TECHNICAL NOTE NO. 527

STRENGTH TESTS OF THIN-WALLED DURALUMIN
CYLINDERS OF ELLIPTIC SECTION

By Eugene E. Lundquist and Walter F. Burke

SUMMARY

This report is the fifth of a series presenting the results of strength tests of thin-walled cylinders and truncated cones of circular and elliptic section; it includes the results obtained from torsion tests on 30 cylinders, pure bending tests on 30 cylinders, and combined transverse shear and bending tests on 60 cylinders. All the cylinders tested were of elliptic section with the ends clamped to rigid bulkheads. In the pure bending and combined transverse shear and bending tests the loads were applied in the plane of the major axis.

The results of the tests on elliptic cylinders are correlated with the results of corresponding tests on circular cylinders and are presented in charts suitable for use in design.

INTRODUCTION

As part of an investigation of the strength of stressed-skin, or monocoque, structures for aircraft, the National Advisory Committee for Aeronautics in cooperation with the Army Air Corps; the Bureau of Aeronautics, Navy Department; the National Bureau of Standards; and the Bureau of Air Commerce has made an extensive series of tests on thin-walled duralumin cylinders and truncated cones of circular and elliptic section. In these tests, the absolute and relative dimensions of the specimens were varied to study the types of failure and to establish useful quantitative data in the following loading conditions: torsion, compression, bending, and combined loading.

The first four reports of this series (references 1 to 4, inclusive) present the results obtained in the tests of thin-walled cylinders of circular section. This report

presents the results obtained in tests of thin-walled cylinders of elliptic section. In the tests of the elliptic cylinders the loading conditions were torsion, pure bending, and combined transverse shear and bending. In the latter two loading conditions the loads were applied in the plane of the major axis.

MATERIAL

The duralumin (Al. Co. of Am. 17ST) used in these tests was obtained from the manufacturer in sheet form with nominal thicknesses of 0.011, 0.016, and 0.022 inch. The properties of this material as determined by the National Bureau of Standards from specimens selected at random are given in references 1 and 2. As all the test cylinders failed by elastic buckling of the walls at stresses considerably below the yield-point stress, the modulus of elasticity E , which was substantially constant for all sheet thicknesses, is the only important property of the material that need be considered. For all cylinders an average value of E (10.4×10^6 pounds per square inch) was used in the analysis of the results.

SPECIMENS

The test specimens were right elliptic cylinders with a semimajor axis of 7.5 inches and semiminor axes of 6.0 and 4.5 inches. The lengths varied from 3.75 to 22.5 inches. The cylinders were constructed in the following manner: First, a duralumin sheet was cut to the dimensions of the developed surface. The sheet was then wrapped about and clamped to end bulkheads. (See figs. 1, 2, and 3.) With the cylinder thus assembled, a butt strap 1 inch wide and of the same thickness as the sheet was fitted, drilled, and bolted in place to close the seam, which was always located at one end of the minor axis. In the assembly of the specimen, an effort was made to avoid having either a looseness of the skin (soft spots) or wrinkles in the walls when finally constructed. Actually this objective could not be attained at the ends of the minor axis where there was always a slight looseness of the skin which was more pronounced in the thinner sheets than in the thicker ones.

The end bulkheads, to which the loads were applied, were each constructed of two steel plates one-quarter inch

thick separated by a plywood core 1-1/2 inches thick. These parts were bolted together and machined to the specified outside dimensions. Steel bands approximately one-quarter inch thick were used to clamp the duralumin sheet to the bulkheads. These bands were machined to the same dimensions as the bulkheads.

APPARATUS AND METHOD

The thickness of each sheet was measured to an estimated precision of ± 0.0003 inch at a large number of stations by means of a dial gage mounted in a special jig. In general, the variation in thickness throughout a given sheet was not more than 2 percent of the average thickness. The average thicknesses of the sheets were used in all calculations of stress and radius-thickness ratio.

The loads were applied to the elliptic cylinders with the same apparatus used in the corresponding tests on circular cylinders. Descriptions and photographs of the apparatus used in the torsion, pure bending, and combined transverse shear and bending tests are given in references 1, 3, and 4.

DISCUSSION OF RESULTS

The results of the tests on the elliptic cylinders are presented in tables I, II, and III as well as in certain figures discussed later.

Torsion.— The torque loads were applied in increments of about 1 percent of the estimated load at failure. After a few tests, however, the first increment of load was increased to about half the estimated load at first wrinkle. At first wrinkling one or more diagonal wrinkles began to form at the ends of the minor axis. With an increase in load these wrinkles grew steadily in size and number, spreading toward the ends of the major axis until failure occurred by a sudden increase in deformation and the formation of wrinkles in the complete circumference. (See fig. 1.)

Prior to wrinkling it seems reasonable to assume that the conditions of stress within the walls of the cylinder are in accord with the membrane analogy (reference 5).

After wrinkling has occurred, however, the conditions of stress are doubtful and probably vary with the degree of buckling.

By the membrane analogy

$$S = \frac{T}{2At} \quad (1)$$

where

S, shearing stress in the skin.

T, torque applied.

A= π ab, area of the ellipse.

t, thickness of the sheet.

The shearing stress as given by equation (1) was calculated for each test cylinder at the conditions of first wrinkle and ultimate load. These stresses are used in plotting the experimental points in figure 4, which is the same type of chart used by Donnell in reference 6 for presenting the results of torsion tests on thin-walled cylinders of circular section. It will be noted that the experimental points for ultimate load plot between the theoretical curves and those recommended for design. As the data from torsion tests of circular cylinders also plot between these same curves (reference 6, fig. 1), it may be concluded that the shearing stress at ultimate load for an elliptic cylinder is the same as that for the circumscribed circular cylinder of the same sheet thickness and length. Actually the membrane analogy does not give a true picture of the stress condition at ultimate load but gives a shearing stress which lies between that at the ends of the semi-major and semiminor axes. It must therefore be regarded as an average shearing stress for the elliptic cylinder and analogous to the modulus of rupture in beams.

As the curvature of the sheet varies from a minimum at the ends of the minor axis to a maximum at the ends of the major axis, it is natural to expect that wrinkling prior to failure will occur in an elliptic cylinder subjected to torsion. In a perfectly constructed cylinder it is not likely that first wrinkling would occur until the shearing stress reaches or exceeds S_0 , the shearing stress at failure for a circular cylinder of the same sheet thickness and length but with a radius equal to the

radius of curvature at the ends of the minor axis. The effect of imperfections, which are always present, is to cause a premature wrinkling. Consequently, the shearing stress at first wrinkle S_w was divided by S_0 and the ratio plotted as a percentage in figure 5. With the exception of one point, all of the results plot below 100 percent. This figure is analogous to figure 10 of reference 1.

When calculating the value of S_0 for the points in figure 5, the equation given in reference 1 was used because it is more representative of the technic used in this series of tests. For general design, the equations given in reference 6 are recommended.

Pure bending.— In the pure bending tests the loads were applied in the plane of the major axis of the ellipse. As in the torsion tests, the loads were applied in increments of about 1 percent of the estimated load at failure. In the case of the 0.8 ellipse ($\frac{b}{a} = 0.8$), wrinkling did not usually occur prior to failure. Failure is defined as the complete collapse of the compression side of the cylinders with the formation of diamond-shaped wrinkles. (See fig. 2.) In the case of the 0.6 ellipse ($\frac{b}{a} = 0.6$), preliminary wrinkles usually formed prior to failure. These wrinkles always appeared at about two thirds of the distance from the neutral axis to the extreme fiber.

The reason for preliminary wrinkles forming prior to failure in the 0.6 ellipse and not in the 0.8 ellipse is shown qualitatively in figure 6. The critical compressive stress for any element is approximately proportional to the curvature, and hence to the abscissa, of the solid curves in figure 6. In a cylinder subjected to pure bending the actual stress varies linearly from the neutral axis to the extreme fiber. When the loading has reached such a point that the actual stress is approximately that shown by the dotted lines, first wrinkling is likely to occur at the point where the solid and dotted curves touch. For the 0.6 ellipse, the elements at the extreme fiber are capable of resisting a much higher stress than indicated by the dotted line with the result that failure is delayed until a much higher load is reached. For the 0.8 ellipse failure tends to occur at or soon after first wrinkling because the elements on the extreme fiber and for a considerable distance toward the neutral axis are not capable of resisting any large increase in stress.

In the presentation of the results of the pure bending tests, it has been assumed that the ordinary theory of bending applies and that the stress on the extreme compression fiber at failure is given by the equation

$$S_b = \frac{Mc}{I} = \frac{M}{k_b a^2 t} \quad (2)$$

where M is the bending moment applied in the plane of the major axis of the ellipse

a , the semimajor axis of the ellipse

and k_b , a nondimensional coefficient that varies with the eccentricity of the ellipse. (See fig. 7.)

The stress on the extreme fiber at failure as given by equation (2) is comparable with the corresponding stress calculated for the pure bending tests on circular cylinders (reference 3) and, for comparison, is plotted in a like manner in figure 8. Inspection of this figure shows that the stress on the extreme fiber at failure increases with decrease in the ratio b/a . The increased strength for the more eccentric ellipse is obviously caused by the greater stability of the more sharply curved portion at the end of the major axis where the fibers are more highly stressed. It will be noted in figure 8 that the results of the tests of elliptic cylinders scatter almost as widely as do the results of the tests of circular cylinders. The designer in using these data may therefore choose strength values more or less conservatively, as desired.

Combined transverse shear and bending.— The loads in the transverse shear and bending tests were applied in the plane of the major axis of the ellipse in increments of about 1 percent of the estimated load at failure. When the position of the transverse load was such that the ratio of moment to shear was small, failure occurred by shear. Prior to failure, diagonal shear wrinkles formed on the sides of the cylinder. With an increase in load, these wrinkles grew steadily in size until failure occurred by a collapse of the outermost compression elements. When the position of the transverse load was such that the ratio of moment to shear was large, failure occurred by bending in the same manner as in the pure bending tests. When the ratio of moment to shear had an intermediate value, failure occurred by a combination of shear and bending. (See photographs of cylinders after failure, fig. 3.)

The variation of the bending stress at failure with the ratio of moment to shear is studied for each of the following groups of cylinders tested.

Group	$\frac{b}{a}$	$\frac{\text{length}}{a}$	$\frac{a}{t}$	Nominal sheet thickness
				Inch
1	0.8	0.50	630 - 682	0.011
2	.6	.50	625 - 688	.011
3	.8	1.00	658 - 707	.011
4	.6	1.00	658 - 721	.011
5	.6	2.00	630 - 682	.011
6	.8	2.00	630 - 682	.011

For each group, the results of the tests are presented in a manner similar to that used for the corresponding tests on circular cylinders (reference 4). In figure 9 the nondimensional parameter $\frac{M}{r'V}$ represents the loading and stress conditions and is therefore analogous to $\frac{M}{rV}$ in reference 4. The value of r' was so chosen that for the elliptic cylinder

$$\frac{M}{r'V} = \frac{f_b}{f_v} \quad (3)$$

where f_b and f_v are the bending stress on the extreme fiber and the shearing stress at the neutral axis respectively as given by the following equations derived by the ordinary theory of bending

$$f_b = \frac{M}{k_b a^3 t} \quad (4)$$

$$f_v = \frac{V}{k_v a t} \quad (5)$$

In equation (5) V is the transverse shear in the plane of the major axis of the ellipse and k_v a nondimensional coefficient that varies with the eccentricity of the ellipse. (See fig. 7.)

In figure 9 lines a and b represent the upper and lower limits of the strength in pure bending. These limiting values show the dispersion of the results of the pure bending tests and were obtained for elliptic cylinders of the average $\frac{a}{t}$ ratio in each group by interpolation of the results plotted in figure 8. At large values of $\frac{M}{rIV}$ the bending-stress diagrams approach lines a and b as an upper limit but with a tendency to plot just below them in some cases. (See fig. 9a, in particular.) The tendency for the bending-stress diagrams to plot below lines a and b seems to be more pronounced for the 0.8 than for the 0.6 ellipse although the test data are not sufficiently extensive to draw a definite conclusion. For the 0.8 ellipse in pure bending the elements on the extreme fiber and for a considerable distance toward the neutral axis tend to reach a condition of incipient failure at about the same time; whereas the 0.6 ellipse seems to have the capacity of supporting an increased load after first wrinkling. (See fig. 6.) It is therefore probable that the reduced bending strength in combined transverse shear and bending is caused by the presence of shear which might conceivably affect the strength of the 0.8 ellipse more than the strength of the 0.6 ellipse. In any case, it appears that the lower limit of the strength in pure bending is a good value to use for the bending strength of thin-walled elliptic cylinders in combined transverse shear and bending at large values of $\frac{M}{rIV}$.

At small values of $\frac{M}{rIV}$ failure occurred by shear. For comparison of the strength in transverse shear with the strength in torsion, lines c and d have been drawn in figure 9 representing the probable upper and lower limits for shear failure. These lines were drawn by plotting the equation

$$\frac{f_b}{E} = \frac{S}{E} \frac{M}{rIV} \quad (6)$$

Equation (6) is obtained from equation (3) by transposing terms, dividing by E , and substituting S for

f_v , where S is the average shearing stress at failure for an elliptic cylinder in torsion. The lines c and d for shear failure in figure 9 are shown for the two values of S obtained from figure 4 for the largest and smallest sheet thickness for each group of cylinders. When reading values from figure 4 a straight line was imagined to be drawn through the experimental points for the elliptic cylinders of 0.011-inch nominal sheet thickness.

Inspection of figure 9 shows that the bending-stress diagrams at the very low values of $\frac{M}{r^2V}$, corresponding to shear failure, plot above lines c and d . As in the case of circular cylinders (reference 4), this fact indicates that the transverse shearing stress on the neutral axis at failure is higher than the shearing stress at failure in torsion. Consequently, in a like manner the ratio of the two stresses $\frac{f_v}{S}$ is plotted against $\frac{M}{r^2V}$ in figure 10 for each of the tests. It will be noted that as $\frac{M}{r^2V}$ approaches 0 the ratio $\frac{f_v}{S}$ approaches a value between 1.2 and 1.48. Thus, if S_v is the shearing stress on the neutral axis at failure in pure transverse shear and S is the shearing stress at failure for a cylinder of the same dimensions in torsion, S_v and S may be related by the following approximate equation

$$S_v = 1.25 S \quad (7)$$

The coefficient 1.25 is somewhat conservative but its use is recommended so that the same relationship will hold for both elliptic and circular cylinders. (See reference 4, equation (5).)

At intermediate values of $\frac{M}{r^2V}$, near the intersection of lines a and b with lines c and d in figure 9, there is a transition from shear to bending failure. As the point of transition is approached, there seems to be developed an increased strength similar to that shown by elastic theory when the number of waves in the buckled pattern changes from n to $(n \pm 1)$. The increased strength at the transition seems to be confined to a small range of $\frac{M}{r^2V}$ and is not always developed in the tests. For practical considerations, it therefore seems that the transition

from shear to bending failure can be given by the design chart for circular cylinders presented in reference 4 if $\frac{M}{rV}$ is replaced by $\frac{M}{r'V}$. With this change, the design chart for elliptic cylinders is given in figure 11. The solid curves in figure 9 were obtained from this chart using in one case the value of $\frac{S_b}{S_v}$ corresponding to lines a and c and in the other case the value corresponding to lines b and d. An inspection of the figures for the different groups indicates that, except for the increased strength previously discussed, these two curves represent quite well the limits of the experimental data in the transition from shear to bending failure.

In order to use the curves of figure 11 in design, it is necessary to know the loading condition $\frac{M}{r'V}$ and to be able to predict the values of S_b and S_v for the elliptic cylinder. If these three quantities are known, the maximum allowable moment and/or stress on the extreme fiber can be read from the chart as a percentage of that for pure bending. The strength in shear then need not be investigated because its effect has been taken into account by a reduced bending strength.

When checking the strength of any section between adjacent bulkheads, the largest value of $\frac{M}{r'V}$ in that section should be used to enter the chart of figure 11. This procedure tends toward conservatism and is certainly justified by the wide scattering of the test data.

CONCLUSIONS

1. In torsion, the shearing stress at failure for thin-walled elliptic cylinders was found to be equal to the shearing stress at failure for circumscribed circular cylinders of the same sheet thickness and length. Because buckling of the walls occurred at the ends of the minor axis prior to failure, the shearing stress calculated for the elliptic cylinder must be regarded as analogous to the modulus of rupture and so used in strength calculations.

2. For pure bending in the plane of the major axis,

the calculated stress on the extreme fiber at failure was greater than the corresponding stress for circumscribed circular cylinders of the same sheet thickness and length. As in the case of circular cylinders, it was found that slight imperfections caused the test results to scatter widely. In view of this scattering, the bending strength must be considered somewhat indefinite and should therefore be estimated after consideration of all the experimental data for both elliptic and circular cylinders. Design values may then be chosen more or less conservatively as desired.

3. For combined transverse shear and bending in the plane of the major axis, the strength was dependent upon the loading condition as described by the term $\frac{M}{r'V}$. At small values of $\frac{M}{r'V}$, failure occurred in shear and, as $\frac{M}{r'V}$ approached zero (a condition of pure transverse shear), the shearing stress on the neutral axis at failure as calculated by the ordinary beam theory was approximately 1.25 times the shearing stress at failure in torsion.

At large values of $\frac{M}{r'V}$, failure occurred in bending and the strength developed was approximately equal to the lowest strengths developed for cylinders of the same dimension in pure bending.

At intermediate values of $\frac{M}{r'V}$, there was a transition from shear to bending failure. For use in calculating the strength of elliptic cylinders in combined transverse shear and bending it was found that a chart previously derived for circular cylinders may be used.
