Pulitzer race. The drag-lift ratio is there unfavorable, however.

[^1]:    *Most of the data were taken from the N.f.L. and its predecessors, "Flugarchiv" (1920, partially reproduced in the 1920 ZFM) and "Luftfahrt-Rundschau" (ZFM 1919, the technical portions of which were edited by me.)

[^2]:    *The use of the abacus for finding ascending and descending speeds, as well as for other purposes, with reference to altitude and air density, efficiency and aspec ratio, will shortly be described in the ZFM. In this connection, we are only considering the speed.
