SUMMARY

The Search for Extraterrestrial Intelligence, currently being planned by NASA, will require that an enormous amount of data be analyzed in real time by special-purpose hardware, and it is expected that overlapped Hann data windows will play an important role in this analysis. In order to understand the statistical implications of this approach, it has been necessary to compute detection statistics for overlapped Hann spectra. Tables of signal detection statistics are given for false alarm rates from 10^{-14} to 10^{-1} and signal detection probabilities from 0.50 to 0.99; the number of computed spectra ranges from 4 to 2000.

INTRODUCTION

The Search for Extraterrestrial Intelligence (SETI), currently being planned by NASA, will require that an enormous amount of data be analyzed in real time by special-purpose hardware, and it is expected that overlapped Hann (sometimes called Hanning) data windows will play an important role in this analysis. (A discussion of signal processing in SETI, and arguments for using overlapped Hann spectra, are given in refs. 1 and 2, and a good technical discussion of overlapped Hann spectra is given by Harris in ref. 3.) In order to understand the statistical implications of this approach, it has been necessary to compute detection statistics for overlapped Hann spectra. The main purpose of this report is to present tables of signal detection statistics for overlapped Hann spectra and demonstrate how to use them. Tables are given for false alarm rates from 10^{-14} to 10^{-1} and signal detection probabilities from 0.50 to 0.99; the number of computed spectra ranges from 4 to 2000 (tables 1-14).

This work was funded in part by NASA #NCC 2-580 at Ames Research Center.

METHOD OF COMPUTATION

The statistical parameters are found by integrating the characteristic function ϕ to find the cumulative distribution function F . Given the characteristic function, there are several ways to find the cumulative distribution function and the probability density function f (ref. 4, chap. 29). Three different methods have been used, as a cross-check to guard against programming mistakes. One of the more useful approaches is to compute the cumulative distribution directly from the characteristic function:

$$F(x) = \frac{1}{2} - \frac{1}{\pi} \int_0^\infty \text{Im}\{e^{-i\omega x} \phi(\omega)\} \frac{d\omega}{\omega}$$

All of the needed statistical parameters can be found by using this equation, although this is a tricky integral for two reasons: the integral is an oscillatory integral, and the upper limit is infinity. These problems can be overcome by using Q-precision Gauss-Legendre quadrature and determining an "effective infinity" related to the number of computed spectra. The appropriate characteristic function, which is quite complicated, is discussed in some detail by Deans, Cullers, and Stauduhar (ref. 2).

USE OF THE TABLES

Use of the tables is straightforward. The quantity m represents the number of computed spectra. This is related to the number n of independent spectra by $m = 2n - 1$ when there is a 50% overlap and end effects are included. (Here it is assumed that the probability density function for the n sample average of the output of a square-law detector is a noncentral chi-square distribution with $2n$ degrees of freedom.) If τ represents the threshold, then the false alarm probability is given by

$$P_{fa} = \int_{\tau}^{\infty} f(x) dx$$

where $f(x)$ is the central overlapped Hann probability density function with $2m$ degrees of freedom, normalized so the mean noise power is unity. In the tables this threshold is expressed in decibels (dB),

$$T(\text{dB}) = 10 \log_{10} \tau$$

Given the threshold, the detection probability can be computed in terms of the signal-to-noise ratio r . This ratio is often expressed in decibels,

$$\text{SNR}(\text{dB}) = 10 \log_{10} r$$

The detection probability is found by integrating the noncentral probability density function for overlapped Hann spectra,

$$P_d = \int_{\tau}^{\infty} g(x, r) dx$$

EXAMPLE. Suppose $P_{fa} = 10^{-12}$ and $m = 500$. The signal-to-noise ratio that yields a detection probability of 0.50 is -4.4235 dB.

OMB No. 0704-0188*

Public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden, to Washington Headquarters Services, Directorate for Information Operations and Reports, 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302, and to the Office of Management and Budget, Paperwork Reduction Project (0704-0188), Washington, DC 20503.

| 13. ABSTRACT (<i>Maximum 200 words</i>) The Search for Extraterrestrial Intelligence, currently being planned by NASA, will require that an enormous amount of data be analyzed in real time by special-purpose hardware, and it is expected that overlapped Hann data windows will play an important role in this analysis. In order to understand the statistical implications of this approach, it has been necessary to compute detection statistics for overlapped Hann spectra. Tables of signal detection statistics are given for false alarm rates from 10^{-14} to 10^{-1} and signal detection probabilities from 0.50 to 0.99; the number of computed spectra ranges from 4 to 2000. | | | | | | | |
