Acknowledgements

The authors wish to thank the GEODYN/SOLVE software development groups for their support and rapid response to software additions and changes which were required to make this analysis possible. Specifically, we would like to acknowledge for their technical leadership; Barbara Putney of the Space Geodesy Branch at Goddard Space Flight Center, Tom Martin of EG&G/Washington Analytical Services Center, now with Van Martin Inc., and Bill Eddy and John McCarthy, both of ST Systems Corp. The overall design for these analysis tools was largely put in place by these individuals. For the actual line-by-line GEODYN software development and their spirit of cooperation, we express our gratitude to Dave Rowlands, Despina Pavlis, J. Andrew Marshall, Scott Luthcke and Lucia Tsaoussi. Their efforts, deep in the trenches of obscure reference material and GEODYN FORTRAN code, made this research possible. The maintenance of a smoothly running version of SOLVE was due to the work of Richard Ullman, for which we are very grateful.

We wish to thank the personnel at the NASA Center for Computational Sciences (NCCS) for their support in providing special computer assistance.

Several individuals helped to review this manuscript before publication. We especially want to thank Dave Rubincam of the Geodynamics Branch at GSFC for his suggestions which strengthened the section on non-conservative force parameters and Bernie Chovitz at ST Systems Corporation for scrupulously reading the entire text.

Finally, this research effort would not have been possible without the support of the Geodynamics Program Office at NASA Headquarters and the Crustal Dynamics Project at GSFC. We are indebted to the scientific visions of Tom Fischetti and of the late Ted Flinn who helped to establish firmly the viability of space geodetic techniques applied toward measuring crustal motions and deformations. The establishment and capable management of the laser network by Bob Coates and John Bosworth has insured timely acquisition of the tracking data. The efforts of the field crews and data verification teams at Bendix Field Engineering are greatly appreciated. Data cataloging and archiving services were provided by the Crustal Dynamics Data Information Service (CDDIS) under the careful direction of Henry Linder and Carey Noll.

1. Introduction

1.1 Overview and History of Satellite Laser Ranging (SLR) Solutions

This document describes the latest in a series of Satellite Laser solutions, SL7.1, performed at NASA's Goddard Space Flight Center. Through the analysis of globally acquired satellite laser observations, the time-averaged three-dimensional coordinates of the tracking sites are determined for prescribed time intervals. To meaningfully measure tectonic motions of the tracking sites, knowledge of the orbiting LAser GEOdynamic Satellite (LAGEOS) trajectory is required at a level of accuracy approaching that of the laser ranges themselves: one centimeter. The SL7.1 analysis, which represents our fourth global solution, utilized the complete (through 1988) laser tracking data set and incorporates the latest (as of 1987) improvements in force and measurement models.

Starting with the experimental SL4 solution which took place in the early 1980s, the investigation entailed the estimation of *annual* station coordinates computed from laser tracking data sets then available. Although undocumented, the SL4 results demonstrated that the analysis concept was sound and viable given the status of the then-available hardware and software. When the GEM-L2 gravity model [*Lerch et al.*, 1985] became available (which, for its time, made major advances in the knowledge of the long-wavelength portion of the geopotential), the possibility of computing orbit trajectories of sufficient accuracy to resolve station motions due to plate tectonics was realized. The follow-on solution, SL5, made use of GEM-L2 and additionally, made use of laser *normal points* (discussed fully in Sect. 4.2) to provide data uniformity [*Smith et al.*, 1985]. Based on laser tracking data taken between 1979 and 1983, estimates of tectonic motion between five of the Earth's major plates were made and reported in *Christodoulidis et al.* [1985]. The SL5 solution provided the first Satellite Laser Ranging (SLR)-based geodetic confirmation that global plate tectonic motions were detectable and occurring in real time. Additional data, as well as improved models of Earth nutations and solid-Earth and ocean tides were included in subsequent solutions resulting in the SL6 solution [*Christodoulidis et al.*, 1986a]. The SL6 series of annual station coordinate solutions, based on tracking data spanning 1976-84, yielded estimates of horizontal velocities for a dozen sites. Many of these sites were centrally located on major tectonic plates and exhibited SLR-determined motions strongly resembling those predicted by the global tectonic model developed by *Minster and Jordan* [1978] from geologic and geophysical data.

The SL7.1 solution realizes, to date, the most dynamically consistent reference frame based on our analyses of LAGEOS ranging data. Nearly 13 years of LAGEOS tracking data have been analyzed to provide *quarterly* solutions spanning the time period from May 1976 (LAGEOS' launch date) to December 1988. This solution uses the GEM-T1 gravity model [*Marsh et al.*, 1988] within which the invariant and tidal parts of the geopotential were estimated simultaneously. The present work is intended to act as a companion volume to *Smith et al.* [1990b] which dealt more with the tectonic implications of the SL7.1 solution. This volume contains details regarding the data reduction, modeling, data and product evaluation steps taken, as well as the ancillary experiments and design decisions made during the analysis leading to the SL7.1 solution presented herein.

1.2 NASA's Role in the Development of Satellite Geodesy

Historically, the development of physical models to describe satellite tracking observations has provided a wealth of geophysical information. From the earliest measurements, using instruments which, at times, were no more sophisticated than binoculars and stopwatches (such as that used in the Smithsonian Astrophysical Observatory's project "Moonwatch" [*Mueller*, 1964, p. 236]), it soon became clear that satellite observations would both improve and change our understanding of the elements shaping our planet and its upper atmosphere. The earliest observed changes in orbits on the order of a few parts in a thousand quickly confirmed and refined the asymmetrical variations of the Earth's gravity field [*Merson and King-Hele*, 1958, and *O'Keefe et al.*, 1959]. These original determinations of global characteristics of the Earth through the application of space technologies initiated the growth of the subdiscipline of *satellite geodesy*. These early discoveries inspired developments in satellite tracking technology which have continued since the launch of Sputnik in 1957.

During the 1960s, NASA established the National Geodetic Satellite Program (NGSP) to advance and build a space geodesy program. The purpose of the early program was to establish a fiducial geocentric tracking station network which would unify the world's diverse regional geodetic datums into a single system [*Henriksen*, 1977]. To support the early requirements of precise orbit determination, constants were estimated and established to describe the central term (GM) and inhomogeneous portions of the Earth's gravitational field. The NGSP began as an effort to provide time-invariant positions of the participating tracking sites utilizing a variety of tracking technologies, such as optical, radio and electro-optical methods. As observational quality and physical models improved, the notion that estimates of crustal deformation and plate motions on global scales could be obtained via further technological refinement became more popular throughout the geodetic community. This led to the Williamstown Conference [*Kaula*, 1970] where plans were outlined to give direction towards achieving these goals.

Experiments utilizing satellite laser ranging began in the mid-1960s. From early experiences, improvements in the laser technologies led to the development of a second generation of tracking systems which offered 2-3 decimeter ranging accuracies, further encouraging the geodetic community to work towards the realization of more precise ranging systems. In 1972, an experiment began which was designed to test the capabilities of SLR to detect the effects of plate motion and deformation across California. This experiment, the San Andreas Fault Experiment (SAFE), sought to provide repeated measurements along a north-south, 896-km line straddling this complicated fault system [*Smith and Vonbun*, 1974]. The early success of SAFE, coupled with advances in the radio astronomic technology of Very Long Baseline Interferometry (VLBI), led NASA to increase the scope of its support for precise station positioning. The Earth and Ocean Dynamics Application Program (EODAP), formulated in 1972, specifically called for the development of centimeter-level VLBI and SLR systems to support geodynamic and oceanographic flight missions [*Geodynamics Program Office*, 1983, p. 7]. Details on the SLR system development and deployment can be found in *Degnan* [1985] and *Shawe and Adelman* [1985].

As an outgrowth of both the EODAP and the Earthquake Hazard Reduction Act of 1977, the NASA Crustal Dynamics Project (CDP) was founded in 1979 under the auspices of NASA's Geodynamics Program. The CDP was responsible for: (1) designing and developing space technology systems to acquire precise geodetic measurements for crustal dynamics investigations, (2) delineating measurement strategies enabling these investigations to proceed, (3) organizing and collecting the observations taken during the measurement program, and (4) supporting the analysis and interpretation of these results [*Geodynamics Program Office*, 1983, pp. 67-73]. CDP activities have sparked intense international interest in high-precision space-based point positioning. Through the participation and cooperation of over 30 countries, the capabilities of SLR and VLBI for geodetic monitoring of global tectonic processes continues to improve [*Coates et al.*, 1985 and *Flinn and Baltuck*, 1989]. Outlines for future developments promise improvements in scientific capabilities by expanding network coverage and by strengthening data acquisition strategies [*NASA Office of Space Science and Applications*, 1991].

1.3 The Laser Geodynamics Satellite - LAGEOS

The LAGEOS satellite was designed as a passive target for precise laser ranging. The satellite is a 60-cm-diameter sphere having a mass of 407 kg (Figure 1.1). The outer portion of the satellite is made of aluminum with 426 corner cube reflectors embedded within its surface. Of these, 422 reflectors are composed of fused silica with the remainder being composed of germanium. The satellite has a 175-kg cylindrical inner core made of brass. A complete description of the structural details of LAGEOS can be found in *Cohen and Smith* [1985].

LAGEOS was launched from the Western Test Range in California on May 4, 1976. It was placed into a high-altitude, near-circular orbit having an inclination of 109.8°. At an altitude of nearly 6000 km, LAGEOS experiences a minimal amount of atmospheric drag and is less apt to be perturbed by short-wavelength components of the Earth's gravitational and tidal fields. By minimizing the effects of non-conservative forces and higher frequency geopotential effects, LAGEOS acts as a target which has a highly predictable behavior; a quality that is necessary for the estimation of the motions of the tracking stations.

Through the global acquisition of high-precision laser tracking of LAGEOS, the data can be analyzed to yield information regarding geophysical parameters other than station positions and their ongoing motions. For example, improvements of the long-wavelength portion of the Earth's gravitational field from the analysis of LAGEOS data has been reported by *Lerch et al.* [1985] and *Marsh et al.* [1988]. Polar motion has been estimated [*Tapley et al.*, 1985] and high-frequency estimation of polar motion has been investigated and reported by *Pavlis et al.* [1988] and *Caporali et al.* [1990]. Tidal parameter estimation from LAGEOS data has been reported by *Christodoulidis et al.* [1986a]. Although not directly a geophysical parameter, a more physically appropriate model for general relativity and its effects on near-Earth satellites was studied and tested by *Martin et al.* [1985] and *Ries et al.* [1988]. Both studies concluded that within the noise limits of the laser measurement system, no significant effects were detectable. Ranging data to LAGEOS have provided a rich source of information from which advances in Earth science and physics have been and will continue to be made.

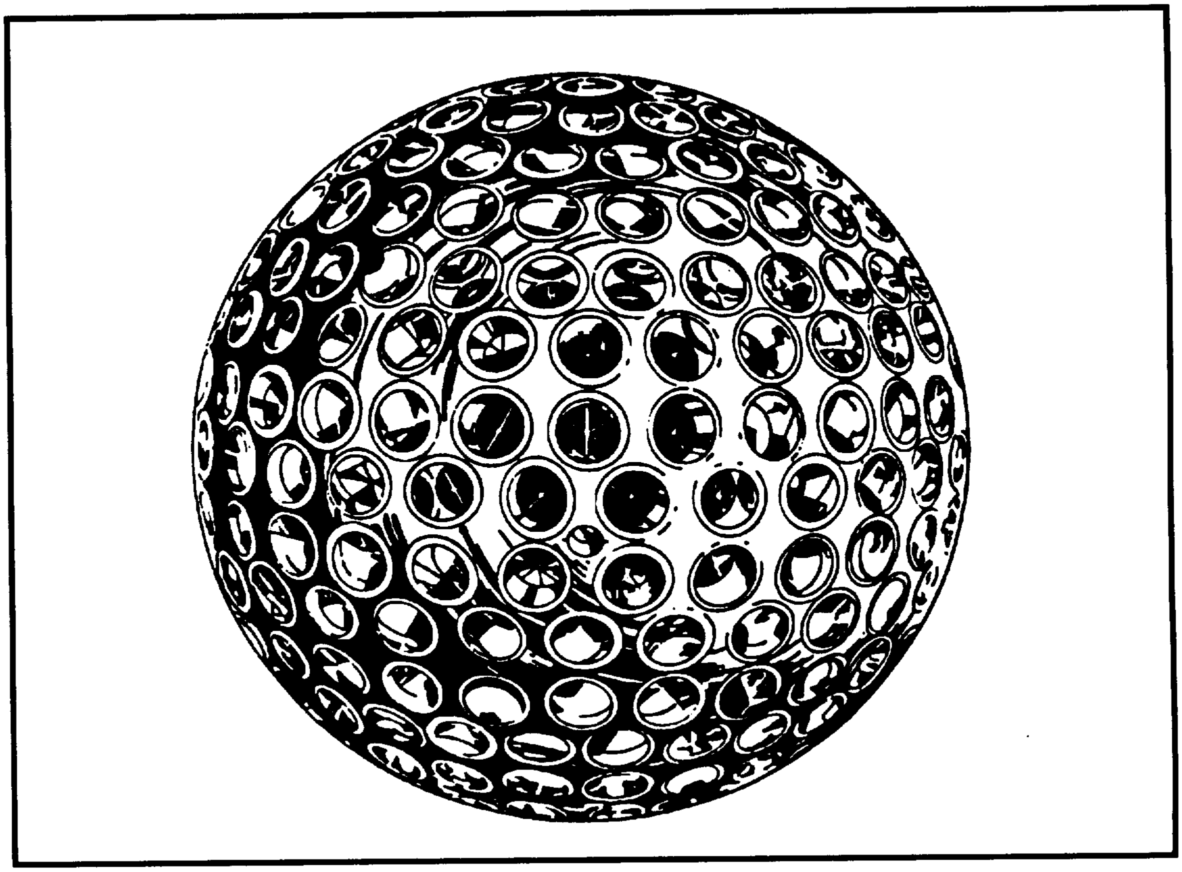

Figure 1.1 The LAGEOS laser reflecting geodynamic satellite launched by NASA.

2. Methodology, Definitions, and Rationale

2.1 Solution Strategies

2.1.1 *Introduction*

Satellite geodesy has traditionally been divided into two techniques; one based on geometric methods, and the other on dynamic methods. The geometric method utilizes the satellite simply as a high-flying target. Knowledge of the satellite's orbit is only required to locate the satellite during tracking. The dynamic method treats the satellite as a sensor as it passes through the Earth's gravitational field. Both methods have their merits and difficulties, but, as is explained below, the SL7.1 solution is based on the dynamic method.

2.1.2 *Dynamic Satellite Geodesy*

The theory behind the dynamic method has its roots in the works of various pioneers in the field of celestial mechanics. However, the specialized theory for close-Earth satellites did not emerge until the launch of Sputnik and the development of high-speed computing machines. Comprehensive texts of the theory have been made by *Mueller* [1964], *Kaula* [1966], and recently by *Schneider* [1988], although the latter is available only in German. Another book, by *Seeber* [1988] shares the same title as Schneider's book and is also in German, but its focus is not so much theoretical as technological.

The dynamic method relies on accurate modeling of the satellite's orbital behavior. The behavior of the class of satellite flown for geodetic purposes is largely dictated by the Earth's gravitational field. Additionally, for high-precision satellite tracking, known perturbing forces on the spacecraft, arising from non-gravitational sources, must be accurately modeled. Knowledge of the location of the satellite along its orbit and the orientation of the orbital plane with respect to the tracking station network, which rotates below on the Earth's surface, are required as a function of time. This provides the *dynamic* description of both the satellite's motion and orbital evolution and provides the connection to the Earth-based tracking system observing the satellite through time.

In the dynamic satellite approach, the solution parameters are estimated via least squares in an iterative manner until the parameters cease to improve (i.e., they have reached a prespecified level of convergence). The parameters which describe the physical situation for the tracking sites on the Earth (i.e. locations, polar motion, etc.), are estimated simultaneously with the parameters used to describe the orbit. In this scheme, the Earth orientation parameters are implicitly referenced to a system based on the LAGEOS orbit plane, and are directly relatable to the adopted model for the dynamical equator and equinox.

Other dynamic solution strategies have been used in various, primarily regional, investigations. For example, the work by *Klosko et al.*, [1990] utilized simultaneous LAGEOS tracking data in a technique dubbed "BEST" (Best Estimate from Simultaneous Tracking) [*Kolenkiewicz et al.*, 1985] to estimate baseline lengths in California and the Baja Peninsula averaged over 5 to 30 days. The technique is purely dynamic, but by using simultaneous data, the effects of orbit error are minimized. A similar technique called "translocation" was used by *Stolz et al.* [1989] to estimate the baseline rate between sites in California. The technique of "Pseudo Short-Arc" SLR analysis has been developed and used by *Sellers and Cross* [1990] to estimate baseline lengths in the northeastern Mediterranean. This technique is quite similar to the BEST technique but differs in that a consistent reference frame is maintained through the monthly arcs.

2.1.3 *The Geometric Approach*

The simplicity of the geometric approach, wherein the satellite dynamics are not required for the solution, must be tempered by the reality of whether sufficient tracking is likely to be available. The geometric method is based on triangulation or trilateration principles, or combinations thereof (see, for example, *Escobal et al.* [1973] and *Henriksen* [1977], Chapter 7, by H. Schmid) employing strictly simultaneous observations. Within the existing laser tracking data set, the choice of stations that qualify for mutual satellite inter-visibility is limited by deployment schedules and weather conditions which further restrict the overall size of the data set satisfying the condition of simultaneity, particularly for intercontinental station separations. Even when strong geometry is achieved, strictly geometric methods exhibit a strong sensitivity to data quality, both in (a): the ability to detect and separate unavoidable systematic errors and in (b): the difficult decisions for weighting of observations from instruments of differing precision. For these reasons the geometric approach could not be fruitfully applied in the global laser analyses for SL7.1.

2.2 Software Implementation

The software system utilized for the dynamic analysis of satellite laser ranging data is GEODYN II, which employs direct numerical integration of the satellite's equations of motion and variational equations in rectangular coordinates. Direct numerical models of a large number of satellite perturbing forces are evaluated at each integration step. Section 3 below describes the force modeling formulation, defines the adopted reference system, and details the measurement correction algorithms. The GEODYN System [*Henriksen*, 1977, Section 5.4.1, by B. Putney, *Putney et al.*, 1990 and *Eddy et al.*, 1990] is designed to apply a Bayesian weighted least squares algorithm but in practice, all *a priori* knowledge of the estimable parameters is relaxed so that *a priori* constraints are not generally applied to the estimated quantities, with rare exceptions.

In order to efficiently implement the required multi-arc capability for spanning many independent orbital arcs of data and for enabling a single simultaneous solution for orbit state vectors, station positions, Earth orientation parameters, tidal coefficients and other elements of the force model, the GEODYN system generates an intermediate data form (a matrix) consisting of a system of normal equations. These matrices are generated for each arc of data and are combined to yield a multi-arc solution in the SOLVE program [*Majer*, 1986] in which the full solution matrix is created by summing the selected rows and columns in the arc-normals and is inverted. The SL7 series are the first GSFC tectonic solutions to utilize the vector processing computer facility at Goddard: GEODYN II and SOLVE II were radically redesigned for operation on the CYBER 205 computer. The substantial improvement in resource utilization and details regarding program development can be found in Chapter 2 of *Marsh et al.* [1987].

2.3 The Role of Monthly, Quarterly, Annual and Global Solutions

The design of the software system allows considerable flexibility in choosing both the data time-span within which the analysis is to take place and the set of parameters to be adjusted in the solution. As was mentioned above, SOLVE can be directed to invert single-arc matrices as well as matrices formed by combining several subsequent arcs. In the course of the analysis, the arcs are combined in several different ways in order to provide a means to assess data quality and to estimate parameters which are dependent upon data continuous across time.

Initially, the raw range data to LAGEOS goes through a number of steps in order to prepare the data for full analysis (described in Chapter 4). The resulting data set is collected into data groups, called *arcs*, which accumulate all tracking data acquired over a specific time span. The time span chosen for the SL7.1 analysis is typically 30 or 35 days in duration. Error analysis studies indicated that this length of time was appropriate for the estimation of geodetic parameters. Arcs of this length have 180 continuous revolutions and several hundred passes of tracking making them quite stable. These *monthly arcs*, as processed in the form of matrices by GEODYN, provide the basic information for subsequent single- and multi-arc inversions by the SOLVE program. Each monthly arc is separately processed, evaluated, and qualified within GEODYN. If any data within an arc exhibits anomalous results, it undergoes further scrutiny via residual analyses to isolate the cause of the anomalous behavior.

Error analyses show that monthly arcs are capable of yielding precise station coordinates since perturbing forces acting on arcs of this length are well known. This capability is hampered by variations in local weather, system maintenance schedules, and other logistical and unforeseen operational problems. Since 1979, the tracking network has become well-distributed geographically and, for most months, yields accurate monthly positions for the stations having successful tracking campaigns. By combining several monthly arcs into a single solution, a more rigorous solution for all but the very weakest tracking sites can be made. We have chosen to make 3-month solutions, called *quarterly solutions*, to provide the principal means by which we estimate global tectonic motion for the tracking sites.

Just as monthly arcs are used to monitor individual station data quality, we also use *annual solutions* to assess global force model parameters such as the product of the gravitational constant with the Earth's mass (GM). The annual estimation of GM can yield important information about the variations in overall scale within the solution. However, the most accurate determination of global parameters such as GM, Earth orientation, and Earth and ocean tidal parameters is obtained by combining all monthly arcs into a single *global solution*. In this scheme, plate motion of the tracking stations is modeled in order to prevent a secular drift of the estimated pole which would occur due to the neglect of plate motion. This global solution yields a continuous Earth orientation series in a continuous reference system as well as a consistent monthly satellite ephemeris, simultaneously with the global geodetic parameters of interest.

In all these solutions, the parameters of chief importance include the tracking station locations in a center of mass system, the polar motion and UT1 variations of the Earth's rotation, and mean station tidal displacement terms. The gravity field and the Earth and ocean tidal modes affect our solution, as well as arc-dependent orbit vectors, radiation pressure coefficients, and along-track acceleration parameters which are used to empirically model a drag-like effect on LAGEOS. These quantities are either held fixed to values consistent with the most recently accepted models, or are estimated in the least-squares adjustment, as discussed individually in the next chapter.

3. Reference Frames, Constants, and Models

3.1 Reference Systems and Frames

The analysis of experimental data requires that one maintain the ability to compare the obtained results with those based on other observations or analysis procedures. It is implicit that a framework be defined which is adhered to by all analyzing the data and in all techniques. This provides the common ground on which we can base our comparisons and derive conclusions. This framework is termed the *reference system*.

For any given reference system it is possible to adopt various sets of numerical constants, mathematical models, and formalisms that will realize it, each with a different level of accuracy. Naturally, we are interested in adopting the most up-to-date and most accurate ones available. This adopted set of constants, models, etc., that realizes our preferred framework is known as the *reference frame*.

Not all of the required entities are preset to adopted values. Depending on the kind of data we are dealing with, we may find that these data are quite sensitive to certain parameters that enter the definition of our reference frame. In that case, the data themselves may actually determine improved values which are then more consistent with the data. For example, the LAGEOS laser ranging data can determine very accurately the value of the Earth's gravitational constant, GM. Although a reference value for this parameter has been adopted (through international accords), we have chosen to estimate it. This permits us to study its temporal variation and test the plausibility of theories as to the meaning and consequences of its variation.

The SL7.1 solution focuses on the temporal variation of several physical quantities which are of interest to a wide number of scientific disciplines. The experiments that we analyze are events in the space-time continuum in the sense of the general theory of relativity. We should point out, however, that the formalism adopted for the current analysis follows the classical Newtonian description rather than that of Einstein's geometro-dynamics.

Unlike the reference system which is a congregate of concepts alone, the reference frame comprises several categories of entities discussed below. Models for physical processes contain parameters set to adopted values and/or parameters which are estimated as part of the data analysis. The gravity field is an example of such a model. The central term of the field GM is estimated, but the remaining terms of the expansion are set to prescribed adopted values. The motion of the Earth's spin axis with respect to the crust is also amenable to different parameterizations. We have adopted the one that happens to be most commonly used, albeit not the only one possible.

Ancillary data sets are usually combinations of mathematical models and numerical values that complement our approximation of the natural environment where the observations take place. The Solar, Lunar and Planetary Ephemerides required in the integration of LAGEOS' orbit are a prime example for this category. We have chosen to use the ephemerides developed by the California Institute of Technology's Jet Propulsion Laboratory Development Ephemeris 200 and Lunar Ephemeris 200 (DE200/LE200) even though other ephemerides exist.

Finally, the way in which the data are analyzed is as important in defining the reference frame, as is the integrity of the data themselves. Dynamic satellite geodesy offers various options; the stability of the resulting reference frame in each case is different, and depending on the phenomena studied, one can have certain advantages over another. In the following subsections we describe the Reference System used in the present analysis of the LAGEOS data, and we discuss in summary the constants and numerical models that realize this system, i.e., the associated Reference Frame.

3.1.1 *Reference Systems*

In general, it suffices to use a single reference system within which we describe our experiment. Traditionally, and mostly for reasons of convenience, we use two such systems: one that is motionless with respect to the "fixed stars," the *Inertial System*, and one that is motionless with respect to the Earth's crust, the *Terrestrial System*.

The realization of these two systems is only an approximation of the actual concept of either of them. To stress this explicitly, it is common practice to refer to these as the *Conventional Inertial Reference System (CIRS)* and the *Conventional Terrestrial Reference System (CTRS)*, [*Kovalevsky and Mueller*, 1981]. The two systems are related to each other through three rotations which are functions of the fourth coordinate, time. We will not differentiate here between proper and coordinate time since, in the classical theory, they are assumed to be identical. The adopted free variable in the equations of motion is measured on the *Atomic Time* scale and the orientation of the Earth is specified in terms of the *Universal Time* scale. The first is chosen because of its uniformity, while the second is periodically stepped to keep it closer to the scale defined by the Earth's actual rotation. With the time coordinate defined, we proceed to the definition of the spatial coordinate system.

The international organization responsible for the definition of astrodynamical reference systems is the International Astronomical Union, (IAU). Our definitions follow as closely as possible those of the IAU. We have strived to maintain this parity by adopting their most recent recommendations every time a new cycle of analysis commences.

Traditionally, astronomers defined reference systems for their use by means of catalogs of repeatedly observed stars. When dynamical theories advanced and the contemporary instrumentation allowed it, the ephemerides of the planets, the Sun, and the Moon were realizations of the first dynamical reference system. The large distances between the bodies warranted that little attention be given to the issue of elaborate force modeling for the equations of motion. The very close approximation of the true motions by such simple point mass models was the main reason these ephemerides were used as stable frames of reference for a very long period of time.

The advent of satellite geodesy offered other options in the choice of the bodies whose orbits define the reference system. Precise tracking of artificial satellites provides an accurate measure of the observer's location relative to the spacecraft. However, the closer the satellite to the Earth, the stronger is the influence of the irregularities of the Earth's gravitational field and atmosphere on its trajectory. This is a drawback for the definition of a reference frame. The geopotential is not perfectly known, and the modeling of non-conservative forces such as atmospheric drag, Earth radiation, Solar radiation, etc., are in most cases incomplete at best. Therefore, the forces which perturb the orbit need to be estimated and they are undoubtedly of significant scientific importance. While this may improve the results, errors will still be present, for the model remains incomplete and imperfect. Clearly not all satellites are of equal use for the definition of a dynamical system despite the fact they may all be useful for other purposes.

The LAGEOS orbit can be determined through highly accurate laser ranging observations, thereby establishing a dynamical reference system which is directly accessible. When the results of the SL7.1 analysis are presented it will be clear that the goals set forth in the LAGEOS mission have been met and most of them surpassed by an order of magnitude. Nevertheless, the long term stability of the system is still limited due to unmodeled very long period perturbations, especially in the angular elements (node, inclination) which are yet to be fully modeled. As our modeling improves, we find that we more effectively use the satellite orbit as the means to define a dynamical reference system (even though imperfect), which we can access through direct observations from the Earth's crust.

This system is related to the astrodynamical reference systems defined through the planetary ephemerides by a weak link: the relatively small orbital perturbations that the rest of the solar system's bodies have on LAGEOS' trajectory. The astrodynamical system which is realized by these ephemerides is well studied [*Newhall et al.*, 1983, and *Lieske and Standish*, 1981]. The resulting system will, to a certain extent, violate one of the defining principles of a dynamical system based on the theory of the motion of some bodies in the solar system constructed in such a way that there remains no rotational term in the equations of motion. To reiterate, there are imperfections in the force modeling of LAGEOS' motion which may introduce frame distortions; our system will slowly rotate with respect to the inertial space, and the rate will be a function of the mis-modeled force effects.

Since we cannot define a truly inertial system, but rather a quasi-inertial one, we must associate a date with our definition. We use the IAU-adopted fundamental epoch of Noon January 1, 2000 Julian Ephemeris Date, designated by *J2000*. The first axis of the CIRS is defined as the intersection of two fundamental planes: the ecliptic and the mean celestial equator. By convention, the positive direction is that which points in the direction of the ascending node of the ecliptic on the equator, that is, the Mean Vernal Equinox of date. The third coordinate axis is perpendicular to the plane of the mean equator of J2000. Lastly, the second axis completes the orthogonal triad on the equator.

As we have already mentioned, the CIRS and the CTRS are related through three independent rotations which are functions of time. In order to study various phenomena that have vastly different origins or magnitudes, and because part of the total rotation is well represented by theoretical models, the total rotation is decomposed into several successive rotations which are all time-dependent. The mean places of the fundamental epoch are related to the mean places at the observation epoch through the *precessional* rotation. The short periodic (relatively speaking) variations of the Earth's orientation in space are modeled through the *nutational* rotation at the observation epoch. Both of these motions are forced and directly attributable to the gravitational torque of the solar system's bodies exerted on the Earth due to its oblateness. At this point, there are no other motions with respect to the inertial space. The interim system we have reached is what astronomers call the "true of date system" and for the sake of uniformity we shall call it the *Celestial Ephemeris Reference System (CERS)*. It is described in Figure 3.1.

To relate this to the CTRS we must still define the rotations of the CERS with respect to the CTRS. These are: the orientation of the instantaneous equatorial plane, or equivalently, an axis perpendicular to it, the sidereal rotation, and the non-uniform rotation rate of the Earth on the Equator (see Figure 3.2). The sidereal diurnal rotation is modeled through a polynomial in time which describes at any instant the angular separation of the equinox and the conventionally adopted origin of longitudes on the Earth. The first two rotations account for the highly irregular polar motion while the last refers to the spin rate irregularities. Because these motions are "free" responses of Earth, polar motion and Earth rotation variations are, by and large, unpredictable to the required accuracy by any current theory. Therefore, they must be determined through observation. Their estimates orient the observer on the Earth's crust with respect to the CERS as materialized by the satellite's orbit. In fact, an accurate determination of these parameters is one of the goals of this analysis since their temporal variation can provide us with vital additional information about the inner structure and the elastic properties of the Earth.

The axis whose polar motion is "observed" by the various techniques must be uniquely defined and naturally "observable." The definition of this axis - the *Celestial Ephemeris Pole (CEP)* - has been a controversial issue since the 1970s, (cf. a historical review in [*Moritz and Mueller*, 1987]), and it is only recently (1984) that the issue has been settled. The IAU-adopted definition for the CEP is that it should have "no periodic diurnal motion relative to the crust (not the mantle) or the CIRS" [*Mueller*, 1981]. We should note that the CEP is the third axis of the CERS and it is the axis to which our nutation model refers. Since the nutation is derived from a model which is necessarily only an approximation of reality, it is important to choose a model that complies with it in order to conform with the above definition.

3.1.2 *Reference Frames*

The first international campaign to utilize laser ranging data for the definition of a dynamical system was ISAGEX, the International Satellite Geodesy Experiment. The accuracy of early-1970s ranging systems that participated was between 1 and 2 meters. Since the errors from the gravity field were large at the time, the resulting reference frame had an estimated accuracy of only about 5 meters. Instrumentation, however, has improved tremendously, and our

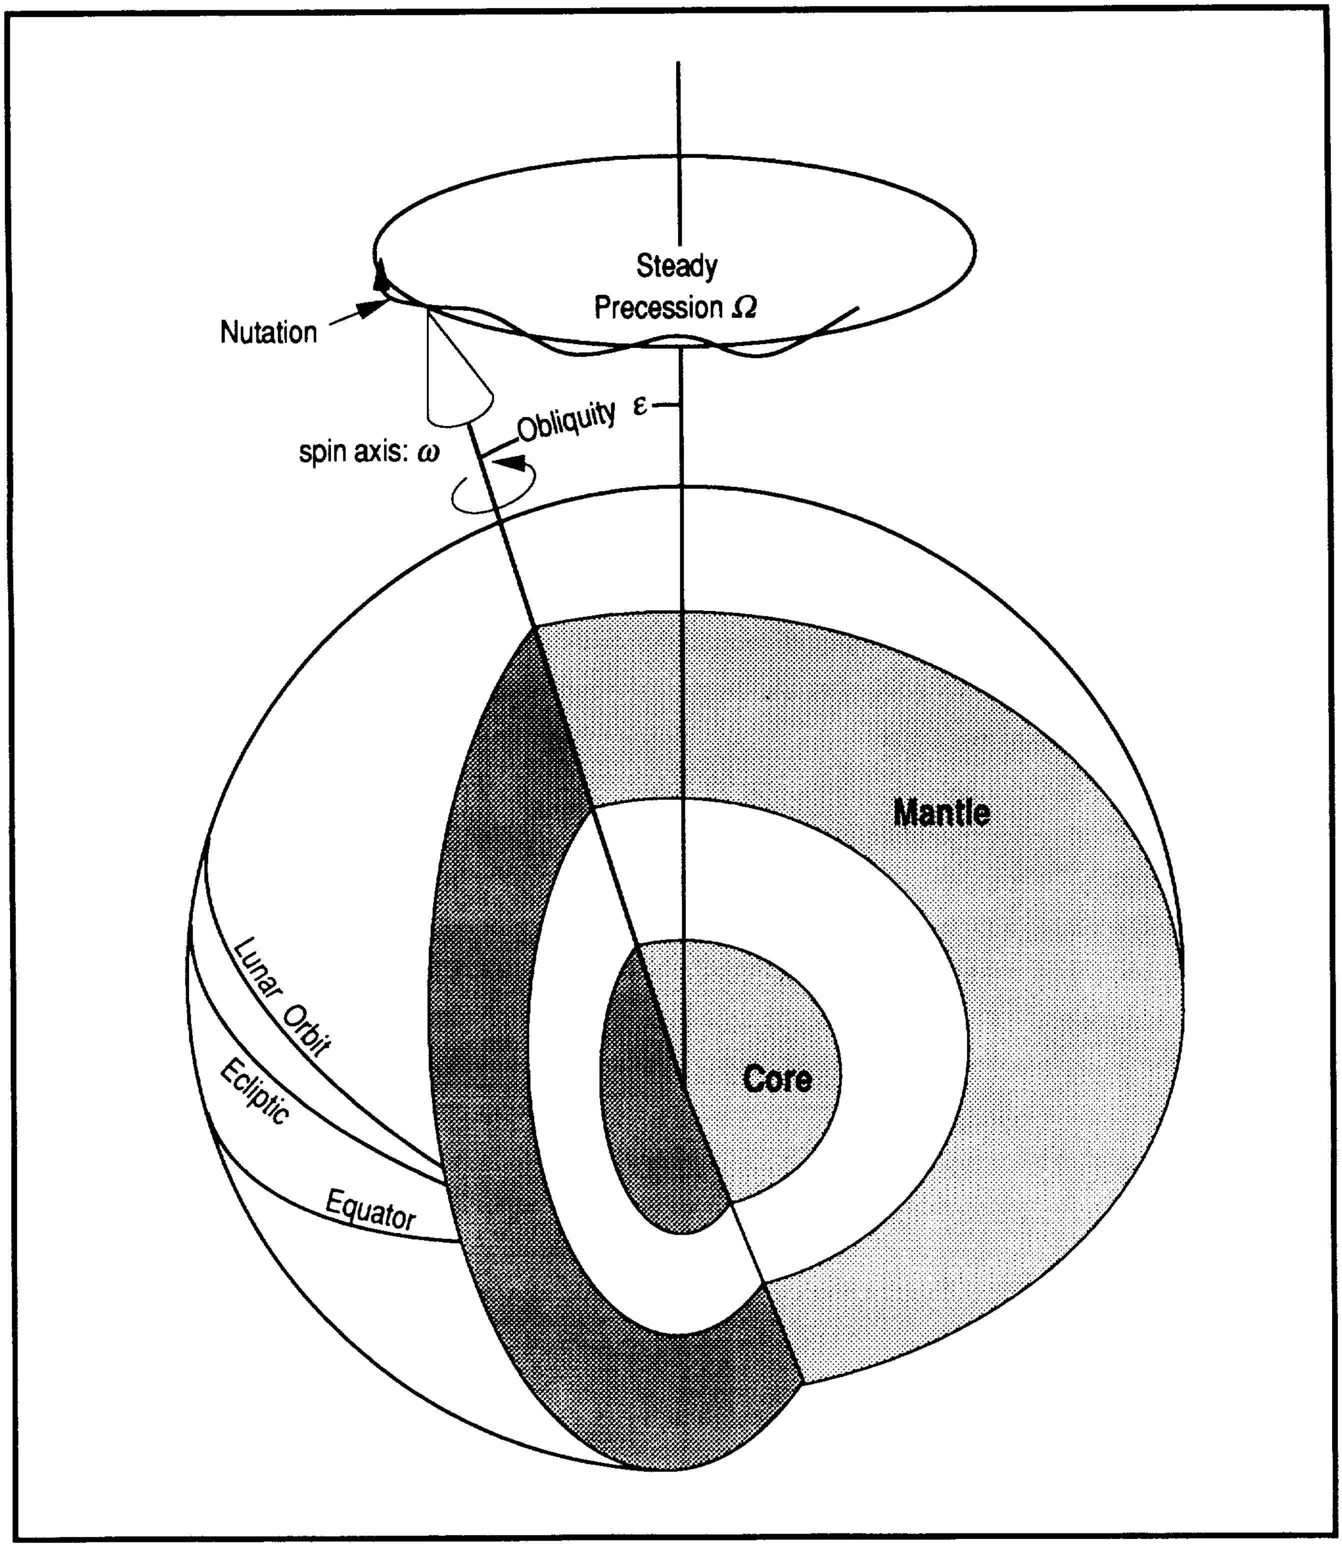

Figure 3.1 Earth rotation in inertial space: Precession and nutation.

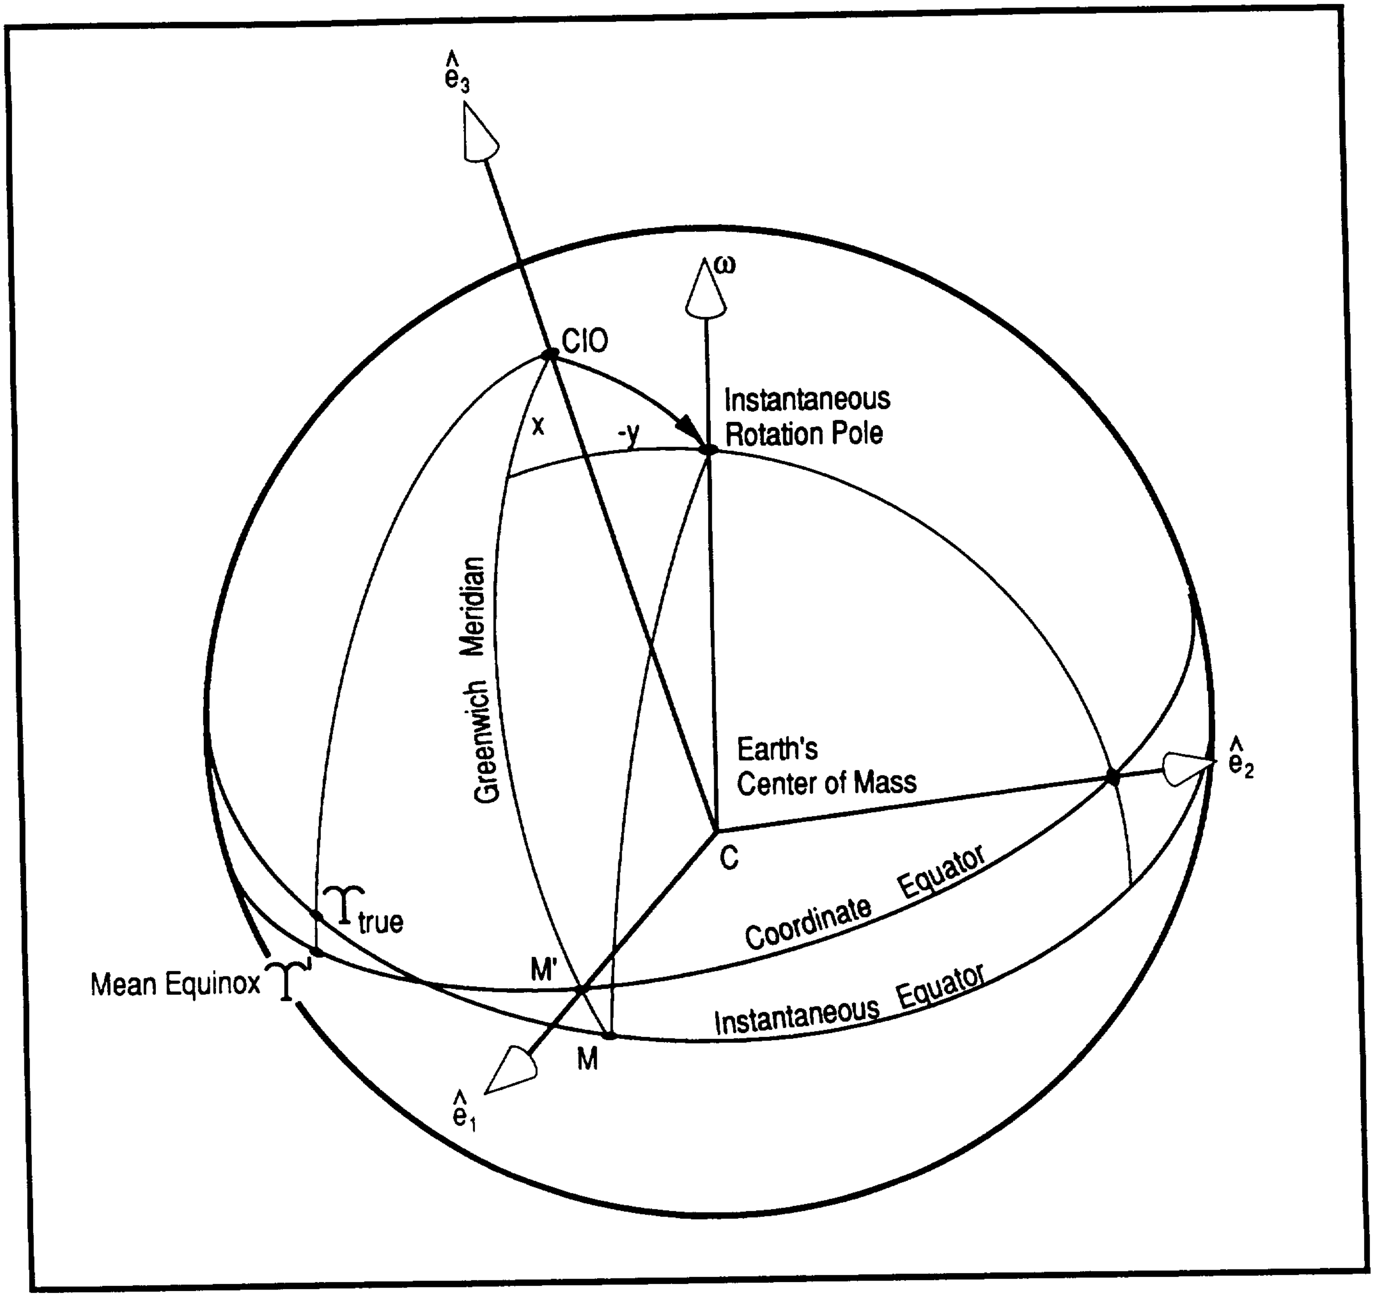

Figure 3.2 The terrestrial system: Polar motion and Earth rotation angles.

understanding and modeling of the gravity field and other forces acting on near-Earth satellites has advanced by orders of magnitude.

One of the most successful recent international campaigns organized for the purpose of studying Geodynamics was MERIT; it covered the period September 1983 through October 1984. MERIT was a program of international collaboration to Monitor Earth Rotation and to Intercompare the Techniques of observation and analysis, [*Mueller*, 1985]. Tracking of LAGEOS and the analysis of the collected data were main contributors to its success. Due to the high quality and abundance of data, and the variety of estimated geodynamic quantities, the MERIT campaign has had a major influence on subsequent international efforts in geodynamics.

As part of the preparation for this campaign the "MERIT Standards" [*Melbourne et al.*, 1983] were instituted and applied to a wide range of analyses. Therein one found a collection of constants, models, and formalisms that were used to define the reference frames associated with Project MERIT. Regardless of whether these Standards provided the most accurate or most popular values, their single most important contribution was bringing together in one document the entities one needed to adopt in the process of establishing a reference frame. In most cases, we only have to describe minor deviations from MERIT, rather than re-enumerate every single value required. To a great extent, this accurately describes the standards adopted for the SL7.

3.1.2.1 The Inertial Frame

The adopted definition for the CIRS is that of J2000. This frame is connected to the CERS frame at any instant through the IAU 1976 model for precession [*Lieske et al.*, 1977, and *Lieske*, 1979] and the nutations of the IAU 1980 model [*Wahr*, 1981]. The definition of the reference pole for Wahr's model happens to be such that it fulfills the CEP definition consistent with J2000. The obliquity of the ecliptic of date with respect to the reference ecliptic of J2000 is modeled through the IAU 1976 adopted formula [*Kaplan*, 1981], which is consistent with the adopted model for the precession. The adopted Solar, Lunar and Planetary ephemerides, JPL's DE200/LE200, are also consistent with J2000.

The connection of the CERS with the CTRS involves a model for the orientation of the first axis of one with respect to that of the other: the Greenwich Mean Sidereal Time, GMST. The formula that we have adopted is consistent with the IAU 1976 resolution [*Kaplan*, 1981, p. 8]. It complies with the definition of the Celestial Equator implied by the above-mentioned formula for the obliquity of the ecliptic as well as the definition of the CEP through Wahr's nutation model.

Application of the CIRS to the CERS transformation defines (as we already noted), an "instantaneously inertial" frame in which the orbit of the satellite is observed. This orbit is the "link" through which the aforementioned models effect the connection between the two frames. We know however, that there are no "bench marks" in space to define the CIRS and that today's adopted models are mere mathematical abstractions. If we were to reverse the argument about the "orbit link," we could see how the definition of the CIRS is realized indirectly through the dynamics of the satellite orbit. It is therefore clear why such a reference frame is termed a dynamical one.

3.1.2.2 The Terrestrial Frame

The connection of the CERS with the CTRS requires the knowledge of the Earth Orientation Parameters (EOP), namely the variation in the sidereal rotation and the polar motion coordinates. We have already mentioned that the systematic part of the first rotation is given by the GMST formula. To refer this angle to the true Equinox of date we must add to GMST the "Equation of the Equinox," which is the effect of the nutation on the mean Equinox. The resultant angle is the Greenwich Apparent Sidereal Time, GAST. The fact that the Earth rotates with a variable rate about an axis which has an irregular motion with respect to the crust, forces us to determine through observation the remaining portion of the three Eulerian angles.

The observatories which collect the tracking data are fixed on the Earth's crust. The polyhedron whose vertices are the observatories provides a crude approximation of the crust; the denser and more uniform the distribution of the observatories, the closer the approximation. Were the Earth's crust completely rigid, a few stations would suffice. Due to the motion associated with plate tectonics, this is not the case. Monitoring the magnitude and direction of these motions is currently an important task in geodynamics and is of chief interest in this study. Tectonic models exist to describe these motions, but are based mostly on geological data and make simplistic assumptions about the rigidity of the internal plate structure. These models can have large uncertainties associated with them and they reflect average behavior over several million years. Short-term variations can only be determined through direct observation and can provide us with vital information on precursory seismic events with obvious societal implications.

We are in a situation where we have no model demonstrably accurate enough to represent the global tectonic motions present in the tracking network, whose effects are large enough to affect the rest of the parameters that will define the CTRS station positions. The general rule in such cases is to estimate the effect from the data themselves. In fact, to help our solution converge faster, we have adopted as a first approximation the model AM0-2 of *Minster and Jordan* [1978]. The correction to the underlying model is made by allowing the observing station locations to adjust to new time-averaged positions over a prescribed interval of time. Depending on the purpose of the solution, this interval can be as short as a month or as long as a year, as described in Section 2.3. This procedure, along with the AM0-2 model, accounts for crustal motions within our analysis. We have thus reached the point where a set of piece-wise continuous station positions and an adopted model of crustal motion define our approximation of the Earth's crust.

The satellite dynamics are sensitive to the location of the observatory to the extent that the observatory's position can be determined from its observations along with the satellite trajectory. In particular, the analysis of ranging data to estimate tracking site positions is a problem which theoretically has only one singularity: the definition of the origin of longitudes. It is not necessary then to adopt positions for the "mean" places of the stations, we can simply estimate them from the data themselves. We only need to constrain the longitude of one station to remove the singularity (Figure 3.3). This would suffice for the solution to the definition of our CTRS if it were not for the simultaneous estimation of the Earth orientation parameters. An examination of the range equation in terms of this enlarged set of estimated parameters reveals that a change in the station position can be accommodated by an opposite change of the CTRS with no change in the observation residual itself. To remove this singularity, we need to define the location of the third axis on the already defined zeroth meridian. This can be accomplished through the adoption of the latitude of the already constrained station. One further constraint is required which will remove the rotational degree of freedom of the zeroth meridian plane about its equatorial axis. This can be effected in one of two ways : fixing the latitude of a station which is approximately on the same parallel and 90 degrees away in longitude (Figure 3.4), or fixing the longitude of a station nearly on the same meridian and about 90 degrees away in latitude (Figure 3.5).

We have used both approaches in different test solutions, considering in each case which of the two stations had stronger tracking. The nominally constrained stations adopted were: Greenbelt, Maryland, selected to serve as the primary station (fixing both latitude and longitude), and for the second station we had a choice between either Maui, Hawaii (fixing its latitude) or Arequipa, Peru (fixing its longitude). The applied constraints force these coordinates to change in time with a predefined tectonic motion provided by the AM0-2 model. It can be easily verified that these particular constraints are selected in such a way that the estimated changes in distance due to the tectonic motion between the constrained stations remain nearly unaffected over time.

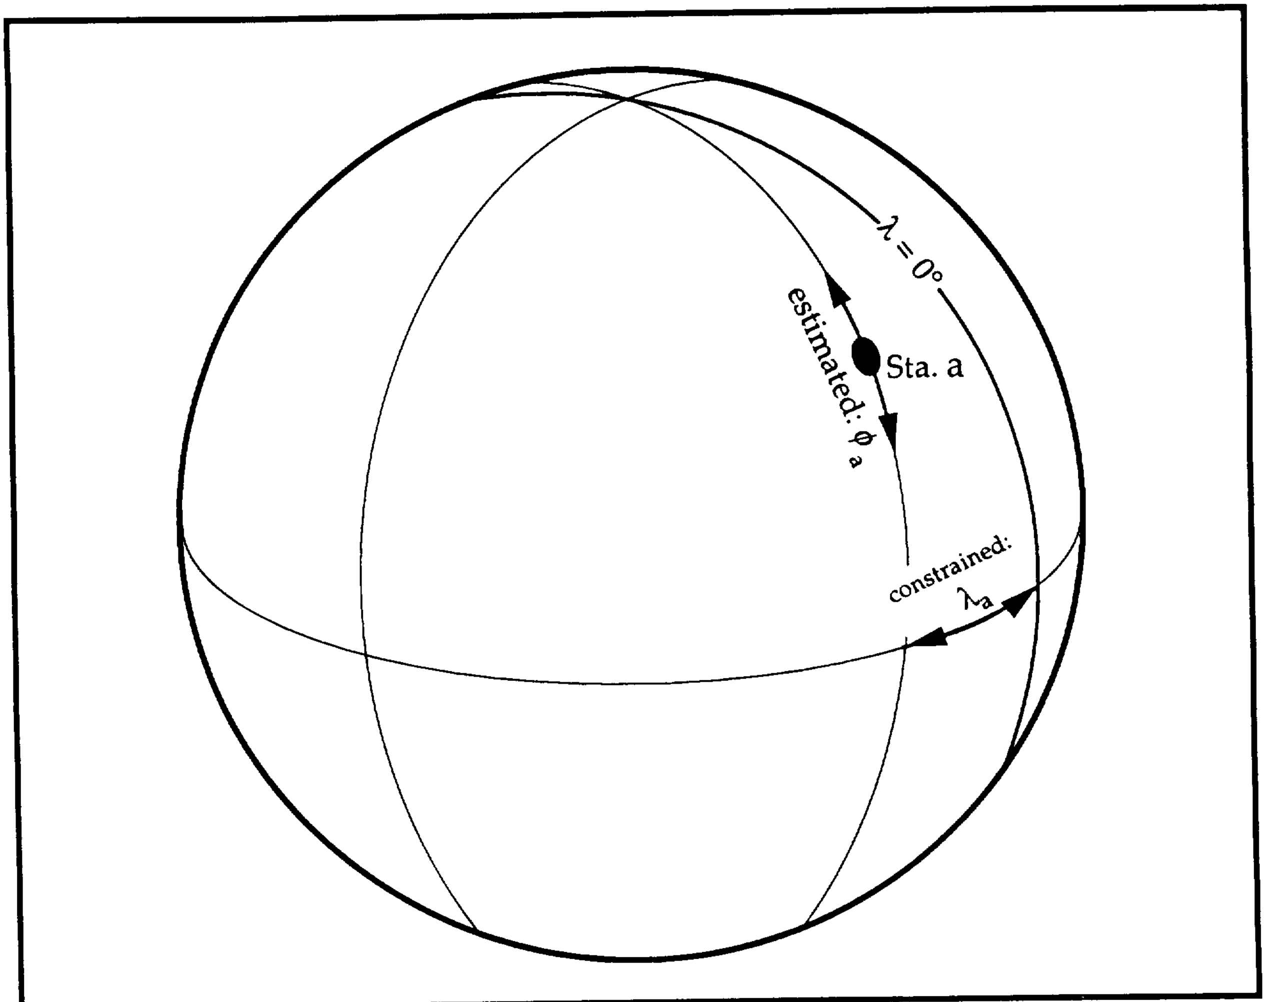

Figure 3.3 Minimal constraint required to establish a CTRS in a solution where Earth orientation parameters are not being estimated.

The initial approximate positions for the tracking stations were the result of the previous cycle of analysis, the SL6 solution. For stations that appeared after 1984, the values were obtained from preliminary solutions within the frame of the SL6 stations. The starting EOP set (the approximation for the estimates), was of mixed origin. For the 1976 through 1979 period we have used the values provided by BIH Circular D, and the same holds for the 1985-86 period. For the 1980-84 period, we have used the pole positions derived from the SL6 cycle of analysis. In all cases the BIH Circular D values were used for Earth rotation variations, described through the UT1-UTC.

The sequential application of the orthogonal rotations described in the last two subsections effects the connection of the CTRS to the CIRS, in other words, the observer's frame of reference to that of the inertial space as it is realized by the orbit of LAGEOS. The final solution which

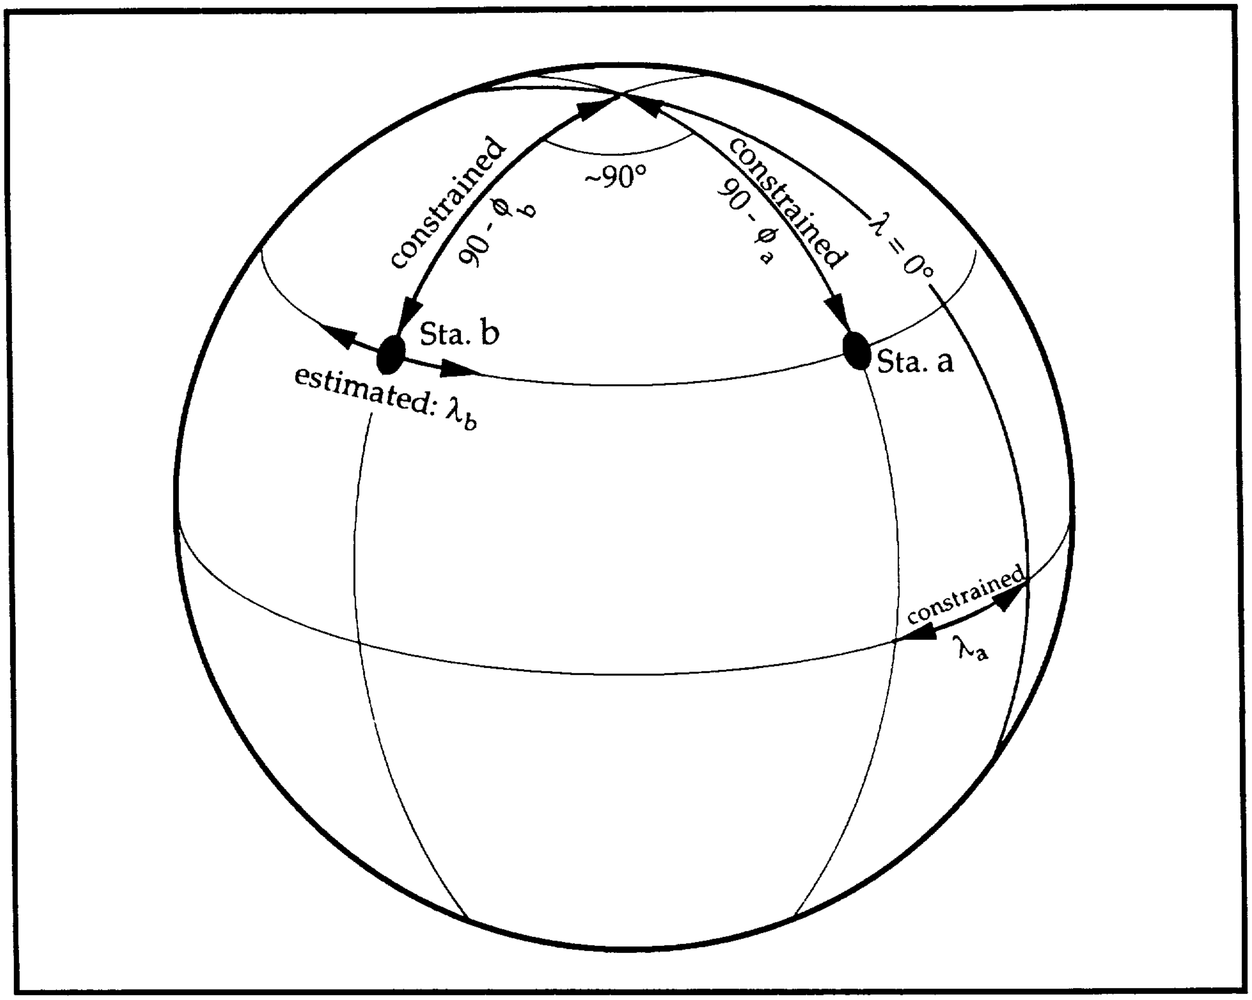

Figure 3.4 Minimal constraint required to establish a CTRS in a solution in which Earth orientation parameters are being estimated. Case 1: two stations on the same parallel.

is presented here, is the result of a second iteration to minimize non-linearity effects. As such, we must point out that these results have been based on using as *a priori*, information which has been derived from the previous iteration. This statement encompasses all of the adjusted parameters with the exception of the arc-dependent solar radiation pressure coefficients and the along-track acceleration series.

3.2 Adopted Constants

The following tables list the values adopted for constants that enter into the models used in the reduction of the observations. Only the more important ones have been included. We have

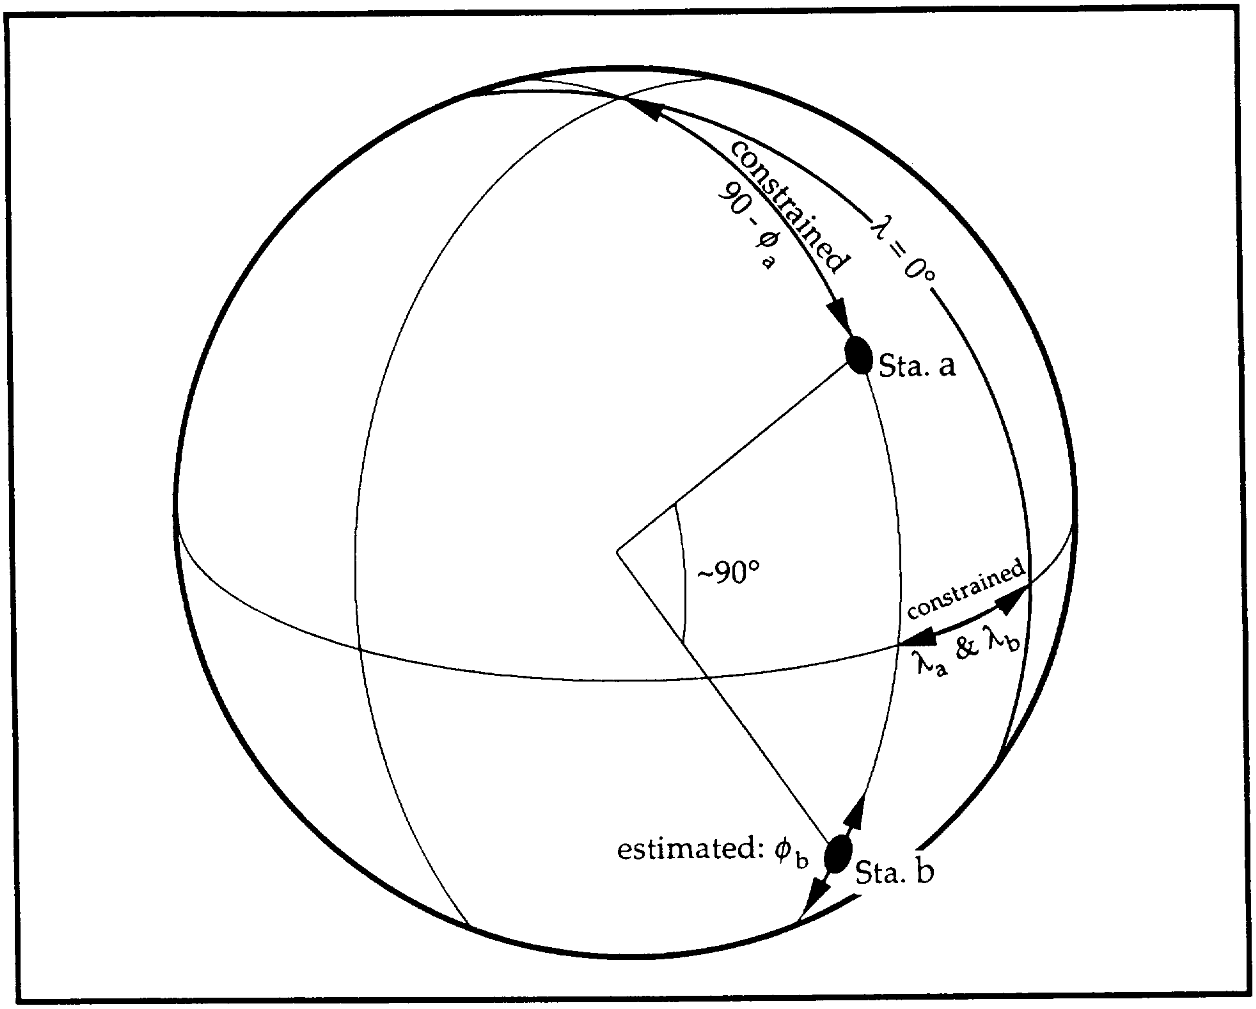

Figure 3.5 Minimal constraint required to establish a CTRS in a solution in which Earth orientation parameters are being estimated. Case 2: two stations on the same meridian.

also avoided repeating numbers which are implicitly embedded in standard models which we have adopted in the whole, e.g., the constants describing Wahr's nutation model, or Lieske's expressions for the precessional matrix.

3.2.1 *Astronomical Constants*

Speed of light	299792458 m/s
Equatorial radius of the Earth	6378137 m
Flattening of the Earth	1 / 298.257
Mean spin rate of the Earth	0.00007292115 rad/s
Geocentric gravitational constant	398600.440 km^3/s^2

Ratio of Earth to Moon mass	0.012300034
Ratio of Solar to Earth mass	332946.038
Astronomical unit	149597870660 m

3.2.2 *Dynamical Models*

Geopotential expansion	GEM - T1 (to degree and order 20)
Solid-Earth tides	Wahr model
Ocean tides	GEM - T1
Radiation pressure at 1 AU	0.0000045783 $kg/m/s^2$
Mass of LAGEOS	406.965 kg
LAGEOS cross-sectional area	0.28274 m^2
LAGEOS reflectance coefficient	1.13

3.2.3 *Measurement Model*

Troposphere	Marini-Murray model
Satellite center of mass correction	0.24 m
Station tidal displacements	Wahr model

3.2.4 *Reference System*

CIRS	J2000.0
Planetary Ephemeris	DE200/LE200
Terrestrial time scale	UTC(USNO)
Precession	IAU 1976 (Lieske model)
Nutation	IAU 1980 (Wahr model)
CTRS	Global Solution 11.7 y
Tidal variations in UT1	Yoder model
Tectonic motion model	Minster & Jordan AM0-2

3.3 Force Modeling

This section describes the force models of GEODYN and their specific application in the SL7.1 solution. The complete mathematical descriptions are found in *Eddy et al.* [1990].

The numerous forces which accelerate a satellite are naturally classified as conservative potential effects and non-conservative effects. The potential effects modeled include the geopotential due to the static mass distribution of the Earth and the temporally varying geopotential due to the deformation of the Earth by the gravitational forces of the Sun and Moon. The third body effects augment the conventional point mass potential to include the effect of Earth's dominant non-spherical component, C_{20}, that is, the "indirect oblateness" effect is modeled.

3.3.1 *Potential Effects*

The static geopotential is typically represented as a series of spherical harmonics by [*Heiskanen and Moritz*, 1967]:

$$U^s = \frac{GM}{r}\left[1 + \sum_{n=2}^{nmax}\sum_{m=0}^{n}\left(\frac{a_e}{r}\right)^n \overline{P}_{nm}(\sin\phi)\left(\overline{C}_{nm}\cos m\lambda + \overline{S}_{nm}\sin m\lambda\right)\right] \tag{3.1}$$

where GM is the gravitational constant of the Earth; r, ϕ and λ are the geocentric distance, latitude, and east longitude, respectively, at the point of evaluation; $\overline{P}_{nm}(\sin\varphi)$ are the associated Legendre functions of the first kind; and $\overline{C}_{nm}$ and $\overline{S}_{nm}$ are the geopotential coefficients, sometimes referred to as the Stokes' coefficients, which represent the inhomogeneous mass distribution of the Earth. The use of the normalized harmonics is indicated by the overbars. To completely represent the geopotential, $nmax$ should be very large. However, for the purposes of modeling satellite behavior, the series can be truncated with minimal loss of accuracy due to the gravitational attenuation with altitude. The evolution of LAGEOS' orbit and the forces acting upon LAGEOS at any one moment are predominantly influenced by the geopotential. The static geopotential model is further augmented with a model describing the dynamically varying indirect tidal potential, which may simply be regarded as the above model with the prescribed astronomic forcing.

The tidal potential adopted is split into two components; the solid body tide potential and the ocean tide potential. The body tide potential is modeled based on the frequency-dependent elastic response of the Earth [*Wahr*, 1981]. The ocean tide model is based upon the spherical harmonic expansion of a simple surface density layer model. Both of these potentials may be expressed in the standard spherical harmonic form given in equation 3.1, where the coefficients vary with time. However, tidal potentials are more conventionally expressed in terms of amplitude and phase, where the amplitudes are related to either surface tidal heights (ocean tides) or to their contribution to the elasticity parameter k_2 (for the solid-Earth tides).

The formulation for the tidal potentials in GEODYN is fully documented in *Christodoulidis et al.*, [1988]. The body tide potential is expressed as (for either the Sun or the Moon):

$$U^b = \sum_f k_{2,f} \overline{A}_f G_D \frac{3-m}{3} \left[\frac{a_e}{r}\right]^3 P_{2m}(\sin\phi)\cos\alpha_f^{SE} \qquad (3.2)$$

and the ocean tide potential is similarly expressed as

$$U^o = \sum_f \sum_{l,q,\pm} 4\pi G_D a_e \rho_o \left(\frac{1+k_l'}{2l+1}\right) C_{lq,f}^{\pm} \left[\frac{a_e}{r}\right]^{l+1} P_{lq}(\sin\phi)\cos\alpha_{lq,f}^{\pm} \qquad (3.3)$$

where

$\sum_f$	indicates summation over all tidal constituents f in the expression of the tide-generating potential.
$k_{2,f}$, $\delta_{2,f}$	are the second-degree Love number amplitude and phase respectively, which describe the body response of the Earth.
$\overline{A}_f$	is equivalent to the Doodson coefficient (given by equation A7 in *Christodoulidis et al.* [1988]).
G_D	equivalent of the Doodson Constant given by $G_D = 3\mu_m R^2 / \left(4a_m^3\right)$ where μ_m is the product of the gravitational constant with the mass of the Moon and a_m is the semi-major axis of the lunar orbit (likewise for the solar case), R is the mean radius of the Earth.
m	is the order associated with f which is 0 for the long-period tides, 1 for the diurnal tides, and 2 for the semi-diurnal tides.
ρ_o	average density of ocean water.
k_l'	load deformation coefficients.
$C_{lq}^{\pm}$, $\varepsilon_{lq,f}^{\pm}$	are the amplitude and phase of the $(l,q,\pm)$ subharmonic of the ocean tide generated by constituent f.

and where the angular arguments are:

$$\alpha_f^{SE} = (\mp)\left[(2-2h)\omega^* + (2-2h+j)M^* + k\Omega^*\right] + m\Theta_g + m\lambda + \pi - m\frac{\pi}{2} + \delta_{2,f} \qquad (3.3a)$$

$$\alpha_{lq,f}^{\pm} = (\mp)\left[(2-2h)\omega^* + (2-2h+j)M^* + k\Omega^*\right] + m\Theta_g + q\lambda + \pi - m\frac{\pi}{2} + \varepsilon_{lq,f}^{\pm} \qquad (3.3b)$$

and finally where

ω^*, M^*, Ω^*	are the traditional Keplerian elements for the disturbing body refered to the ecliptic, and the
$h, j, k, q, \pm$	are combinations of factors which map the six Doodson angular arguments into subscripts suitable for application with the Keplerian elements of the Moon and apparent Sun.
Θ_g	is the Greenwich sidereal hour angle.

The eccentricity and inclination of the osculating elements of the perturbing body are incorporated in the Doodson coefficient.

Each constituent f is associated with an unique frequency. It should be noted that if

$$k_{2,f} \equiv k_2$$
$$\delta_{2,f} \equiv \delta_2 \tag{3.4}$$

for all f (i.e., the solid-Earth Love number is frequency invariant) (including f=0, see comment below), then the total body tide potential may be simply computed in the time domain using the simple second-degree potential

$$U^b = \sum_d k_2 \frac{\mu_d a_e^2}{r_d^2}\left[\frac{a_e}{r}\right]^3 \left\{\frac{3}{2}\left[\frac{\bar{r}_d \cdot \bar{r}}{r_d r}\right]^2 - \frac{1}{2}\right\} \tag{3.5}$$

based on the point mass attraction of the third bodies and the Earth's deformation given by a constant Love number. Hence, $\bar{r}_d$ is the geocentric vector to the Sun or Moon, μ_d is the gravitational constant of the Sun or Moon and $\bar{r}$ is the position vector to the point of computation. For a more realistic frequency-dependent model for the Love numbers, most of the variations are concentrated in a single band (the diurnal). It is computationally efficient to use a simple frequency-invariant background model as a complete description of the solid Earth tides (as in equation 3.5) and correct select terms for which the Love numbers differ significantly from the background reference values. This procedure was adopted in our analysis.

Because terms with $f = 0$ were included in the tidal acceleration of the spacecraft, the resulting gravity field, its geoid etc., have all the permanent-body tidal deformation completely removed. In this way, they happen to be in agreement with earlier IAG resolutions on modeling the permanent tide and conflict with those which are most recent.

The tidal constituent f is uniquely identified by the Doodson argument number. Table 3.1 identifies the principal tidal frequencies and gives the (approximate) matching Darwinian symbol for each corresponding Doodson number. The frequencies are based upon the ecliptic constant element rates. Note that these same frequencies are also present in the ocean tide effects.

The direct potential effects of the other disturbing bodies are modeled as point mass effects:

$$U^d = \mu_d \left(\frac{1}{\rho} - \frac{\bar{r}_d \cdot \bar{r}}{r_d^3} \right) \tag{3.6}$$

where $\rho = |\bar{r}_d - \bar{r}|$ is the distance from the satellite to the disturbing third body. The second term refers the accelerations of the satellite to the center of the Earth.

In the case of the Earth-Moon system, the effect of the Earth's oblateness must be included in the precise computation of third-body accelerations. The effect of the Earth's gravity on the Moon is given by Equation. 3.1. As the force exerted on the Moon by the gravity of the Earth is matched by an equal and opposite force by the Moon on the Earth, the additional acceleration to be applied to the satellite radially and in latitude is:

$$\ddot{r} = \frac{-1.5\mu_m}{r_m^4} a_e^2 C_{20} (3\sin\phi_m - 1) \tag{3.7a}$$

$$\ddot{\phi} = 3\frac{\mu_m}{r_m^3} a_e^2 C_{20} \sin\phi \cos\phi_m \tag{3.7b}$$

where μ_m and r_m correspond to μ_d and r_d for the Moon and ϕ_m is the latitude of the Moon. The inclusion of this effect more precisely refers the accelerations of the satellite to the center of the Earth.

3.3.1.1 The *A Priori* Static Geopotential Model: GEM-T1

The *a priori* gravitational model adopted was the Goddard Earth Model - T1 (GEM-T1) using terms through degree and order 20. GEM-T1 resulted from a major new computation of the terrestrial gravitational field by the Geodynamics Branch of Goddard Space Flight Center.

Table 3.1. Principal Tidal Components

Darwinian Symbol	Doodson's Argument Number	Period (hr)	Description
M2	255.555	12.42	Principal lunar semidiurnal
S2	273.555	12.00	Principal solar semidiurnal
N2	245.655	12.66	Larger lunar elliptic semidiurnal

K1	165.555	23.93	Lunar/Solar diurnal
O1	145.555	25.82	Principal lunar diurnal
P1	163.555	24.07	Principal solar diurnal
Mf	075.555	13.66d	Lunar fortnightly
Mm	065.455	27.55d	Lunar monthly
Ssa	057.555	188.62d	Solar semi-annual

A simultaneous solution was made for spherical harmonic parameters of both tidal and invariant parts of the gravitational field (*Marsh et al.*, 1988, *Christodoulidis et al.*, 1988).

The GEM-T1 model adopted the latest IAG reference constants and was solved in the J2000 Reference System. This gravitational model was based on modern ellipsoidal parameters (a_e=6378137m and 1/f=298.257) and the adopted speed of light (c=2999792.458 km sec^{-1}). It provided a simultaneous solution for a gravity model in spherical harmonics complete to degree and order 36; and a subset of 66 ocean tidal coefficients for the long wave-length components of 12 major tides. This adjustment was made in the presence of 550 other ocean tidal coefficients representing 32 major and minor tides and the Wahr frequency-dependent solid-Earth tidal model.

GEM-T1 was derived exclusively from satellite tracking data acquired on 17 different satellites whose inclinations ranged from 15 degrees to polar. In all, almost 800,000 observations were used, half of which were from third-generation laser systems. LAGEOS contributed nearly 5 years of observations to this solution. The calibration of the model accuracies performed for GEM-T1 show it to be a great improvement over all earlier GSFC "satellite-only" models for both orbital and geoidal modeling applications. For the longest wavelength portion of the geoid (to 8 x 8), GEM-T1 appears to be an improvement over all earlier GEM models, even those containing altimetry and surface gravimetry, including GEM-L2 [*Lerch et al.*, 1985] which was adopted by the MERIT Campaign for LAGEOS data analyses. Figure 3.6 compares the calibrated accuracy of the GEM-L2 and GEM-T1 potential models revealing the basis for its adoption for the SL7.1 analysis.

3.3.1.2 The *A Priori* Body Tide Model: Wahr

Table 3.2 gives the Love numbers computed by *Wahr* [1981], based upon the Earth Model 1066A of *Gilbert & Dziewonski* [1975]. Note that $\delta_{2,f}$ is zero for this elastic model, i.e., the model is free of dissipation. These Love numbers characterize the response of the 1066A Earth to the non-loading tide generating potential.

3.3.1.3 *A Priori* Ocean Tides Models: GEM-T1 Solution

The response of the oceans caused by the tide generating potential is a set of constituent tide heights

$$\xi_f(P) = A_f(P)\cos\left(\omega_f - \psi_f(P)\right) \qquad (3.8)$$

where ω_f is the angular argument associated with constituent f and $A_f(P)$ and $\psi_f(P)$ are the tidal amplitude and phase, respectively, at point P. The amplitudes and phases are computed from numerical solutions of the Laplace Tide Equations. Such solutions involve a high computational burden and presently such models are available for only a limited number of tidal constituents.

The tidal heights are expanded into spherical harmonics by:

$$\xi_f(P) = \sum_{l,q,\pm} C^{\pm}_{lq,f} P_{lq}(\sin\phi)\cos\left(\sigma^{\pm}_{lq,f} \pm \varepsilon^{\pm}_{lq,f}\right) \qquad (3.9)$$

Given the global tidal heights, the coefficients $C^{\pm}_{lq,f}$ and phases $\varepsilon^{\pm}_{lq,f}$ necessary for the evaluation of the potential can be computed.

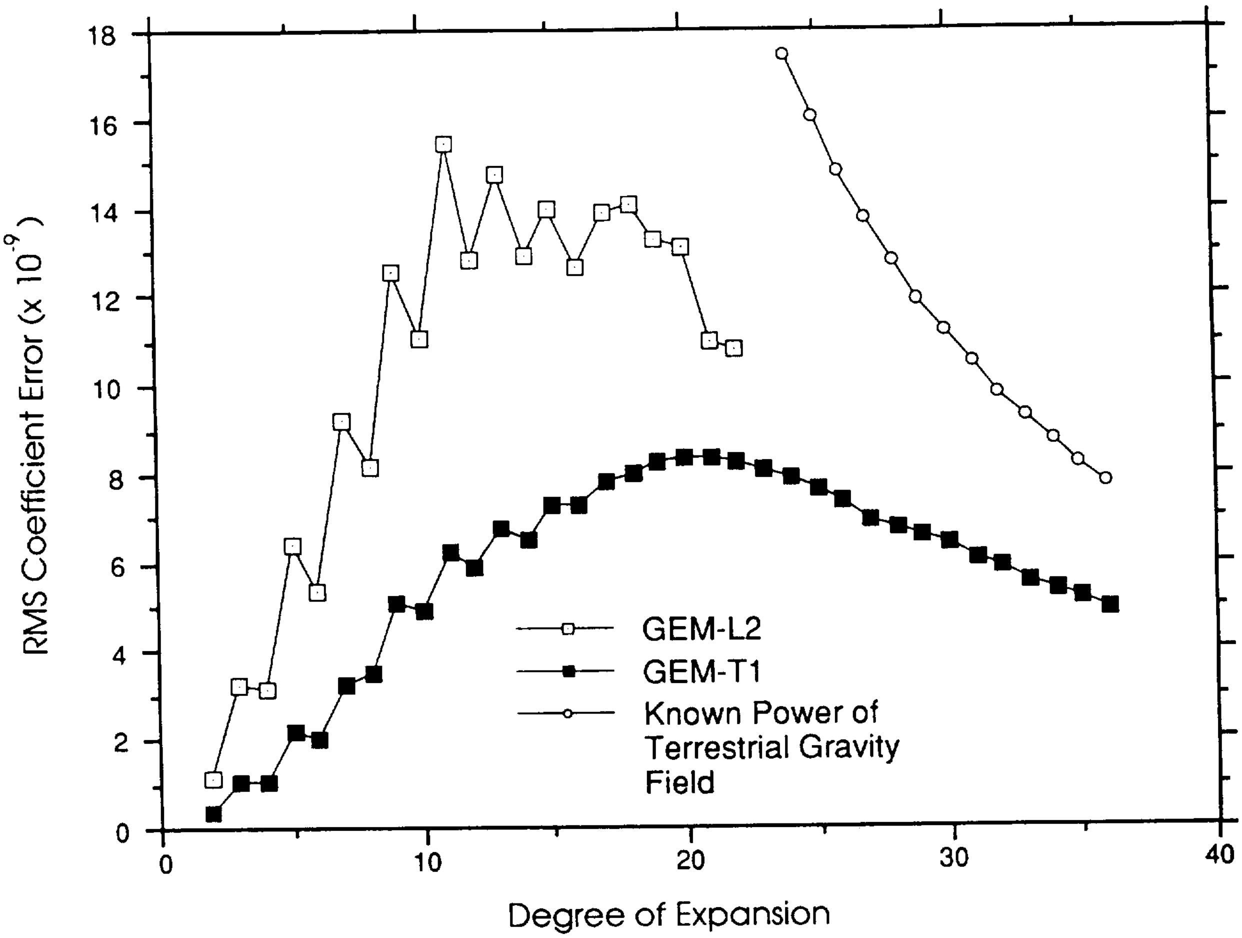

Figure 3.6 Gravity model RMS coefficient error by degree. The known power of the terrestrial fields is given by Kaula's rule which shows the approximate power of the field and gives a basis for estimating the percent accuracy of the harmonics of the field. Figure taken from *Marsh et al.* [1987].

Observed tide models for 11 major tide constituents in the semidiurnal, diurnal, and long-period bands have been computed on a 1° x 1° global grid by E.W. Schwiderski using an integration scheme which incorporates the available deep-sea tide gauge data. These tidal constituents typically account for over 90% of the total ocean tide amplitude at any point. However, numerous minor ocean tidal constituents, although small in amplitude, can have significant perturbing effects on satellite orbits. Models for these were developed using linear admittances from the oceanographic tide models [*Christodoulidis et al.*, 1986b].

With the advent of centimeter-level satellite geodesy and geodynamics, it is necessary to accurately model the tidal deformation of the Earth and its oceans, i.e., the dominant temporal variations of the geopotential. This is in part because the data distribution in time and space cannot be selected so that the effects of these temporal variations average out. All these tides

Table 3.2. Wahr Love Numbers for 1077A

Band	Tidal Line	$k_{2,f}$

Semi Diurnal	All	.302

have significant perturbations on all near-Earth satellites of geodetic interest. In fact, geodetic satellites form a sensitive measurement system for monitoring tidal effects. Table 3.3 shows the periods of the principal long-period tidal perturbations on the orbits of most of the laser satellites. The diurnal and semidiurnal perturbations are quite different in frequency than the corresponding periodicities of the tides on the Earth's surface, because it is the satellite's nodal precession with respect to the third bodies and not the Earth's rotation which defines these periodicities. The amplitude of the major tides on the orbital inclination and ascending node of Starlette, (a satellite similar in design to LAGEOS, but orbiting in a slightly eccentric orbit at 800-1200 km altitude), and LAGEOS are shown in Figures 3.7 and 3.8.

Dynamic values for select terms in the ocean tides which are most orbit sensitive were derived as part of the GEM-T1 gravity solution. The body tides were held fixed according to the Wahr values during this development as given in Section 3.3.1.2 and the adopted precession and nutation are the IAU 1980 models. Because the body tides are not separable from the ocean tides using orbital dynamics, only the ocean tides were adjusted in GEM-T1. The ocean tides which were recovered simultaneously in this model actually represent a determination of the total temporal variations of the geopotential exterior to the Earth's atmosphere in the presence of a fixed solid-Earth tidal model [*Marsh et al.*, 1987; *Christodoulidis et al.*, 1988] and thereby are an aggregate mass transport model.

Table 3.4 summarizes the ocean tidal terms which were modeled in the development of SL7.1 and indicates which were adjusted in the GEM-T1 solution. Due to attenuation by the distance

of the satellite from the oceans, the tidal model is only required to degree 6 in the SL7.1 solution development. Partial derivatives for the tides most significant on the evolution of the LAGEOS orbit were computed to add flexibility to the SL7.1 analysis.

3.3.2 *Non-Conservative Forces: Atmospheric Drag and Solar Radiation Pressure*

The non-conservative forces which are of concern in modeling the evolution of the LAGEOS orbit are the forces of an apparent "drag-like" effect and solar radiation pressure. We are presently not modeling Earth albedo: we believe we have minimized any unmodeled albedo effects by adjusting empirical coefficients.

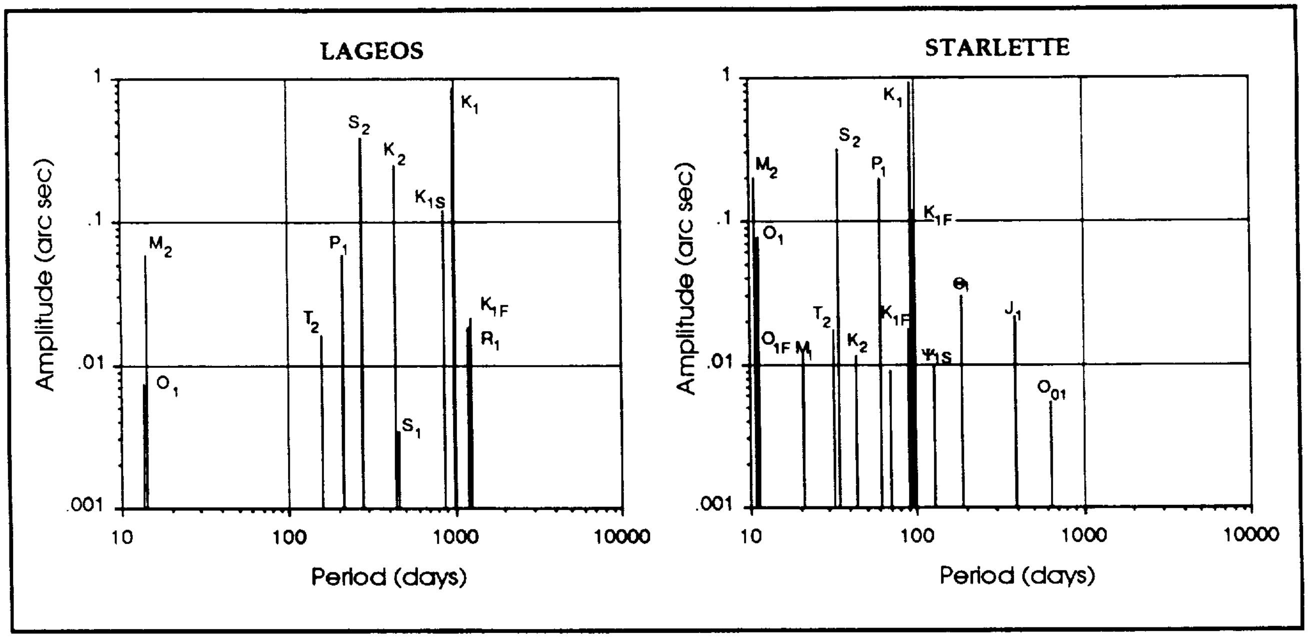

Figure 3.7 Effects of tidal perturbations on the inclinations of LAGEOS (left) and Starlette (right). Figure taken from *Marsh et al.* [1987].

3.3.2.1 Mathematical Formulation of the Models

The acceleration of an Earth orbiting satellite due to atmospheric drag is commonly expressed as

$$\overline{A}_D = -\frac{1}{2}C_D\left[\frac{A}{M}\right]\rho_D v_r \overline{v}_r \tag{3.10}$$

where C_D is the satellite drag coefficient, A is the effective cross-sectional area of the satellite, M is the mass of the satellite, ρ_D is the density of the atmosphere, $\overline{v}_r$ is the velocity vector of the satellite relative to the atmosphere and v_r is its modulus. The standard atmosphere model of *Jacchia* [1971] is used by GEODYN to provide atmospheric density values at satellite altitude. Jacchia's model is designed to give density values between 90 and 2500 km altitudes. Due to these limits, density values at LAGEOS altitude are unavailable. However, a "drag-like" decay of the LAGEOS orbit of ~1.3 mm/day in its semi-major axis is observed and a means to precisely model the decay is required. This is accomplished in the SL7.1 solution through the adjustment of along-track acceleration parameters within each monthly arc.

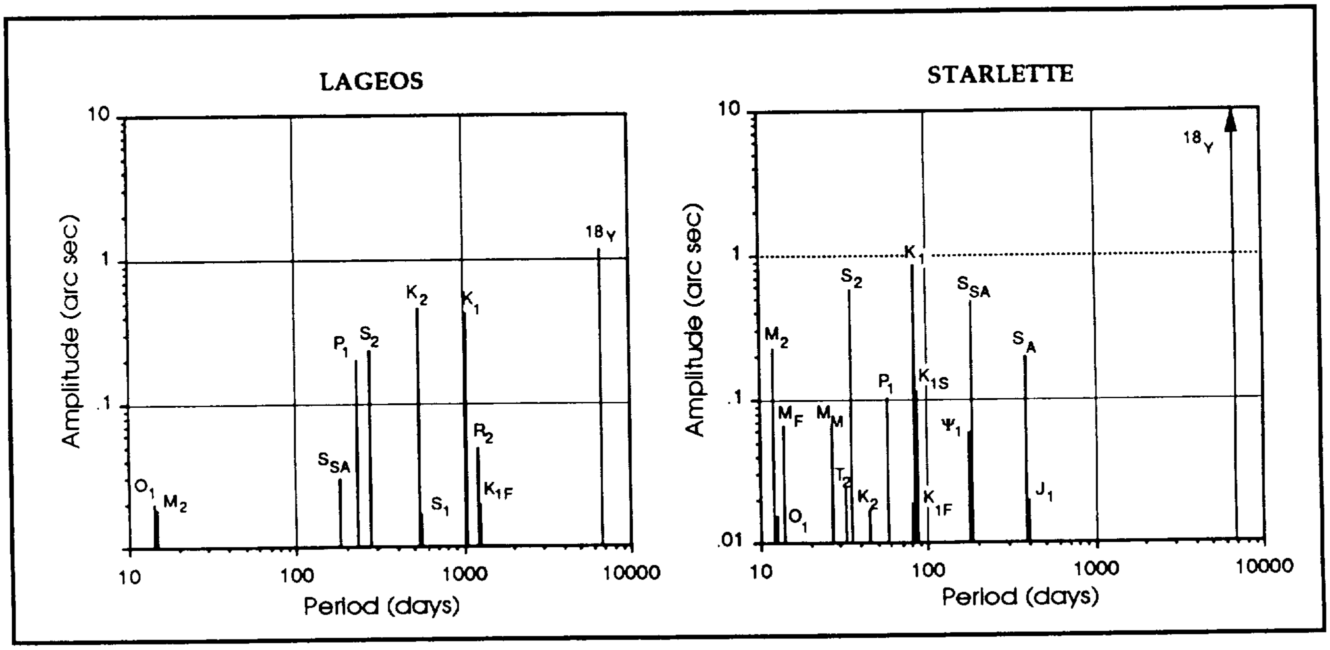

Figure 3.8 Effects of tidal perturbations on the right ascension of the ascending node of LAGEOS (left) and Starlette (right). Figure taken from *Marsh et al.* [1987].

General satellite accelerations can be modeled in GEODYN and have the form

$$\ddot{X} = \alpha \hat{u} \tag{3.11a}$$

where $\hat{u}$ is a unit vector defining the direction of the acceleration (specifiable within GEODYN) and α is the solved-for parameter. The direction of along-track acceleration is defined as

$$\hat{u} = \frac{\overline{v}}{|\overline{v}|} \tag{3.11b}$$

and is in the direction of the satellite's time of date velocity vector. After extensive experimentation, it was concluded that a single α-value for each 15-day period within a monthly orbit properly resolved this observed "drag-like" effect. Many authors have sought to provide the physical explanations for this observed effect. The results and discussion of our estimation of α within the context of the recent developments are given in Section 5.2.

The acceleration due to solar radiation pressure is given by

$$\overline{A}_R = -\nu C_R \left[\frac{A}{M}\right] P_s \hat{r}_s \tag{3.12}$$

where ν is the eclipse factor accounting for shadowing of the satellite by the Earth or Moon, C_R is the satellite radiation pressure coefficient, A and M are as used in equation 3.10, P_s is the solar radiation pressure at the satellite, and $\hat{r}_s$ is the geocentric vector pointing toward the Sun. The quantity P_s is nominally specified by its mean value at 1 astronomical unit and corrected for the distance to the Sun through a term $\left(r_s / r_{1au}\right)^2$. The parameter $C_R = 1 + \rho_s$, where ρ_s, is the (specular) reflectivity of the satellite surface.

An assumption of this simple model is that the satellite is spherical; an assumption that is quite adequate for LAGEOS. Moreover, the adjustment of the along-track acceleration and/or radiation pressure coefficients accommodate much of the model error associated with errors arising in the non-conservative force modeling. This premise was tested in the simulation described below.

3.3.2.2 The Neglect of an Earth Albedo Model

Generally stated, an accurate model for both the diffuse and specularly reflecting Earth is still under development. In modeling the time history of the specular properties of the Earth *Rubincam and Weiss* [1986] have listed several complications which make modeling Earth albedo difficult. These include, among others, geographical variations in albedo, albedo variations in time due to meteorological changes, and reflection and scattering due to the atmosphere itself. Further investigations have been made to assess the magnitude of these effects of Earth albedo on LAGEOS' orbit (cf. Section 5.2).

One assessment of possible albedo effects was made in an experiment (performed courtesy of Richard Eanes at the University of Texas Center for Space Research) where a 15-day orbit of LAGEOS was integrated which included perturbations arising from an along-track drag effect, direct solar radiation pressure, and albedo re-radiative effects using a rather complete model developed by Philip Knocke (private communication). This trajectory was then converted into satellite positions in time which could be used as data for simulation purposes. These values were fit in a least-squares estimation process where the albedo model was no longer used, but one in which the along-track acceleration and solar radiation pressure coefficients were adjusted. The resulting orbit agreed with the original to within 1-cm RMS. This experiment, coupled with a worst-case scenario study by *Rubincam et al.* [1987], support the contention that neglecting an Earth albedo model does not significantly corrupt the SL7.1 solution within the scope of the non-conservative and empirical force models adopted here for our monthly arc lengths.

3.4 Station Motion Model Within the Terrestrial System

There are two distinct sources for temporal variations in the locations of tracking stations relative to the CTRS: the effects of the astronomic tides on the geosphere and the effects of plate motion. This section will describe the models used in SL7.1 and discuss planned improvements.

3.4.1 *Station Tidal Variations*

The tidal forces acting upon the Earth's surface cause the tracking stations to undergo periodic motions. This effect is conveniently modeled as the sum of the response of a spherical elastic Earth to the disturbing potentials of the Sun and Moon plus correction terms due to the frequency-dependent elastic response of a more realistic Earth. A convenient formulation for these motions was derived by *Diamante and Williamson* [1972] and has been implemented in GEODYN as well as having been adopted in the MERIT standards [*Melbourne et al.*, 1983] and subsequent IERS standards [*McCarthy et al.*, 1989].

For the simple elastic model, the vector displacement of the station to a precision of 1 cm is given by *Diamante and Williamson* [1972]:

$$\Delta\bar{r} = \sum_d \frac{\mu_d}{\mu}\frac{r_{sta}^4}{r_d^3}\left\{(3l_2\cos S)\frac{\bar{r}_d}{r_d} + \left[3\left(\frac{h_2}{2} - l_2\right)\cos^2 S - \frac{h_2}{2}\right]\frac{\bar{r}_{sta}}{r_{sta}}\right\} \tag{3.13}$$

where d indicates either the Sun or Moon as the disturbing body, $\bar{r}_d$ is the position vector of the disturbing body, $\bar{r}_{sta}$ is the station position vector, μ_d is the gravitational constant of the disturbing body, μ is the gravitational constant of the Earth, h_2 l_2 are the Love and Shida numbers, respectively, which characterize the Earth's elastic response, and

$$\cos S = \frac{\bar{r}_{sta}\cdot\bar{r}_d}{r_{sta}r_d} \tag{3.14}$$

Nominal values for the Love and Shida numbers are

$h_2 = .6090$ $\qquad$ $l_2 = .0852$

When a more realistic model of the Earth is used, the fluid interior of the Earth causes the deformation response to be frequency dependent. *Wahr* [1980] has shown that this effect in station position can be modeled to better than 5 mm by simply correcting the response of the simple elastic model for the differential response at the K_1 frequency. At this frequency, the Love number h from Wahr's theory is 0.5203. Only the radial displacement needs to be corrected at the 5-mm accuracy level. The additional radial correction, which is also specified by the MERIT and IERS Standards, is (in meters):

$$\overline{\Delta r_2} = -.0253 \sin\phi \cos\phi \sin\left(\theta_g + \lambda\right) \frac{\bar{r}_{sta}}{r_{sta}} \tag{3.15}$$

where ϕ is the station geocentric latitude, λ is the corresponding east longitude, and θ_g is the right ascension of Greenwich. At 45 degrees latitude, this effect reaches a maximum of 13 mm. The total correction vector is given by

$$\Delta\bar{r}_{sta} = \overline{\Delta r_1} + \overline{\Delta r_2} \tag{3.16}$$

For future solutions, an expanded frequency-dependent model including all terms to the millimeter level is anticipated. In addition, ocean and atmospheric loading should also be incorporated. It has been shown that ocean loading can have an effect as large as 17 mm in vertical displacement for locations in the middle of the North American Continent [*Pagiatakis*, 1990]. Ocean loading can be quite sizable (> 50 mm) at coastal sites. Atmospheric loading can cause vertical surface displacements as large as 20 mm and the oceanic response to atmospheric loading can additionally effect the vertical displacements for sites in coastal regions [*Van Dam and Wahr*, 1987].

3.4.2 *A Priori Station Plate Tectonic Motions*

As discussed in Section 3.1.2.2, it is difficult to adopt a completely satisfactory Earth-fixed reference frame due to the motion of the tectonic plates. While the relative location of points on the earth's surface are strictly deterministic, the absolute direction of the station motions are not easily defined in a system useful for geophysical and geological time frames. When confronting this problem, *Minster and Jordan* [1978] considered modeling tectonic motions within four distinct "absolute" systems. These were each developed under differing kinematical constraints: best fitting to hotspot data (mean mesospheric frame, AM1-2), African plate fixed

(AM2-2), Caribbean plate fixed (AM3-2), and a solution whereby the net rotation of the lithosphere is constrained to be zero (AM0-2).

The hot spot system, based on the traces of long-term (~10 million years) centers of mantle plume activity, was thought by *Minster and Jordan* [1978] to best represent an absolute frame. However, as they were aware, the resulting absolute motion model depended on the validity of the Wilson-Morgan fixed hot spot hypothesis which has recently received some challenge. *Molnar and Stock* [1987], and in summary by *Olson* [1987], have determined that the hot spots themselves are moving relative to one another with rates of at least 10 mm/yr and as much as 20 mm/yr. They therefore conclude that the hot spot traces do not define a fixed reference frame. The use of the hot spot frame is additionally complicated by an element of subjectivism with regard to the selection of the hot spots used to define the frame. Although *Minster and Jordan* [1978] were careful in their selection, an omission or addition of one or several hot spots traces could dramatically change the "absolute" motions of the plates.

Other alternatives to defining an "absolute" system include simply fixing one particular plate or applying a constraint which forces the net rotation of the plates to be zero. *Minster and Jordan* [1978] made two plate motion solutions where the African and Caribbean plates were each fixed, respectively, in accordance to certain hypotheses regarding these two plates. Unfortunately, the global data set used by Minster and Jordan was unable to completely support the frames defined by fixing these plates. The application of a no net rotation constraint to the solution yields a uniquely defined reference frame that is free from subjective choices. However, as pointed about by *Jurdy* [1990], this mean lithosphere reference frame is based solely on the plate geometry and velocities and any variation in the velocities will alter the definition of the frame.

As a practical matter, any of these systems would be satisfactory for implementation in SL7.1 for each yields an identical set of temporal changes for inter-station distance determinations. Since the relative tectonic motions of points on the Earth's surface are the principal observational products of the SL7.1 solution, adoption of a frame largely serves to define the directions by which the station network is deforming. Although a more recent and further refined tectonic model is now available, NUVEL-1 [*DeMets et al.*, 1990], we have, throughout the SL7.1 analysis, followed the MERIT standards (cf. Section 3.1.1) and use the AM0-2 model to provide the framework within which to make the solution.

Besides giving absolute reference to the observed tectonic motions of the SLR sites, an *a priori* tectonic motion model has additional application for the subset of quarterly solutions within SL7.1. For quarterly station coordinate determinations, sites located on fast moving plates may have perceptible motions within this averaging interval. Since the tracking data distribution is not consistent across time, the averaging taking place within such a solution may not be adequate for obtaining the location of the sites at their quarterly mid-point. Since earlier SLR results indicated that the relative motions predicted by AM0-2 were largely verified (e.g. *Christodoulidis et al.* [1985]), a more satisfactory result is achieved when the AM0-2 model is used to describe the *a priori* continuous motion of all sites. The quarterly solutions then correct the values for the station positions for the midpoint within each quarter, while simultaneously the change in location of the sites between the start and end of the quarter is modeled by AM0-2.

The mathematical implementation of an "absolute" plate motion model is found in *Melbourne et al.* [1983] as provided by Minster and Jordan. Briefly, let X_o, Y_o, Z_o at time, t_o, be the Cartesian location of a site on a known plate. The calculation of X, Y, Z at a new time, t, is obtained by:

$$\begin{aligned} X &= X_o + \left(\dot{Y} \cdot Z_o - \dot{Z} \cdot Y_o\right)(t - t_o) \\ Y &= Y_o + \left(\dot{Z} \cdot X_o - \dot{X} \cdot Z_o\right)(t - t_o) \\ Z &= Z_o + \left(\dot{X} \cdot Y_o - \dot{Y} \cdot X_o\right)(t - t_o) \end{aligned} \tag{3.17}$$

where the Cartesian velocities $\dot{X}, \dot{Y}, \dot{Z}$ per plate for the AM0-2 model are given in Table 3.5. This is the formulation used in GEODYN II.

Table 3.5. AM0-2 Cartesian Plate Velocities
(degrees/MY)*

Plate	$\dot{X}$	$\dot{Y}$	$\dot{Z}$

4. Data Acquisition, Preparation and Processing

4.1 Laser System Description, Performance and Data Quality Control

Each laser tracking station consists of a variety of subsystems and instruments as illustrated in block form in Figure 4.1. The tracking system's laser and associated telescopes are aimed at a satellite using a target acquisition system which utilizes accurate orbit predictions. Laser pulses are emitted from the station, reflected by the target, and return to the receiving system where the pulses are detected and the elapsed travel time is measured. The detection system typically utilizes a predicted time-of-flight window (technically, a gated discriminator) to eliminate background noise in the returns, and uses filters tuned to the laser wavelength to further improve system sensitivity by rejecting undesired wavelengths. In many of the larger fixed systems, the transmitter optics are separate from the receiving optics, whereas the compact mounts of the transportable systems incorporate common transmit/receive paths. A separate timing system with good long-term stability is used to establish epoch time and is synchronized to a universal time standard using LORAN-C, the Global Positioning System (GPS) or a transportable atomic clock.

Much time and effort has been spent in developing laser tracking systems that minimize the effects from error sources and maximize output efficiency and ease of operation. Throughout the developmental process, all associated subsystems have been thoroughly scrutinized to guarantee successful operation and to insure that the goals set out by the CDP would be achieved. A detailed account of laser system development and the considerations and decisions made regarding the design or selection of each component is found in *Degnan* [1985]. A more recent account of the current (1991) status of the laser tracking system and its capabilities is found in *Murdoch and Decker* [1989]. Specific details on the designs and operations of many of the laser stations can be found in a variety of international laser ranging workshop proceedings. (Of recent note are proceedings from meetings held in 1986 at Antibes Juan-Les-Pins, France, [*Gaignebet and Baumont* , 1986] and in 1989 at Matera, Italy, [*Veillet* , 1990]).

4.1.1 *Laser Ranges, Corrections, and Calibration*

Knowledge regarding the entire ranging system, its relationship to fixed ground points, and certain satellite characteristics are required in order to link the measurements to ongoing

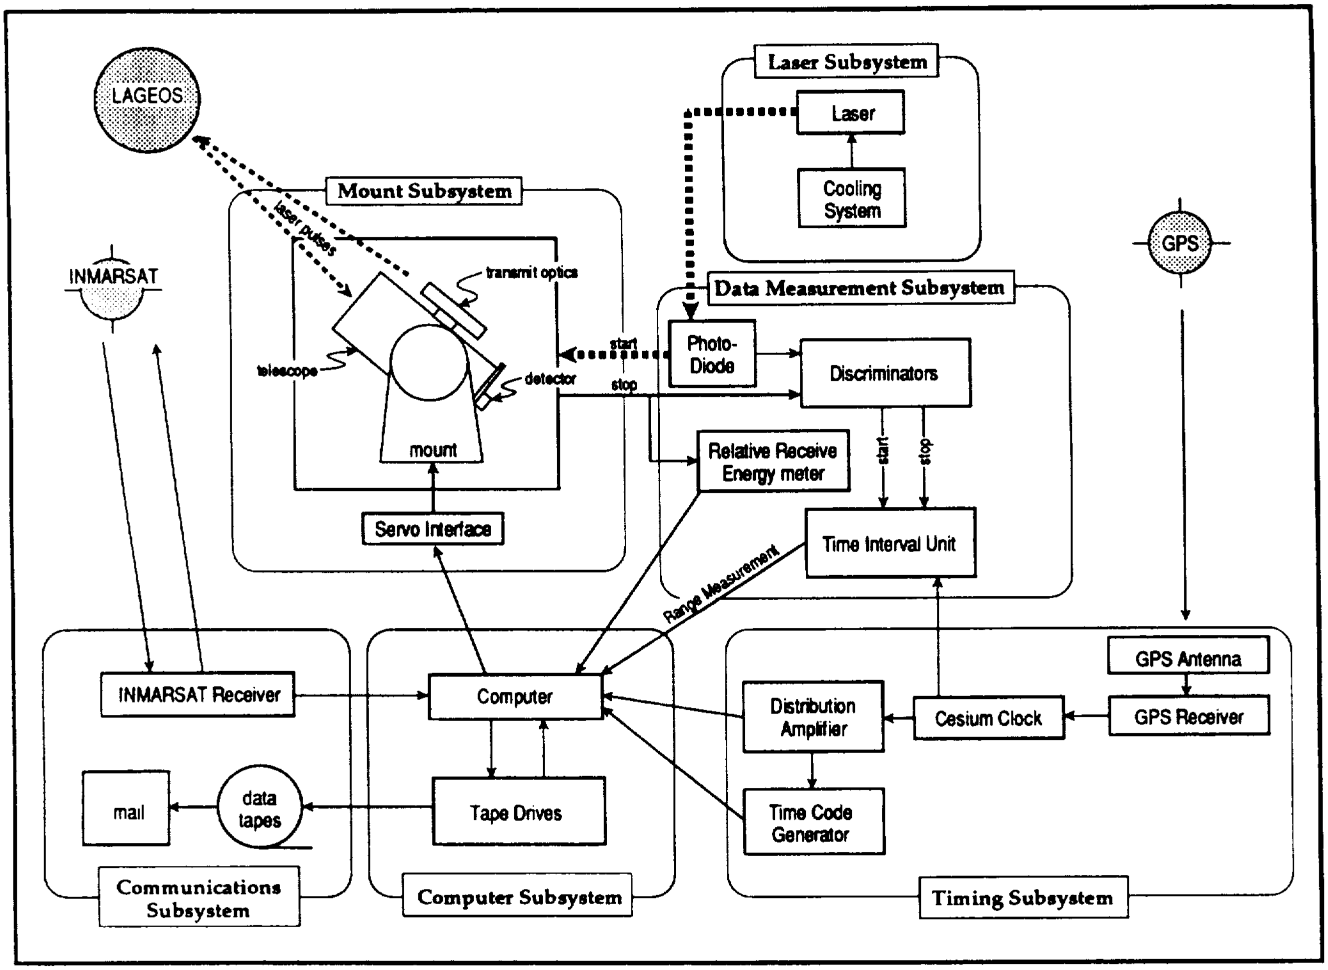

Figure 4.1 Laser tracking system block diagram (modified from *Murdoch and Decker* [1989]).

geophysical and tectonic processes. This knowledge constitutes the range measurement model and through calibration procedures we are able to confidently analyze and interpret the results. In this section we will summarize the elements which form and influence the laser range observations to LAGEOS.

The laser generates pulses of monochromatic, coherent light at repetition rates ranging from a few pulses per minute to 10 pulses per second (pps), and at power levels between 5 mJ and 1.5 J. The *range* between the station and the satellite is taken to be one-half of the product of the round-trip transit time of the laser pulse with the speed of light. The time tag of the measurement must be corrected to satellite reception time, taking into account the transit time of the pulse to reach the satellite (~20 msec for LAGEOS). Each range observation is corrected for the effects of atmospheric refraction with the Marini/Murray algorithm [*Marini and Murray*, 1973], which is based on locally measured meteorological readings taken coincidentally with the laser data at the tracking site. A correction for the offset of the satellite retroreflector from the center of mass of the spacecraft is also made which amounts to 24 cm for LAGEOS [*Fitzmaurice et al.*, 1977]. The fixed laser systems rest firmly on concrete pillars where, in many cases, the measurement reference point is defined by the optical center of the system and, except for instances of equipment upgrades, are considered to be invariant reference points. The mobile systems normally are parked and leveled on concrete pads and surveys are performed during each occupation to locate the optical center of the instrument to a nearby brass marker embedded in concrete. These offsets are known as *site eccentricities* and are crucial in the monitoring of the site's motion across time. These eccentricity offsets are listed by station and time in Appendix 1. At the mobile sites, the SL7.1 solution for station positions refers to the location of these brass markers which are directly constrained through the eccentricity values to the location of the optical centers of the laser for each site occupation.

The stations are calibrated regularly during field operations by tracking targets placed either external to or within the optical system at a known distance. A battery of system-level accuracy checks is routinely performed to ensure that the instruments are working within their specifications, specific details of which can be found in *Degnan* [1985]. Range observations are therefore transmitted from each site with a minimum of error. Further quality control checks are performed at the analysis centers to identify blunders, systematic biases, and registration errors that may be embedded in the data. These aspects are described in Section 4.1.4.

4.1.2 *Collocation Testing*

Each laser tracking system fielded by NASA undergoes a calibration against a fixed standard before it is deployed. The calibration compares, in a side-by-side or collocated fashion, the range measurements and the meteorological observations taken by the independent laser systems. These tests provide the opportunity to identify laser system range biases and to isolate system-dependent systematic error sources. Occasionally, collocation tests are conducted in the field, utilizing a mobile system which has, in turn, been collocated with the fixed standard (typically MOBLAS-7 at Greenbelt, MD). A list of collocation tests is given in Table 4.1, showing the names of systems compared. By regularly conducting these calibration experiments anomalous system behavior can be identified and accuracy at the specified level can be assured.

* GORF: Goddard Optical Research Facility, Greenbelt, MD.

Typically, a collocation test involves a series of procedures and system check-outs. Strict control of the hardware and software set-up, or configuration, throughout the collocation experiment is required to ensure that the results will accurately describe unforeseen system discrepancies. Both systems in the collocation test go through a series of ground tests and satellite ranging tests. The ground tests check system stability parameters by measuring system delays and determining the delays due to any azimuthal and elevation dependence. For the TLRS-1 and MOBLAS-7 systems, these delays should meet a 20-mm performance goal. Both systems were shown to have easily achieved these goals in 1987 with the actual performance being measured at the 4 - 5 mm level [*Husson et al.* 1987]. In the satellite tests, the systems are run in two modes; calibration mode having a performance goal of 20 mm and satellite ranging mode having a performance goal of 30 mm. Again, TLRS-1 and MOBLAS-7 easily achieved these goals by a factor of 2 [*Husson et al.*, 1987]. Meteorological closure is assessed by differencing the meteorological data (e.g. temperature, humidity and barometric pressure) taken by each system during the course of the collocation. Typically these differences are quite small (e.g. < 1 mbar and < 1° C).

The chief assessment of system performance comes from an analysis of simultaneous laser tracking of geodetic satellites in a variety of categories; e.g. by quadrant, by ascending or descending passes, and in daylight passes. The analysis provides information from which detailed bias assessments can be made. These entail examining the data to determine the nature and extent of range biases, and their dependence on azimuth, range and elevation. For example, *Kolenkiewicz et al.* [1987] showed that between TLRS-1 and MOBLAS-7 a mean range bias of 2.7 ± 4.9 mm was measured based on 22 passes of simultaneous LAGEOS tracking.

4.1.3 *System Improvement Milestones*

The systems which were originally built and operated by the Smithsonian Astrophysical Observatory (SAO) underwent their upgrade programs simultaneously (M. Pearlman, private communication). At the time that LAGEOS was launched in May 1976, these stations, situated at Mount Hopkins, Arizona; Arequipa, Peru; Orroral, Australia; and Natal, Brazil were equipped with time digitizers which yielded range observations at a noise level of approximately one meter. Pulse choppers installed in 1978 narrowed the effective pulse length from 25 nanoseconds to 6 nanoseconds, producing a noise level improvement to about 30 cm. Improved shutters were installed in 1980 which further reduced the noise level to 15 cm for a transmitted signal of 3 nanoseconds, and analog detectors were introduced to handle an increased repetition rate from 15 per minute to 30 per minute.

Goddard Space Flight Center fielded a series of five similar laser systems in late 1979 to supplement the three different systems in operation at that time. After temporary deployment, these mobile laser systems settled at Monument Peak, California (MOBLAS-4); Yaragadee, Australia (5); Mazatlan, Mexico (6); Greenbelt, Maryland (7); and Quincy, California (8). The short-pulsed Quantel laser which was implemented in the systems at these locations was modified between 1982 and 1983 to increase the repetition rate from one pulse per second to 5 pps. In 1985 and 1986 the noise level of the systems was reduced from 2 or 3 cm through the installation of a high resolution photomultiplier (micro-channel plate), together with a low noise discriminator. The current noise level for LAGEOS observations taken by each system is for MOBLAS-4: 11 mm, MOBLAS-5: 9 mm, MOBLAS-6: 8 mm, MOBLAS-7: 8 mm and MOBLAS-8: 8 mm.

4.1.4 *Data Quality Control and Estimation of System Biases*

The control of the laser measurement quality is first exercised during the compression of the observations to normal points (details of which are described in Section 4.2). In the orbital fit to the full-rate data, only observations which fall within a 3-m residual window are considered for further analysis. The normal point generation step subsequently eliminates outliers that exceed three times the rms residual about a polynomial fitted to each pass. The normal points themselves are used in the final stage of data quality control. They are fitted to an orbit and their residuals are inspected for unusually high noise and for any systematic bias. Observations failing this quality control step are excluded from the final reduction of the data in which normal equations are generated.

A further quality control step can be taken during the geodetic analysis procedure. A subset global solution is made in which month-by-month range bias values for each station are estimated simultaneously with a single station position for the full mission lifetime. Stations providing concentrated observations over a long period of time can thus allow us to separate persistent systematic range errors from station position. Table 4.2 gives a list of stations exhibiting unusually high range bias estimates, which sometimes occur for only part of the station occupation. The full history of range bias values for the stronger stations is presented in Figures 4.2(a - o).

4.1.5 *Data Catalogs*

The results of the data quality control process are given in Appendix 2 which provides a summary of station characteristics for every monthly arc in which its observations were included. The number of observations, range RMS statistics, bias estimate and the number of passes available for each month are listed for each station. The nature of any corrections to the data used in the SL7.1 solution are listed in Table 4.3, and are the result of confirmed and correctable station anomalies, most of which were trapped by the data quality control procedure at an early stage.

Table 4.2. Stations Showing Significant Range Bias

Station	Number	Data Span (Partial Occupation)	Bias (cm)
McDonald	7086	(8506-8712)	-4 ± 3

*ΔT: correction to a timing error. ΔR: correction to a range error.

4.2 Normal Point Processing

In order to efficiently utilize available computer resources, satellite laser ranging (SLR) data to the LAGEOS satellite have been compressed into *normal points*. Recently the SLR data has become so numerous, with current data rates of 1 to 10 points per second and almost thirty systems tracking worldwide, that an aggregation method has become desirable to avoid excessive costs in the analysis of the data. For a satellite such as LAGEOS, which is orbiting at nearly an earth's radius in altitude, the temporal density of information provided by the full rate data is approximately two orders of magnitude greater than that which is needed to fully monitor the perturbed motion of this satellite. While large data sets of independent observations reduce the influence of data noise on the calculated orbit, experience has shown that data noise is not a dominant error source for dynamic orbit modeling applications of these data. Statistical methods can be used applying the full data density to estimate and then filter out the noise contribution to the observations. The SLR data is then compressed using temporal sampling based upon the presence of some minimum number of data points in the sampling interval. This entire process is known as forming laser normal points.

Other groups, such as *Hauck and Lelgemann* [1982] and *Masters et al.* [1983], have adopted methods to thin the data while at the same time reducing noise in the data set. *Masters et al.* [1983] used successive differences in the second time derivative of the range to edit the data and Chebyshev polynomial fits to short spans (150 sec) of the edited data to produce laser normal points. These procedures were designed to accomplish three major objectives: (1) outlying differences were used to edit anomalistic points, (2) the noise over these short spans was reduced by being averaged over the empirical function, and (3) filtered data, absent this noise, were produced. We have adopted similar procedures to accomplish these same objectives [*Torrence et al.*, 1984]. Our approach was adopted to address not only the formation of normal points but also to assist with the assessment of the systematic stability of the laser systems, and to assess their relative performance with respect to the other laser systems.

4.2.1 *Normal Point Formulation*

Measurements inherently contain random errors or noise. Ideally, the normal points associated with a given set of laser range observations are representative of the same observations free from noise, i.e., the observations which would have been made if the measurement process were noise free. The normal point procedure is not designed to eliminate systematic errors in the data; such analysis normally requires an aggregate fit to the data from many tracking systems in an orbital reduction.

The observed laser range at time t may be expressed as

$$R_o(t) = R(t) + \varepsilon(t) \tag{4.1}$$

where $R(t)$ is the true range and $\varepsilon(t)$ is the observational noise. Optimally, the noise is minimized by averaging sufficient observations at time t so that the expected contribution of the random error to the average is insignificant. (for example, 0.1 mm). However, there is only one measurement at each time t, so the method must rely on having observations taken at a rapid rate over a short period of time, Δt. There must be sufficient observations during Δt so that the expected noise contribution is insignificant. It is also critical for the unmodeled signal in the observation during this Δt to have an insignificant contribution before forming a normal point.

Because the noise removal must be performed over a non-zero time span, the method requires the concept of an observation model and a noise model. The computed range to the satellite at any time $R_c(t)$, is the result of known modelable physical processes, as is done in GEODYN II. These models are capable of representing a range at all times within a pass, not just at the times of the observations, to the same general level of accuracy: it is deterministic, yielding a misclosure of observed vs. computed range on LAGEOS at the sub-decimeter level. While there are errors in our modeling of the "true" range, the model of the evolution of the range in time is correct for the first seven or so significant figures. This error in $R_c(t)$ is given by:

$$\delta R(t) = R(t) + \varepsilon(t) - R_c(t) \tag{4.2}$$

Note that $R(t)$ is the true noiseless range or the "normal" point range which is to be obtained.

Given a process for estimating $R(t)$, normal points can be produced for each observation time. This is a very dense set, with observations occurring far more often than is required to sense the physical phenomena influencing the satellite's orbit. Therefore, along with normal point creation (noise removal), the data are thinned. This desirable decimation is made by just selecting the observation closest in time to the $\Delta t/2$ point, which is the bin midpoint, and forming a normal point with this observation. This, in practice, also yields a uniform distribution of points across each pass.

Several considerations are involved in constructing normal points. First, the expected range as a function of time must be characterized. Through knowledge of the characteristics of the forces acting on a satellite, a "sampling" interval (bin) is determined which permits the reconstruction of all known "true" physical signals in the observed ranges from the thinned normal points. It is necessary to consider the behavior of δR within each bin. The spectra of δR must be known at short period (i.e., the bin width), to leave uncorrupted all meaningful longer periods from unmodeled orbit errors and modeled orbit effects. Harmonic analyses of the force-model error perturbations on LAGEOS show no perturbation greater than a centimeter for periods of less than 5 minutes. A numerical analysis of the order of the orbit integrator and the integration step size available in GEODYN II reveals that a good combination is a twelfth-order integrator coupled with a 150-second step size. Through the consideration of the spectra of the orbit perturbations and the numerical accuracy of GEODYN II, the choice was made to use 2-minute bins for forming normal points.

The orbit errors are found to be modeled adequately by a low-degree polynomial over a pass of residuals and, except for the rarest cases, vary linearly within a properly selected bin width. This is a result of using an accurate R_c. Therefore, the normal point $R_N(t)$ is

$$R_N(t) \equiv R(t) = f(\delta R(t)) + R_c(t) \tag{4.3}$$

where $f(\delta R(t))$ is some empirical function over the pass and bin used to correct the calculated range for the error in our physical models. The coefficients for this function are obtained from the signal left in the range residuals over the pass coupled with piecewise linear fits to the remaining residuals in the bin. The adopted procedure does both in succession.

Therefore, the procedural steps utilized for forming normal points are:

1. GEODYN II, based on our best knowledge of the forces, etc. produces a set of residuals from 15 days worth of global range data. This orbit fit produces a set of range residuals, $\delta R(t)$, representing the misclosure between the observations and the mathematical model of the satellite ephemeris.

$$\delta R(t) = R_o(t) - R_c(t)$$

2. A polynomial, $g(t)$, is fit to the residuals of a pass of data

$$\delta R(t) = g(t) + \xi(t)$$

Each residual is thus characterized in terms of signal and noise. Note that $\delta R(t)$ is distinct from the noise $\xi(t)$ according to the sufficiency of $g(t)$ to absorb the unmodeled signal in the original fitting process – A low-degree polynomial fit to $\delta R(t)$ effectually removes any residual signal. The remaining residual, $\delta r(t)$ is then

$$\delta r(t) = \delta R(t) - g(t)$$

The mean residual in the bin is then calculated

$$\delta \overline{r}_b = \langle \delta r(t) + \xi(t) \rangle$$

3. The expression for the "noiseless range" is given as:

$$R_p(T) = g(T) + R_c(T)$$

where T is mid-point time in the pass measured in uniform 2-minute intervals.

4. The normal point at time T is then:

$$R_B(T) = g(T) + R_c(T) + \delta \overline{r}_b$$

where T is defined as in 3 above, and $\delta \overline{r}_b$ is the "bin" correction. However, to avoid any error in the interpolation of range to an arbitrary time, we select the true observation closest to the bin mid-point to produce a normal point:

$$R_N(t') = R_c(t') + g(t') + \delta \overline{r}_b$$

or alternatively as:

$$R_N(t') = R_o(t') - (\delta r(t) - \delta \overline{r}_b)$$

where t' is the time of an observation closest to the mean observation time within the bin.

In summary, the normal point noise at a specific point is estimated from the residual mean "signal" over the bin width. The noise error at this point is estimated and removed from the original range. Note also that the normal point is at the time of a real observation. An estimate of the noise from this observation to form a "normal point" at the most centrally located observation time within each bin is removed. This is repeated providing one normal point for each 2-minute tracking span.

4.2.2 *Verification of the GSFC Normal Point Computations*

The normal point computation procedure has been verified using a segment of LAGEOS full-rate data. These data were used to verify that the normal points preserve the information content of the full rate data for calculating the orbit and for the recovery of station coordinates.

Two tests were performed to assess the performance of the normal points. In the first test, a common orbit is used as a reference for the determination of tracking station coordinates. The results based on the full-rate observation set are compared to those obtained using the normal points. In the second test, the orbit computed from the normal points is compared to that using the full-rate data with all other models and geodetic parameters held to be constant in the two cases. The differences which are obtained are compared to the formal errors of the parameter recoveries.

When the normal points were utilized, they were given individual observation weights:

$$w = \frac{1}{\sqrt{n}} \text{ meters} \qquad (4.4)$$

where n is the number of full-rate points in the 2-minute bin used to compute the normal point. In contrast, each of the full-rate ranges was given a weight of 1 m. This preserved the data distribution variation as it is seen in the full-rate data.

Table 4.4 shows the difference obtained in a sampling of the adjusting orbit parameters. Shown is the difference in the inertial X position and velocity component, the along-track acceleration and the coefficient of solar radiation pressure for the normal point vs. full-rate orbit determination results. In each of the orbit parameters, the difference was insignificant

Table 4.4. Test of Orbit Adjustment: Four Stations, 3-Day Arc
Values shown are the difference between normal point and full-rate orbital solutions

ΔX (m)	$\Delta(X/t)$ (m/s)	Δ Accel 10^{-11} m/s^2	ΔC_r
0.004	-0.004	0.001	0.0000

when compared to the noise-only uncertainty obtained in the adjustment assuming 10-cm data noise.

Table 4.5 shows a comparison of the station adjustments obtained (taken with respect to the *a priori* coordinates used in the orbital arc) for the full rate vs. normal point determination. Again, the difference in the two adjustments is a small fraction of the noise-only uncertainty of the results. These tests confirm that the normal point process does not alter the fundamental geodetic signals contained within the full-rate ranging data.

Table 4.5. Test of Station Position Adjustment: Four Stations, 3-Day Arc
Values shown are from *a priori* for normal point and full-rate station coordinate solutions

	ΔX (m)	ΔY (m)	ΔZ (m)
Full rate data	-1.327	0.705	0.636
Normal point data	-1.358	0.727	0.652

5. Analysis of Estimated Parameters

5.1 Assessment of SL7.1 Solution Quality

Before presentation of the geodetic results from the SL7.1 solution, an appreciation of the quality of the solution across time is essential in order to assess the solution's strengths and its limitations. The amount of data entering into the solution as given by the number of LAGEOS normal points (1 normal point = 1 "observation" in the SL7.1 solution) is illustrated in Figure 5.1. It can be easily seen that a marked improvement in observational effort has been achieved during the history of LAGEOS tracking with an apparent seasonal variation in the number of normal points. Large troughs in the graph are probably associated with coincidental poor weather conditions across tracking stations as well as network-wide system upgrade programs (both fixed and mobile lasers) in which many sites experienced a considerable amount of down-time simultaneously (or lack of occupations for mobile sites – this was the case in 1986).

The monthly RMS orbital fit also provides a measure of solution quality for each of the monthly solutions and is shown in Figure 5.2. A dramatic improvement in solution quality is shown over the period of May 1976 to July 1989 whereby RMS orbital fits have dropped from ~30 cm to less than 5 cm. This improvement may not be entirely ascribable to system improvements since there appears to be some level of correlation between the number of normal points and the RMS fits as shown in Figure 5.3. It is well known in least-squares theory that as the number of observations increases, the solution uncertainties will decrease. However, in this case, system improvements most likely account for both the increased number of normal points (a measure of system reliability and more progressive measurement schedules) as well as lower RMS orbital fits as can be seen by distinguishing between pre-1980 data and post-1979 data. Since an obvious temporal grouping can be seen, we conclude that system improvements are more likely the cause for improved RMS orbital fits. This is especially the case for months of relatively few normal point observations (<2000) where even though they lack observations, the overall RMS orbital fit remains in the 5- to 15-cm level.

The SL7.1 solution, as assessed by these general measures, is of significantly lesser quality before 1980. Therefore, some of the analyses of the estimated parameters will disregard these results obtained from these early years of tracking. Between early 1980 and mid 1986, improvement in solution quality was slow but consistent, improving at a rate of ~2 cm/yr, in

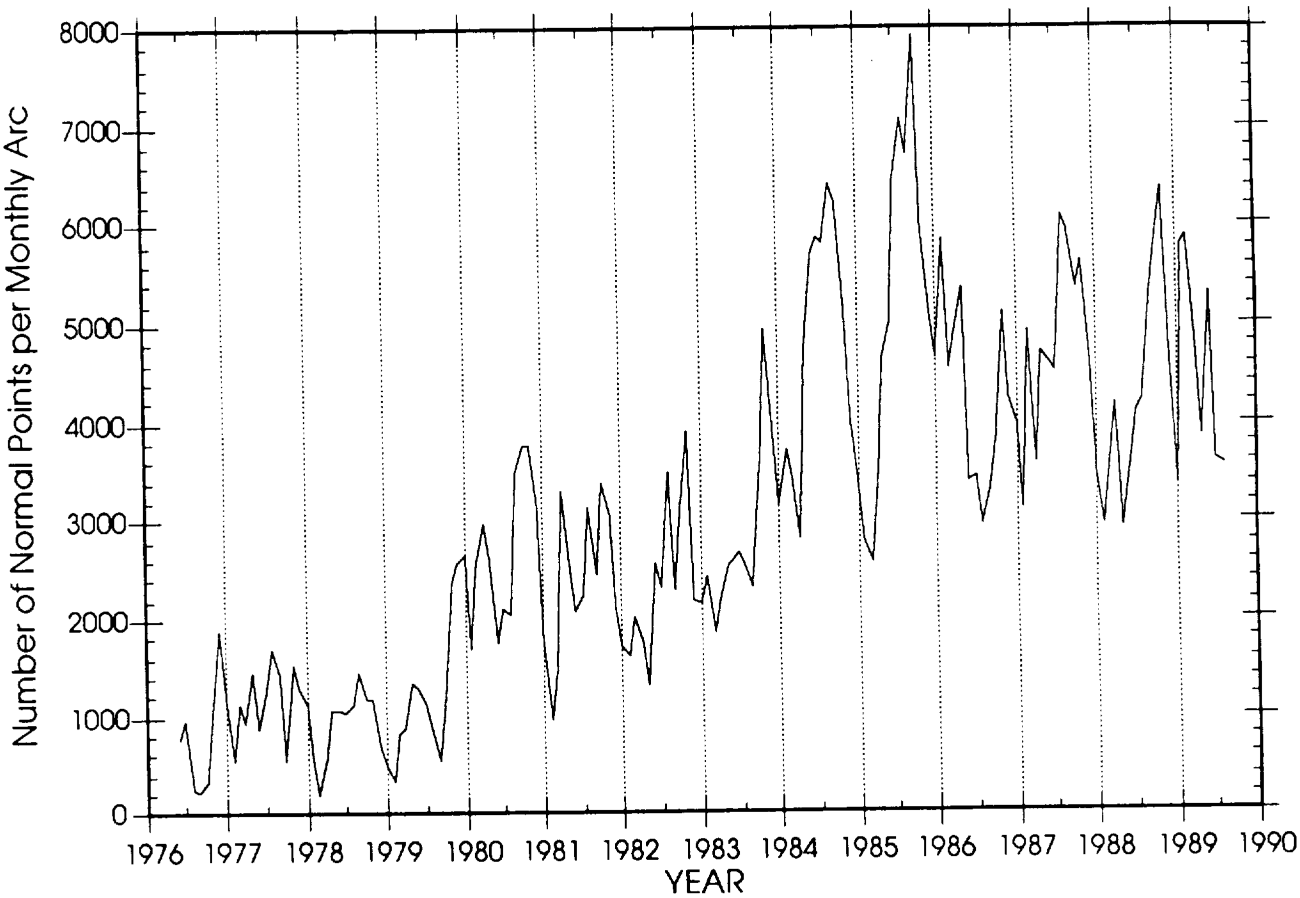

Figure 5.1 Number of monthly normal points utilized in the SL7.1 analysis.

terms of the RMS orbital fit. After 1986, the solution quality has remained rather constant at a level below 5 cm.

5.2 Non-Conservative Force Parameters: Estimation and Analysis

5.2.1 *Introduction*

In addition to the main products of the SL7.1 solution (i.e., station positions and Earth orientation parameters), other parameters related to the orbital environment of LAGEOS are also routinely estimated. These parameters (given in Appendix 3) provide useful information to characterize the evolutionary behavior of LAGEOS' orbit. Analyses of these parameters have proven to be useful in isolating remaining systematic behavior as well as providing information for theorists in their determination of physical models to further explain anomalous satellite behavior. In this section, the results and implications of these parameters are discussed and

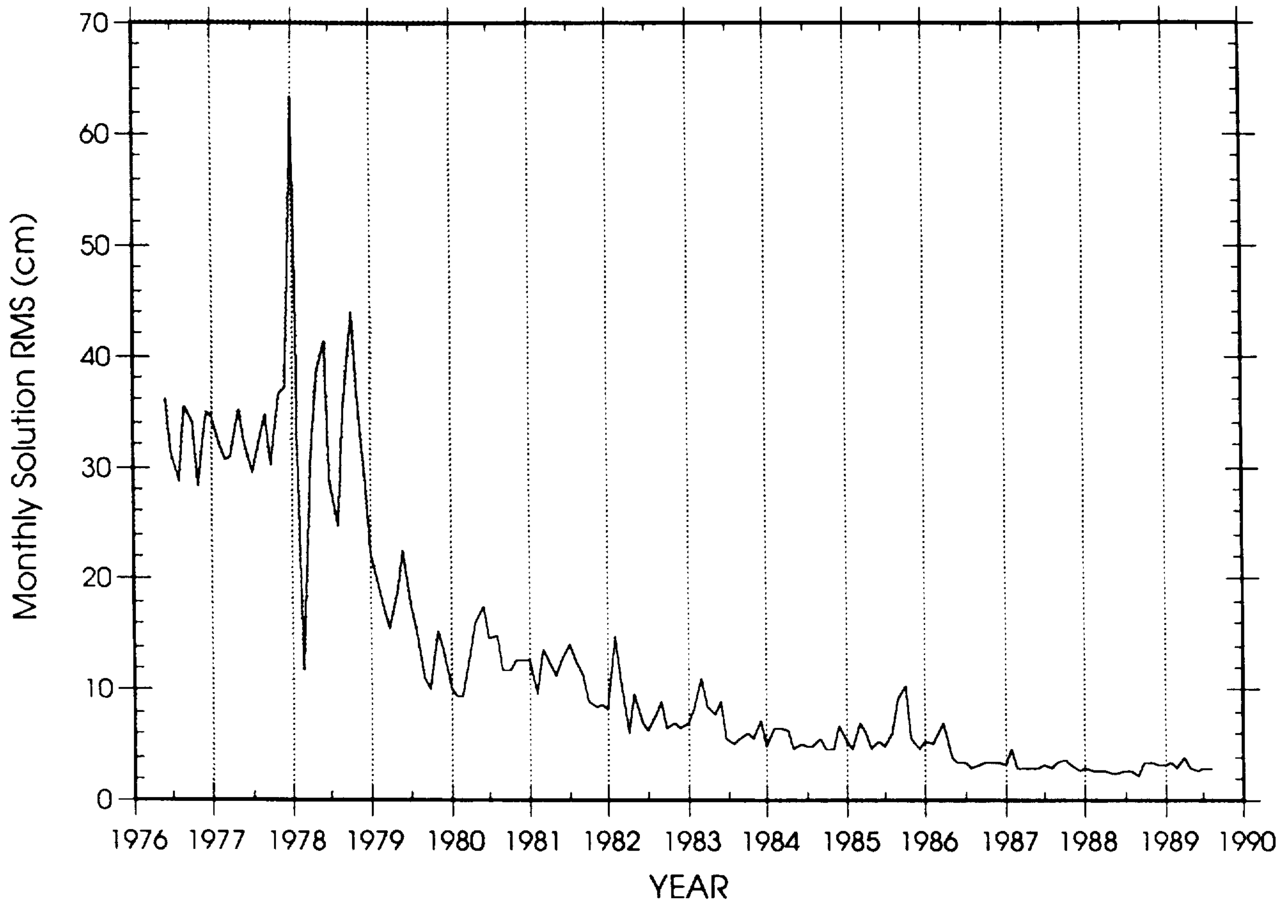

Figure 5.2 Monthly solution RMS orbital fits to LAGEOS. Only data taken after 1980 are used in subsequent spectral analyses of non-conservative force parameters due to the poorer orbital fits in earlier months (shown in the shaded region).

current theories and models are reviewed which, as of this writing, provide consistent explanations to describe a large portion of the systematic aspects that remain in LAGEOS' orbit.

The solar radiation pressure and along-track acceleration parameters are direct effects on LAGEOS which are estimated during the orbit estimation procedure. Fluctuations and trends in these parameters are due to unmodeled effects in the satellite environment which may be modelable or unmodelable, depending on the nature of the effect.

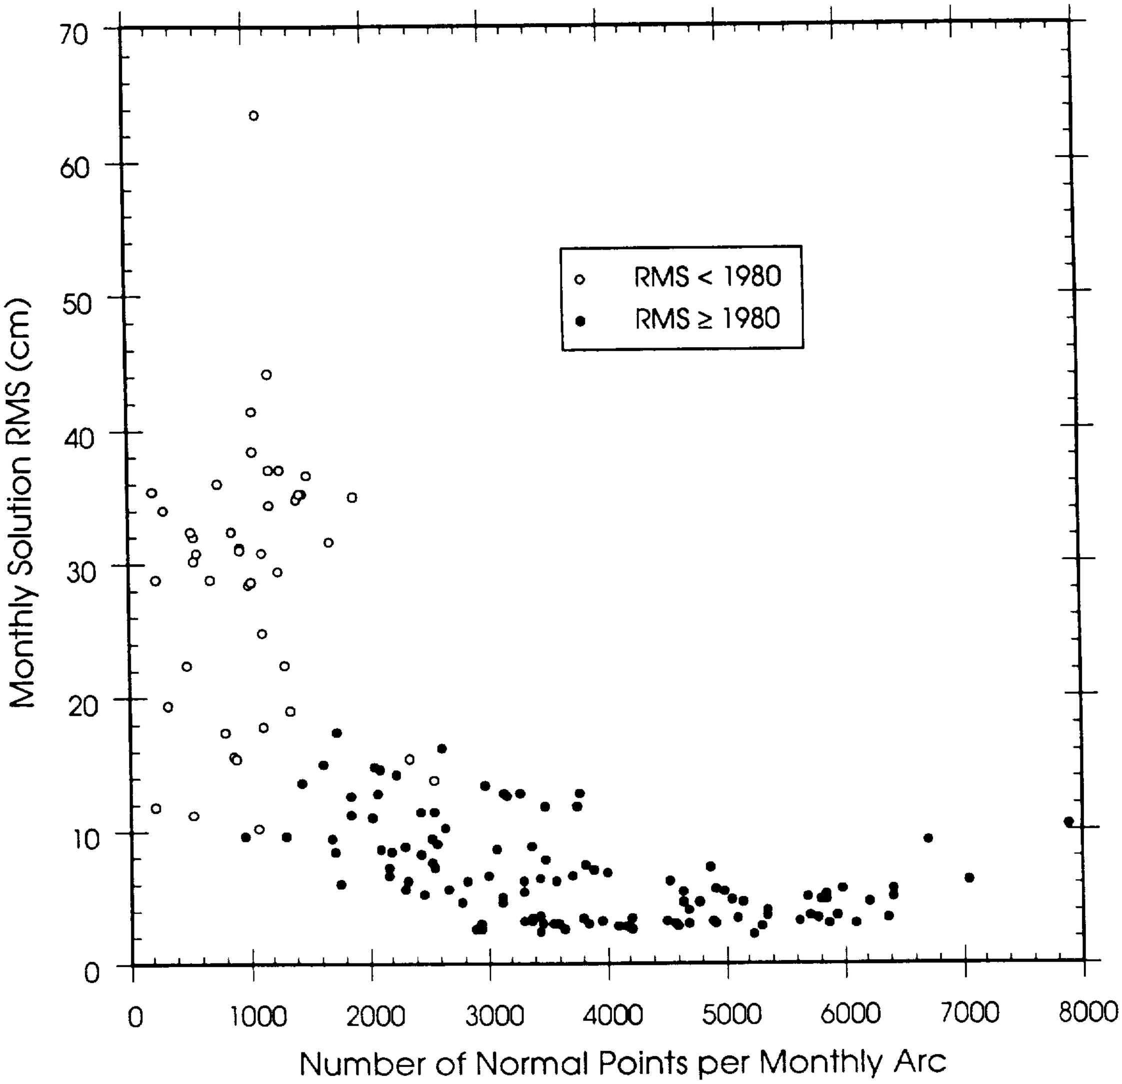

Figure 5.3 SL7.1 monthly solution RMS orbital fits correlated with the number of normal points. Open circles indicate arcs created with data acquired before 1980; blackened circles for arcs created with data acquired hence.

5.2.2 *Solar Radiation Pressure*

Bimonthly values for the solar radiation coefficient as shown by equation (3.12) have been recovered in each of the monthly solutions. The C_R parameter is estimated in these solutions because it has been shown that it helps reduce the overall solution RMS orbital fits by absorbing as yet unmodeled force parameters. By studying the variations in C_R , it may be possible to isolate remaining unmodeled phenomena.

Figure 5.4 presents the time evolution of the bimonthly recovered C_R parameters. LAGEOS' specular reflectivity coefficient ρ_s is quite small due to the brushed aluminum surface of the areas between corner cubes, therefore, C_R is not expected to be much larger than 1. In the figure, rather short-period variations occur primarily in the form of large dips of magnitude roughly 0.1 which appear to occur every 37 months. Interestingly enough, these correspond to the period of the node for LAGEOS.

The portion of the time series after 1979 has been spectrally analyzed producing the spectrum shown in Figure 5.5. The spectral decomposition is performed using a weighted least-squares spectral analysis algorithm of *Wells & Vanicek* [1978] where an average linear bias and slope have been removed. Significant peaks can be seen for periods of 1270 days and 550 days. Due to the broad character of the 1270-day peak, it is possible that this peak is associated with the nodal rate of 37 months (approximately 1120 days). The period at 550 days (nearly half of the nodal rate) also contains a considerable amount of power.

The implication of these results is that there remains some unmodeled force (or forces) which is in some way related to the nodal period. This variation in C_R is a variation in the non-conservative force directed outward from the Sun, and what we see is the least-squares accommodation of the unmodeled effect.

5.2.3 *Along-Track Acceleration*

The orbit of LAGEOS is perhaps the most accurately modeled of any artificial Earth-orbiting geodetic satellite. However, after modeling all of the known forces acting upon LAGEOS, there still remains a residual along-track acceleration that exhibits fluctuations and periodic behavior. Several investigators have reported on this residual acceleration with the general purpose of determining the phenomena that adequately explain the residual behavior, a review of which follows in the next section. By using the formulation explained in Section 3.3.2.1, bimonthly estimates of the along-track acceleration have been recovered in each of the monthly solutions.

The time series for the residual along-track acceleration is shown in Figure 5.6. It is immediately evident that the series is periodic in which a 37-month period is primary. The spectrum of the accelerations is illustrated in Figure 5.7 and exhibits similar character to that determined independently by *Barlier et al.* [1986]. As was the case for the solar radiation

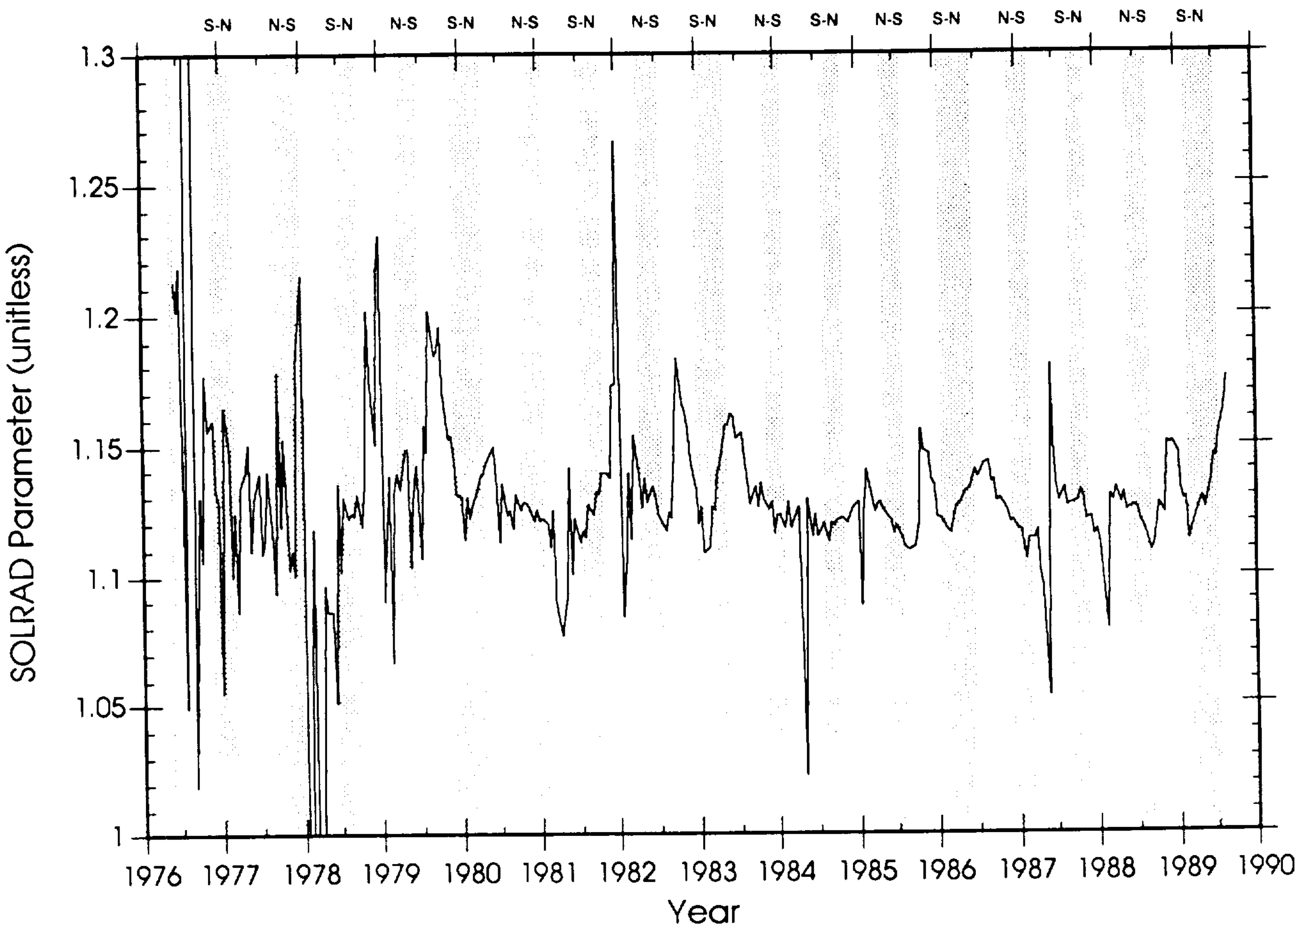

Figure 5.4 Time series of solar radiation pressure parameter (SOLRAD). The "N-S" and "S-N" refer to the orientation of the shadow entry and exit, respectively. Values estimated from 1980 onward were used in the subsequent spectral analysis.

pressure coefficient, two peaks dominate the spectrum. Again, the peak at 1060 days has a fairly broad character which is likely associated with the nodal period of 1120 days. The fact that the peak is skewed in the direction of the nodal period strengthens this conclusion. Again, the peak at 560 days (at half the nodal period) contains a considerable amount of power. The remaining spikes are most probably due to higher order harmonics (e.g., 280- and 140-day periods which correspond to multiples of the nodal frequency) and are probably influenced by the intrinsic noise of the data [*Barlier et al.*, 1986]. A comparison with the radiation pressure coefficient series reveals that the phase of the periodic signature of the along-track acceleration is orthogonal. The correlation diagram in Figure 5.8 shows this quite clearly. The cruciform shape seen in the diagram is a direct outcome of the orthogonal phase relationship. This relationship can be stated as follows: When the along-track acceleration undergoes an excursion away from its mean, the solar pressure coefficient remains at its mean and vice versa.

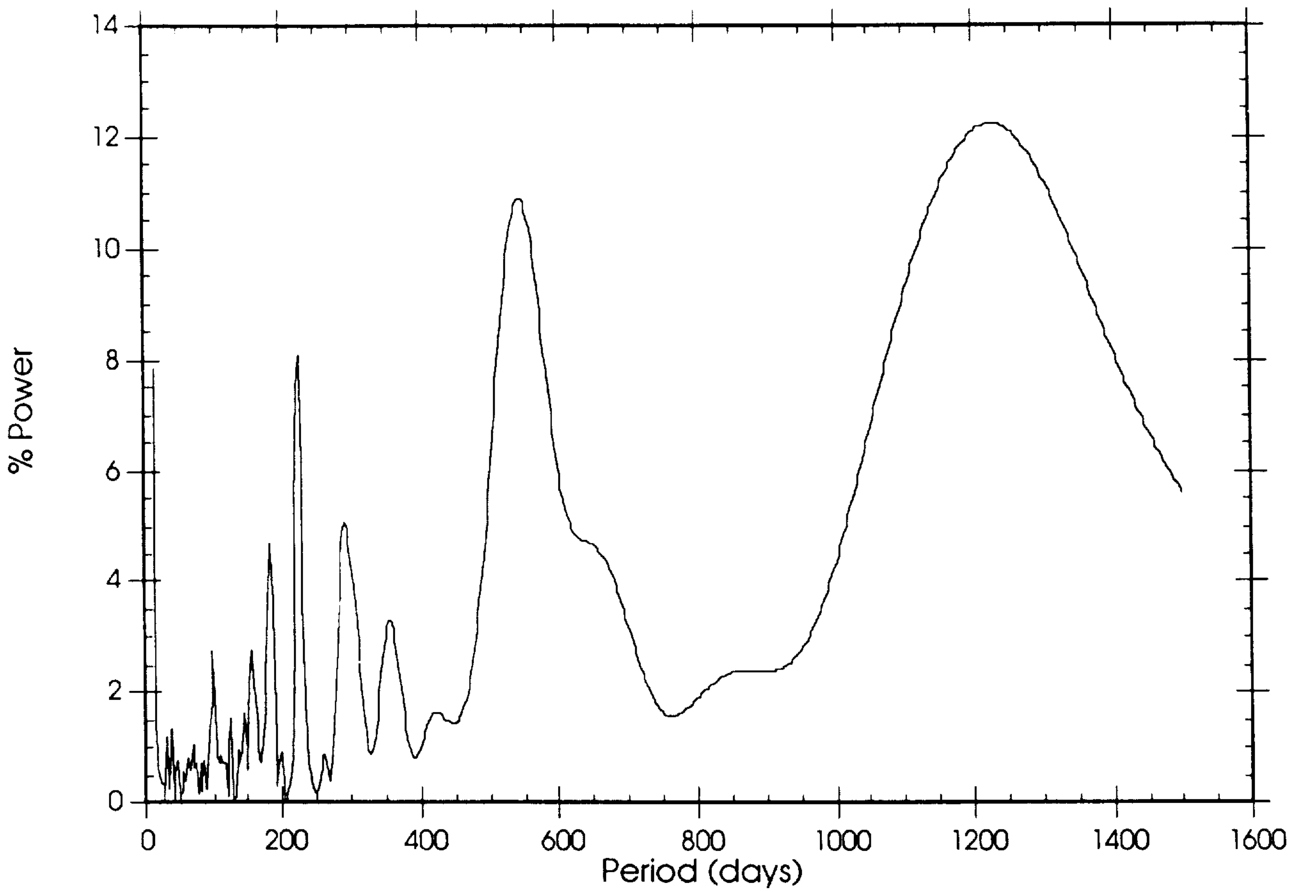

Figure 5.5 Spectral decomposition of the solar radiation pressure.

5.2.4 *Discussion*

From what has been shown, the parameters of the along-track accelerations and solar radiation pressure coefficients behave in a manner that is evidently correlated. Possible sources to explain the average and fluctuating portions of the along-track acceleration behavior were explored in the 1970s by many researchers; these were summarized in an early paper by *Rubincam* [1982]. Further refinements of these proposed models and better measurements to LAGEOS have brought a more complete description of the rather obscure non-conservative forces acting on LAGEOS. These improvements are summarized below.

5.2.4.1 Average Along-Track Acceleration

The average along-track acceleration of approximately -3.5 pms^{-2} was originally thought to be predominantly due to a combination of charged and neutral particle drag (e.g., *Afonso et al.* [1985] and earlier papers referenced therein). Neutral particle drag was shown to account for

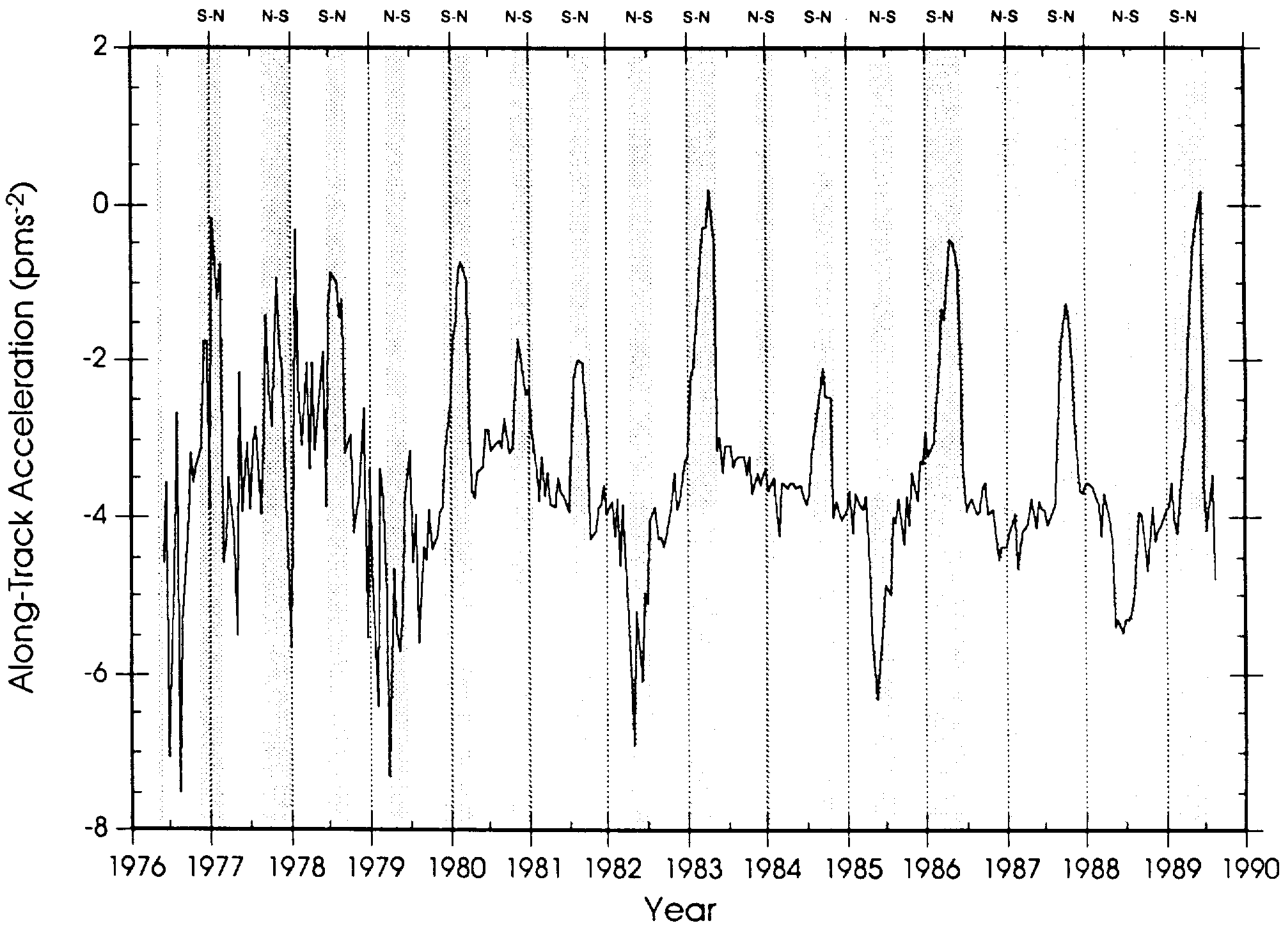

Figure 5.6 Time series of along-track acceleration as experienced by LAGEOS. The "N-S" and "S-N" refer to the orientation of the shadow entry and exit, respectively. Values estimated from 1980 onward were used in the subsequent spectral analysis.

only ~10% of the average along-track acceleration (*Rubincam* [1980] and *Afonso et al.* [1985]). A more recent analysis by *Rubincam* [1990a] indicates that neutral and charged-particle drag on LAGEOS are of similar magnitudes; -0.46 and -0.52 pms^{-2} for neutral and charged-particle drag respectively, accounting, in combination, for about 30% of the total along-track acceleration. In most models developed to date, it is typically assumed that these quantities are invariant, but, as pointed out by *Scharroo et al.* [1991], this is not completely true since it is well known that in the case of charged-particle drag, the drag from protons will vary slightly as the Sun/orbit geometry changes.

Rubincam [1987] proposed that the Yarkovsky thermal drag, or the asymmetric thermal response of LAGEOS upon Earth-emitted infrared radiation accounts for -3.33 pms^{-2} of the

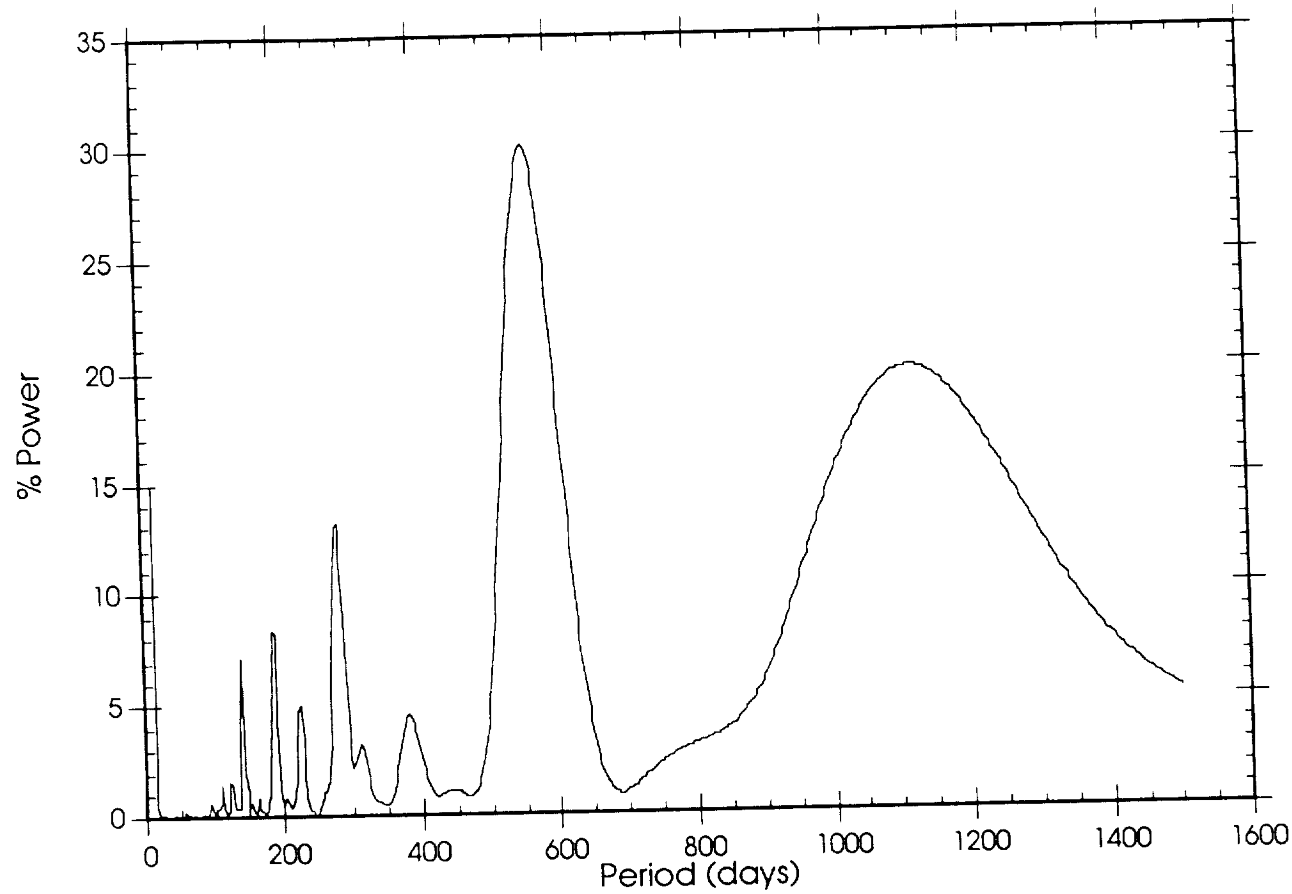

Figure 5.7 Spectral decomposition of the along-track acceleration.

average along-track acceleration observed to be occurring on LAGEOS. This value has since undergone some modification, largely due to refined considerations of the thermal behavior of the corner cubes on-board LAGEOS, to a generally accepted value of -3.08 pms^{-2} (*Rubincam* [1988] and *Scharroo et al.* [1991]). The Yarkovsky thermal drag is modeled through (*Rubincam* [1988])

$$S_{ytd} = \langle S_{max} \rangle [1 - s_z^2 + \frac{1}{2}(3s_z^2 - 1)\sin^2 I + s_z \sin 2I (s_y \cos\Omega - s_x \sin\Omega)$$
$$+ \frac{1}{2}(s_x^2 - s_y^2)\sin^2 I \cos 2\Omega + s_x s_y \sin^2 I \sin 2\Omega] \qquad (5.1)$$

Where $\langle S_{max} \rangle$ = -3.08 pms^{-2}, I is the inclination of the orbit, Ω is the right ascension of the ascending node (a function of time, given by $\Omega = \Omega_o + \dot{\Omega}(t - t_o)$ where $\dot{\Omega}$ is the rate of change of the ascending node and Ω_o is the epoch position of the ascending node at time t_o). The

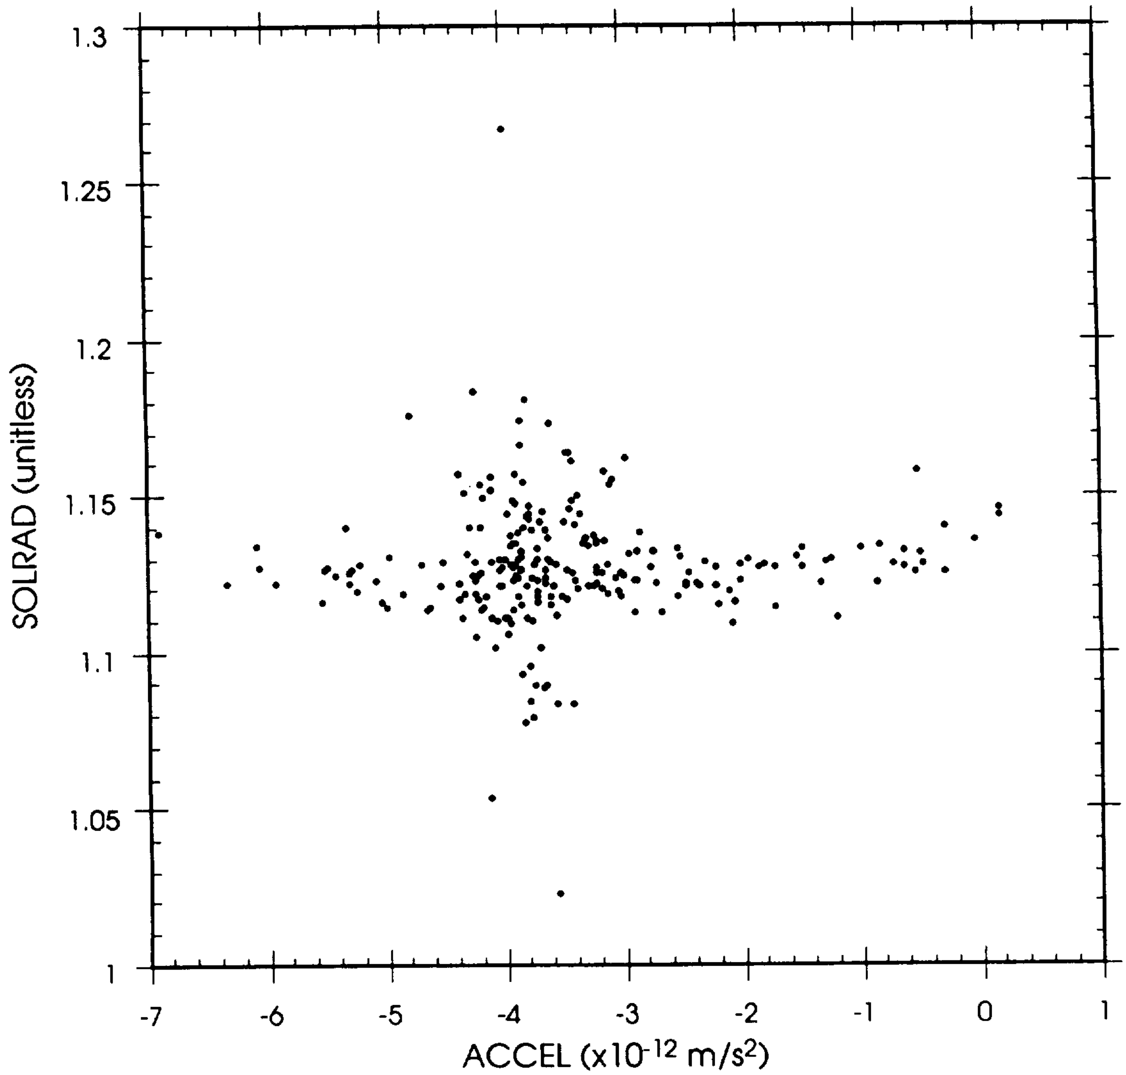

Figure 5.8 Correlation plot of SOLRAD vs. ACCEL.

s_x, s_y, s_z are the unit vector components of the spin axis of LAGEOS in an Earth-centered, celestial coordinate system, given by

$$\begin{aligned} s_x &= \sin\theta\cos\lambda \\ s_y &= \sin\theta\sin\lambda \\ s_z &= \cos\theta \end{aligned} \tag{5.2}$$

where θ and λ are the co-latitude and right ascension of the direction of LAGEOS' spin axis. Originally, the angle θ was thought to be constant at ~22° with respect to the Earth's spin axis, but recently, assessments of magnetic and gravitational torques have shown that LAGEOS' spin axis has been changing as a function of time [*Rubincam*, 1990a]. In the work by *Scharroo et al.* [1991], they have made the assumption that the spin axis of LAGEOS is slowly aligning itself to the Earth's spin axis due to the magnetic torque experienced by LAGEOS' passage through the Earth's magnetic field. This has the effect of reducing the amplitude of the variation of the modeled effect. More recently, *Bertotti and Iess* [1991] have proposed that as the spin axis of LAGEOS comes into close alignment with the Earth's spin axis, gravitational torques will predominate over the forcing of the satellite's spin axis, sending LAGEOS into a chaotic tumbling state of spin. Their prediction is that LAGEOS will reach this chaotic state sometime in late-1991 or in 1992.

For the purposes of discussion here, the exponential progression of the alignment of LAGEOS' spin axis towards the Earth's spin axis has been adopted in a manner similar to that described by *Scharroo et al.* [1991] whereby the spin axis co-latitude decreases by 50% every 6 years; a value which has also been determined empirically by *Ries* [1991]. The combined effects of the Yarkovsky thermal drag and neutral and charged-particle drag are shown superimposed on the observed along-track acceleration in Figure 5.9a with the residual along-track acceleration after removing these effects being shown in Figure 5.9b. With the removal of the average along-track acceleration, the residual acceleration is now centered about zero but still contains excursions (or spikes) from the mean for which explanations have been proposed—discussed in the next paragraphs.

5.2.4.2 Along-Track Acceleration Spikes

Much effort has been spent by several researchers to understand the excursions that had been seen in the along-track acceleration parameter recovered from LAGEOS orbital analyses. Recently, *Scharroo et al.* [1991] have offered two models which reproduce the data remarkably well, at least for the time span from which their analysis was made as the prediction capability of their proposed algorithm appears to degrade after 1989.

The first model was put forth in detail by *Rubincam et al.* [1987] in which it was suggested that an asymmetry of the reflectivity of the satellite might cause the observed excursions in the along-track acceleration parameters. It has further been shown that even small differences in hemispheric reflectivity of LAGEOS could cause a portion of the observed spikes. The model is somewhat controversial because little pre-flight evidence exists that would indicate a variation in albedo on LAGEOS. The surface of the satellite was presumably manufactured in a uniform way and ground tests made on LAGEOS II indicate less than 2% hemispheric

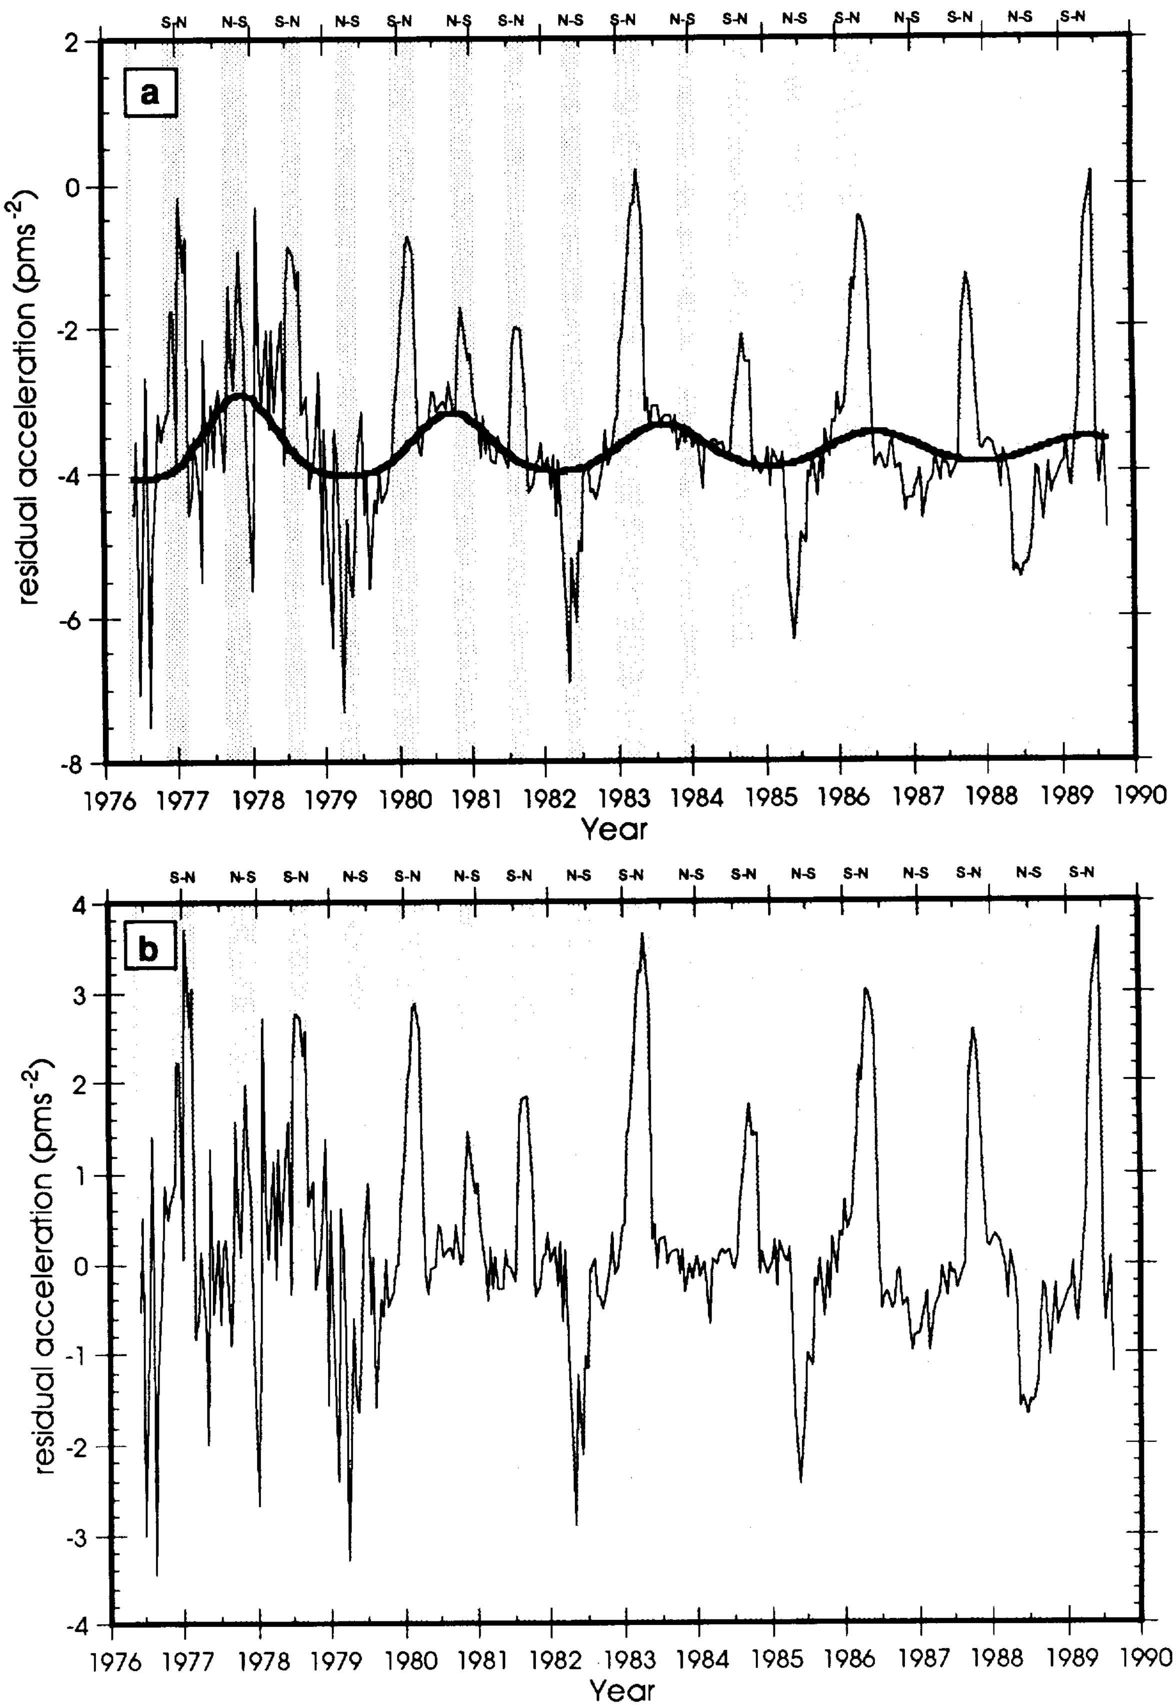

Figure 5.9 (a) Theoretical Yarkovsky thermal drag on LAGEOS shown (heavy line) superimposed on the total along-track acceleration determined by the SL7.1 analysis. (b) Residual along-track acceleration after removal of the Yarkovsky Thermal drag.

variation in reflectivity (*Rubincam*, [1990b]). Nonetheless, *Scharroo et al.* [1991] maintain that a hemispheric reflectivity variation of only 5% adequately explains the observed behavior, the source of which remains an intriguing mystery.

Anisotropic reflection of sunlight, assuming anisotropy exists on the satellite, will cause a recoil in the direction of the region or zone having the lower albedo, since fewer solar photons will rebound in this region. For a satellite having hemispheric variation in albedo and in the course of an orbit, this effect will largely cancel out if the satellite's orientation remains reasonably fixed in inertial space and if the orbit remains in full sunlight. When a portion of the orbit passes through the Earth's shadow, the recoil ceases, thereby causing an apparent force to act on the satellite and giving a net result which has all the appearances as that of an acceleration. Whether the effect takes form as a positive or negative acceleration is strictly a function of which satellite hemisphere enters the shadow zone first. The model takes a relatively simple form as outlined in *Rubincam et al.* [1987] and *Scharroo et al.* [1991]. (The formulation below is from the latter.)

$$S_{ani} = \frac{1}{2\pi} \ddot{s}_{\max}(A_1 - A_2)\sin^2\theta_r \qquad (5.3)$$

where $\ddot{s}_{\max} = -12.1 \text{ pms}^{-2}$, θ_r is the angle between the spin axis of LAGEOS and the Sun, A_1 and A_2 are LAGEOS' unit spin vector mapped onto the direction of the satellite radius vector from the Earth's center at moment (1) when the satellite enters the Earth's shadow and at moment (2) when the satellite exits the Earth's shadow. Once again, the spin axis of LAGEOS is assumed in this work, to be slowly re-aligning itself with the Earth's spin axis.

The second effect proposed by *Rubincam* [1982] and developed later in detail by several investigators is known as the Yarkovsky-Schach effect. This effect shares similar concepts with both the Yarkovsky Thermal Drag model and the anisotropic reflectivity models already mentioned. The Yarkovsky-Schach effect is again a consequence of photon thrust, but in this case we are concerned with solar-produced photons. The effect is similar to the anisotropic reflectivity model in the sense that both are due to the thrust (or recoil) ceasing during the time LAGEOS spends in the Earth's shadow. Again, borrowing from the derivation given in *Scharroo et al.* [1991], the Yarkovsky-Schach model is formulated as

$$S_{yse} = \ddot{s}_{\max} \frac{(A_1 - A_2) + u_o(B_1 - B_2)}{2\pi(1 + u_o^2)} \cos\theta_r \qquad (5.4)$$

where all values are defined as before with the exception that $\ddot{s}_{max}$ = -89.4 pms^{-2} , u_o = 1.45 rad, a constant expressing the thermal response time of a retroreflector, and B_1 and B_2 are like A_1 and A_2 except now the unit spin vector is mapped onto the along-track direction of the satellite at entry and exit points as the orbit passes through the Earth's shadow.

The sum of the anisotropic reflectivity and the Yarkovsky-Schach effects is shown in Figure 5.10a. The residual acceleration is fairly well modeled by these two effects, but some residual spikes can be seen in Figure 5.10b which seem to exhibit some amount of systematic behavior.

5.2.4.3 Along-Track Acceleration Modeling: Discussion

A substantial amount of the signal in the along-track acceleration can be accounted for by the combination of the four models; charged and neutral particle drag; Yarkovsky Thermal drag; anisotropic reflectivity of LAGEOS; and the Yarkovsky-Schach effect. With the exception of the charged and neutral particle drag, all models are dependent upon the direction of the spin axis of LAGEOS. Throughout the present discussion, it has been assumed that the spin axis is slowly realigning itself with the Earth's spin axis as suggested by *Scharroo et al.* [1991]. However, there is evidence that this simple behavior of the spin axis may not be entirely correct.

First, in carefully examining the behavior of the final residual acceleration (shown in Figure 5.10b), the amount of scatter seems to increase after early 1988. In follow-on GSFC solutions to SL7.1 and in the solution of *Ries* [1991], it has been noted that in early 1990, the along-track acceleration exhibits an unexpected positive excursion having an amplitude of ~2 pms^{-2}. The models, as presented here, fail to predict this spike which further raises questions regarding the orientation of LAGEOS' spin axis. If the prediction of *Bertotti and Iess* [1991] is valid, then it may be that the onset of a new spin axis dynamic, namely of a chaotic state, is the root cause of the 1990 spike. It is anticipated that if the spin axis begins to tumble in an uncontrolled fashion, the effects of the Yarkovsky thermal drag, the anisotropic reflectivity and Yarkovsky-Schach effect will be reduced, leaving approximately -1 pms^{-2} of along-track acceleration due to charged and neutral particle drag. In essence, the spiky nature of LAGEOS' along-track acceleration should be dramatically reduced as well as ~70% of the average along-track acceleration. The state of chaotic behavior is predicted to begin in late 1991 or 1992.

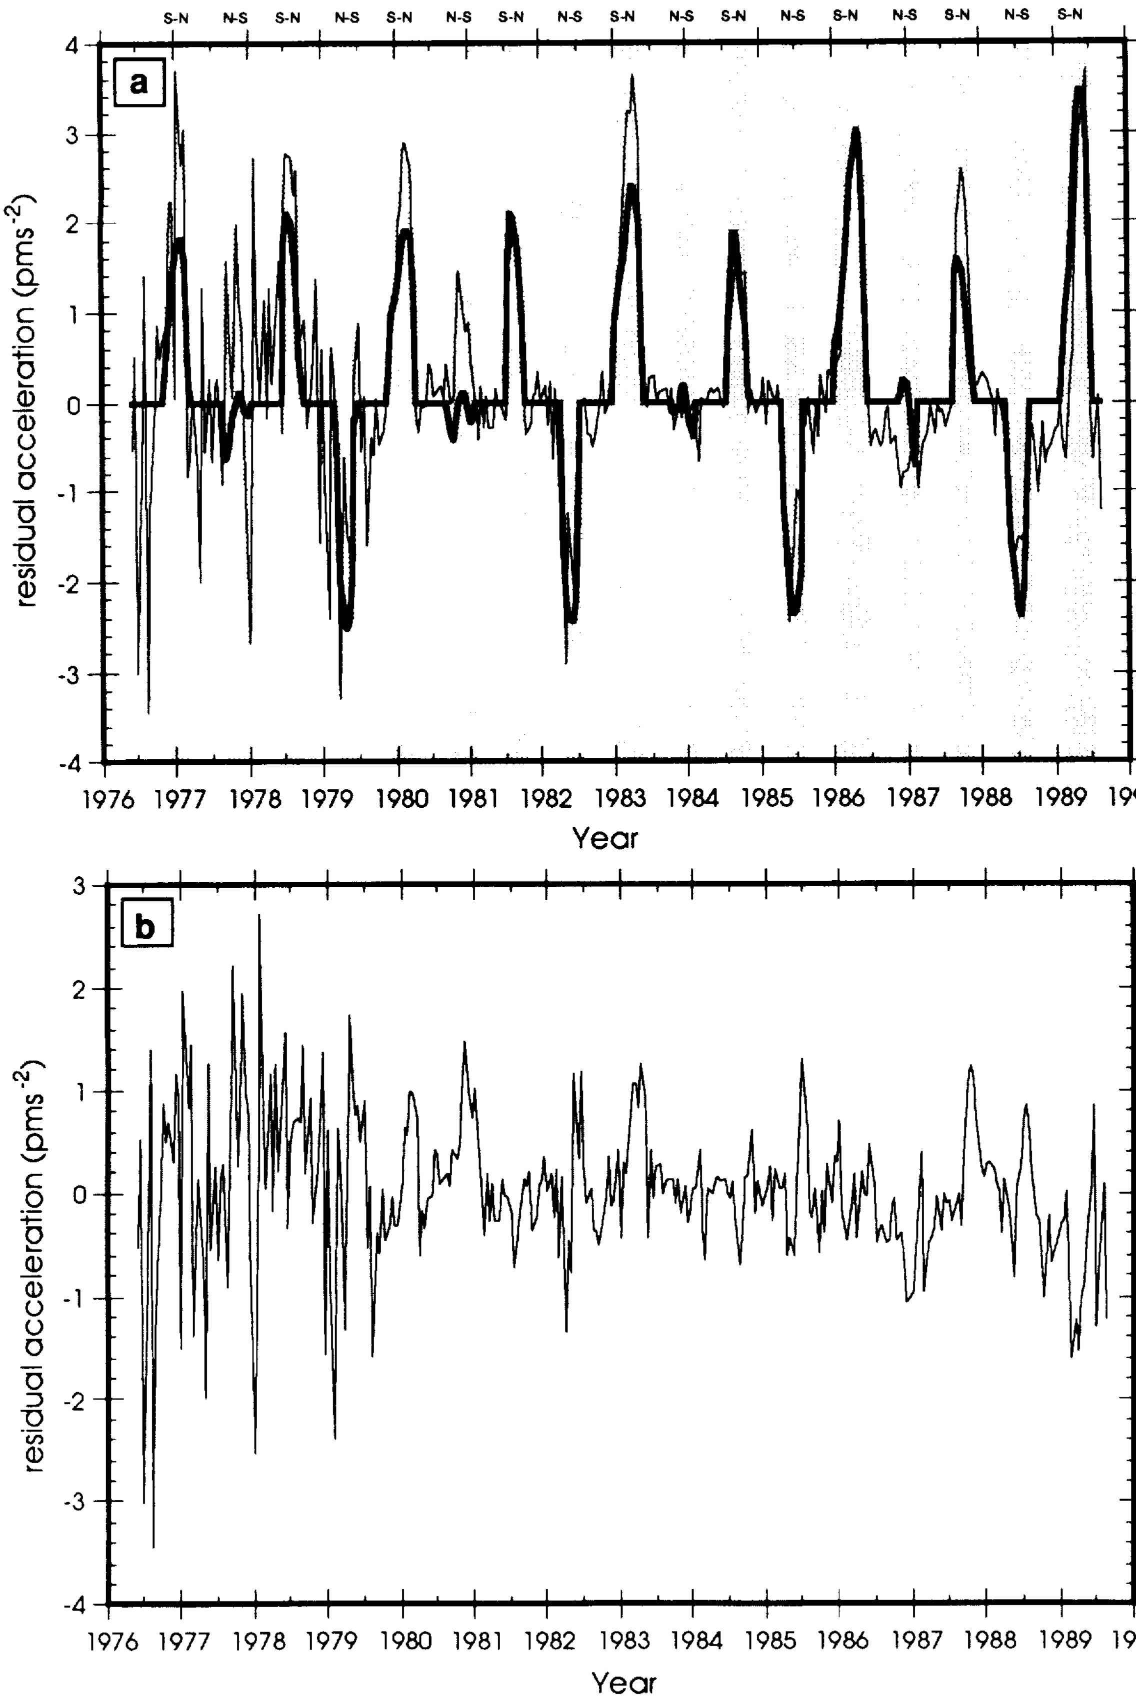

Figure 5.10 (a) Sum of theoretical anisotropic thermal response from Earth infrared radiation and Yarkovsky-Schach photon thrust (heavy line) superimposed on the residual acceleration shown in Figure 5.9b. (b) Residual acceleration after further removal of the anisotropic and Yarkovsky-Schach effects. In this chart, all proposed sources of acceleration variations have been removed.

Continued LAGEOS observations and analyses over this time period will clearly show whether or not the gravitational torque will become dominant, as expected by *Bertotti and Iess* [1991].

Finally, in Figure 5.11, the spectrum of the residual along-track acceleration (after 1979) is shown. Peaks at 885 and 140 days dominate the spectrum. The sources of the peaks remain unexplained. The lack of peaks at the nodal and half-nodal periods indicates that the models described here are effectively removing the signal at these periods.

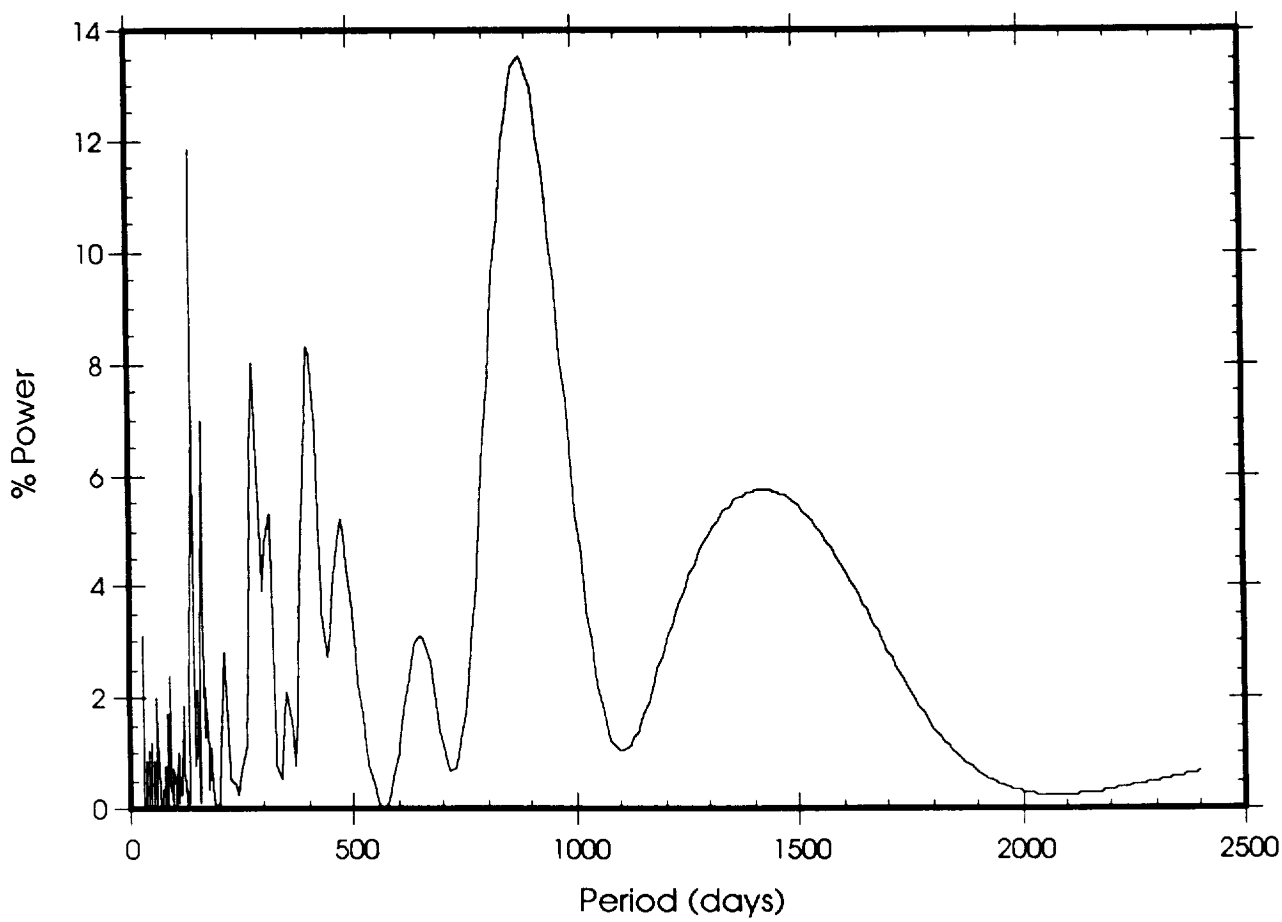

Figure 5.11 Spectral decomposition of the residual along-track acceleration after the effects of the four models have been removed. The five largest peaks are centered at 885, 140, 405, 283 and 163 days, respectively.

5.3 Orbit Evolution Studies

Analysis of LAGEOS' orbital evolution provides one means of assessing errors in the adopted models (gravitational, tidal, etc.) and errors entering into the solution from unmodeled sources. Several techniques have been devised to examine the long-term behavior of LAGEOS' orbital elements. In all of these techniques, it is desirable for the effects of the short-period variations to be minimized in order to understand the longer term fluctuations.

In our analysis, we have chosen to consider the Keplerian elements evaluated when the satellite arrives at a given position, rather than at a given time. Differences in the Kepler elements chosen in this manner from two differently computed osculating orbits reveal the long-period variations due to the different modeling. This enables the estimation of the Kepler element variations due to the errors in the adopted models. These variations must then be interpreted.

5.3.1 *Methodology*

The largest short-period perturbations are due to the Earth's oblateness (J_2). The effects of the Earth's oblateness on the Keplerian elements of a near-Earth satellite are given by *Merson* [1961]. Expressions for the departures δa, δe, δi, and $\delta\Omega$ from nodal conditions are presented in equations (35 - 38) from *Merson* [1961]:

$$\delta a = J_2 R^2 a^2 p^{-3}\left[(1 - e\cos v)^3(1 - 3fS^2) - (1 + e\cos\omega)^3\right] + O(J_2^2) \tag{5.5}$$

$$\begin{aligned}\delta e = 3J_2\left(\frac{R}{p}\right)^2 \Bigg[&\left(-\frac{1}{2}+\frac{f}{3}\right)\cos\omega - \frac{1}{4}e(1+\cos 2\omega) + \left(-\frac{1}{8}-\frac{f}{3}\right)e^2\cos\omega \\ &-\frac{1}{24}e^2\cos 3\omega - \frac{1}{2}feS^2 - \frac{3}{2}feS^2\cos^2 v + \frac{1}{2}e\cos^2 v \\ &+-\frac{1}{3}f(1-e^2)C\cos\omega + \frac{1}{2}\cos v - \left(\frac{7}{6}+\frac{1}{3}e^2\right)fS^2\cos v \\ &-\frac{1}{2}fe^2S^2\cos^3 v + \frac{1}{6}e^2\cos^3 v\Bigg] + O(J_2^2)\end{aligned} \tag{5.6}$$

$$\delta i = -3J_2\left(\frac{R}{p}\right)^2 \sin i\cos i\left[\frac{1}{2}S^2 + \frac{1}{3}e\cos\omega + \frac{1}{3}S^2 e\cos v - \frac{1}{3}Ce\cos\omega\right] + O(J_2^2) \tag{5.7}$$

$$\delta\Omega = -3J_2\left(\frac{R}{p}\right)^2 \cos i\left[\frac{u}{2} + \frac{2}{3}e\sin\omega - \frac{1}{2}SC + \frac{1}{3}S^2 e\sin\nu - \frac{2}{3}Ce\sin\omega\right] + O\left(J_2^2\right) \quad (5.8)$$

in which a, e, i, Ω, ω are the traditional Keplerian elements of the orbit and where:

J_2	$\approx 1.1 \times 10^{-3}$	u	$= \omega + \nu$
R	is the Earth's equatorial radius	S	$= \sin u$
p	$= a\left(1-e^2\right)$; the orbit's latus rectum	C	$= \cos u$

and f = $\sin^2 i$

By grouping terms that are scaled by e and its higher orders, equations (5.5) through (5.8) can be expressed as

$$\delta a = J_2 R^2 a^2 p^{-3}\left[-3fS^2 + e\Delta a\right] + O\left(J_2^2\right) \quad (5.9)$$

$$\delta e = 3J_2\left(\frac{R}{p}\right)^2\left[\left(-\frac{1}{2} + \frac{f}{3} - \frac{1}{2}fC\right)\cos\omega + \left(\frac{1}{2} - \frac{7}{6}f^2\right)\cos\nu + e\Delta e + O\left(e^2\right)\right] + O\left(J_2^2\right) \quad (5.10)$$

$$\delta i = -3J_2\left(\frac{R}{p}\right)^2 \sin i\cos i\left[\frac{1}{2}S^2 + e\Delta i\right] + O\left(J_2^2\right) \quad (5.11)$$

$$\delta\Omega = -3J_2\left(\frac{R}{p}\right)^2 \cos i\left[\frac{u}{2} + \frac{1}{2}SC + e\Delta\Omega\right] + O\left(J_2^2\right) \quad (5.12)$$

in which Δa, Δe, Δi, and $\Delta\Omega$ are functions of the arguments of the satellite's motion ($\omega + \nu$, which are rapidly changing during an orbit). Since e is small for LAGEOS, the major terms in each of the equations (5.9), (5.11) and (5.12) are only functions of the motion of the satellite projected on the Earth's surface and consequently contribute no variation in the differences of the elements when two differently computed osculating orbits are evaluated at the same argument of latitude (u). The eccentricity variation of equation (5.10) does not share this property, but, as it turns out, this element is affected by J_2 significantly less than are the other orbital elements.

As can be seen in the more general formulation of *Kaula* [1967] (equation 3.76), all of the short-period gravitational variations should similarly cancel. Using the same approach, it can also be shown that this is also approximately the case for third-body and non-conservative perturbations, especially if the satellite positions in the trajectories to be compared reach the same latitude at nearly the same time (i.e., the along-track difference between trajectories is not excessively large). The limitation of this approach is that the deviations in the mean orbits must not exceed the amounts describable by the first-order theory we have applied.

The elements of an orbit determined from a continuous data span (in this case, of 30 days duration) are evaluated at a given argument of latitude: we chose $u = 0$, the equator crossing (thereby causing $S = 0$ and $C = 1$ in the above equations), although previous analyses [*Smith and Dunn*, 1980 and *Dunn et al.*, 1973], have considered $u = \pi/2$ which is the point of maximum latitude. These "short arc" elements follow the real satellite orbit in the chosen "Equator crossing" space, but are averaged over the 30-day data interval. In our procedure, they are compared with Keplerian elements evaluated at the Equator crossing points from an orbit calculated over a time span of several years based on the May 1976 initial orbital state. The differences between the "short-arc" and "long-arc" elements shown in Figures 5.12 through 5.16 are measures of the effects of error in the force model used in the orbit determination process and errors introduced from unmodeled sources on Keplerian elements, but are significantly unaffected by short-period terms due to J_2. The differences are similar to those computed using mean elements but offer the advantage of direct evaluation during the data reduction process using GEODYN's versatile numerical integration scheme.

5.3.2 *Results and Discussion*

The slight downward trend observed in the semi-major axis residuals (Figure 5.12) suggests that the along-track acceleration value (-3.1 pms^{-2}) adopted in calculation of the long arc is slightly higher than the true average. This is indeed the case. The along-track acceleration was shown in the previous section (Figure 5.6), and its mean calculated from the bi-monthly estimates is -3.44 pms^{-2}. The excursions about a secular trend correspond to the data excursions in the along-track acceleration described in Section 5.2. The ± 0.2 ppm variations in the difference of the eccentricity (Figure 5.13) may be a result of error in the odd zonal terms of the geopotential and any seasonal variation in them, as well as by any Earth albedo effects and satellite thermal effects, which will additionally influence the length of the semi-major axis.

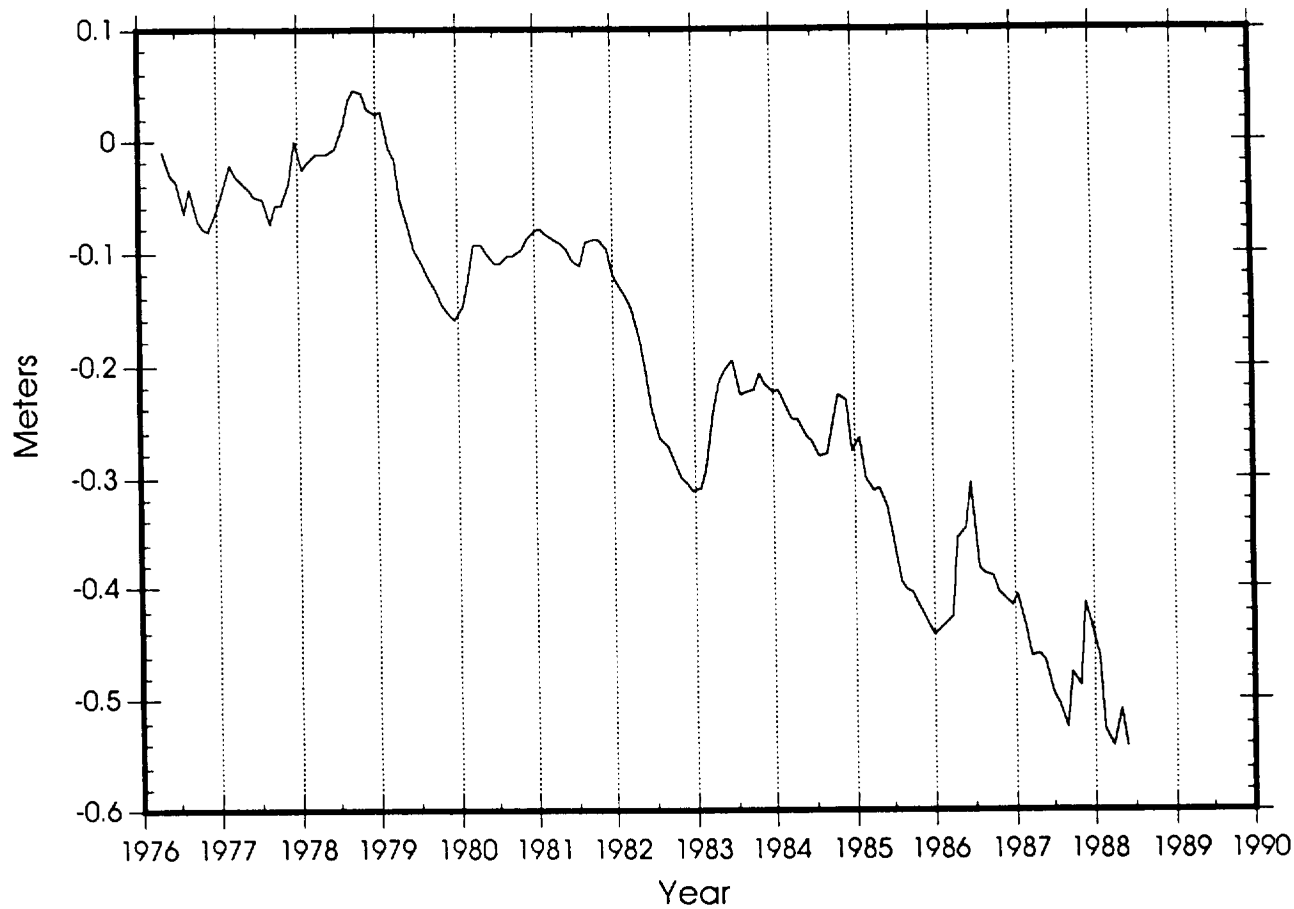

Figure 5.12 Monthly semi-major axis differences taken with respect to a single multi-year orbit calculated using identical force models beginning with the same initial conditions. An assumed average along-track acceleration of -3.1 pms^{-2} has been applied in this chart and in the next 4 figures. The remaining linear trend is due to the fact that the actual along-track acceleration is closer to -3.4 pms^{-2}.

A small upward trend in the inclination residuals (Figure 5.14) can also be attributed to the thermal drag effect described by *Rubincam* [1988] and *Farinella et al.* [1990], but the periodic effects are mainly caused by residual error in the tidal model and possibly by the Yarkovsky-Schach effect [*Farinella et al.*, 1990]. The Earth and ocean tidal errors will produce signatures in the node (Figure 5.15), among which would be included seasonal variations in the SA (annual) and SSA (semi-annual) tidal amplitude [*Smith and Dunn*, 1980]. The large secular effects in the node residuals are due to a combination of the effect of mis-modelling the 18.6-year zonal Earth tide by assuming that $k_{2,f}$ = .30 for this tide with zero phase and neglected ocean tides at this period and that of the rate of change of the second zonal harmonic caused by post-glacial rebound [*Rubincam*, 1984]. A few more years of tracking are required for the full

separation of these two effects. The argument of perigee variation (Figure 5.16) largely corresponds to excursions in the eccentricity.

5.4 Earth Orientation

It has already been discussed in the section on Reference Frames (Section 3.1) that polar motion and variations in the Earth's rotation rate must be determined through observation. In the discussion below, the polar motion and Earth orientation results obtained from the analysis of the LAGEOS laser ranging data is presented. The averaging intervals for the recovered Earth orientation parameters have been chosen for convenience to correspond to those of the BIH Circular D publication .

5.4.1 *The SL7.1 EOP Series*

The values of the SL7.1 recovered EOP series are given in Appendix 4. The series was obtained from a "global" solution (cf. Section 2.3) where all station motions were modeled with an adopted tectonic model; AM0-2 of *Minster and Jordan* [1978]. The horizontal position of Greenbelt, Maryland was unadjusted and constrained to move with AM0-2 motion as was the latitude of Maui, Hawaii. In addition to these, the first epoch estimate of A1-UT1R (the difference between atomic time (A1) and universal time regularized to account for tidal effects (UT1R)) was constrained in each arc, so that it could be decoupled from the node of LAGEOS.

Figures 5.17 through 5.20 graphically depict the estimated series of the coordinates of the pole in the usual conventional frame, the length-of-day, and its variations obtained by forward differencing of the estimated length-of-day (A1-UT1R) values. In Figures 5.21 through 5.23 are shown the standard deviations associated for each of the three components of the EOP series. It is remarkable how vividly the latter reflect the changes in the tracking network strength and the precision of the ranging instruments. Disregarding short transition periods in between major eras, one can clearly identify the existence of three such eras:

1976 - 80:	Weak network, low-precision instruments
1980 - 84:	Better network, higher precision instruments
1984 - 89:	Strong network, high-quality instruments

In Figure 5.24, there is shown a plot of the polhode, the actual trajectory of the Celestial Ephemeris Pole as determined in SL7.1, projected on a plane tangent to the Earth's surface at the Conventional International Origin (CIO).

5.4.2 *Uniformization of the EOP Solution*

The analysis of the SLR data produces a continuous series for polar motion (both components), and a discontinuous series of Earth rotation variations. The inability to separate the absolute magnitude of the Earth's angle of orientation in space from the satellite node requires us to

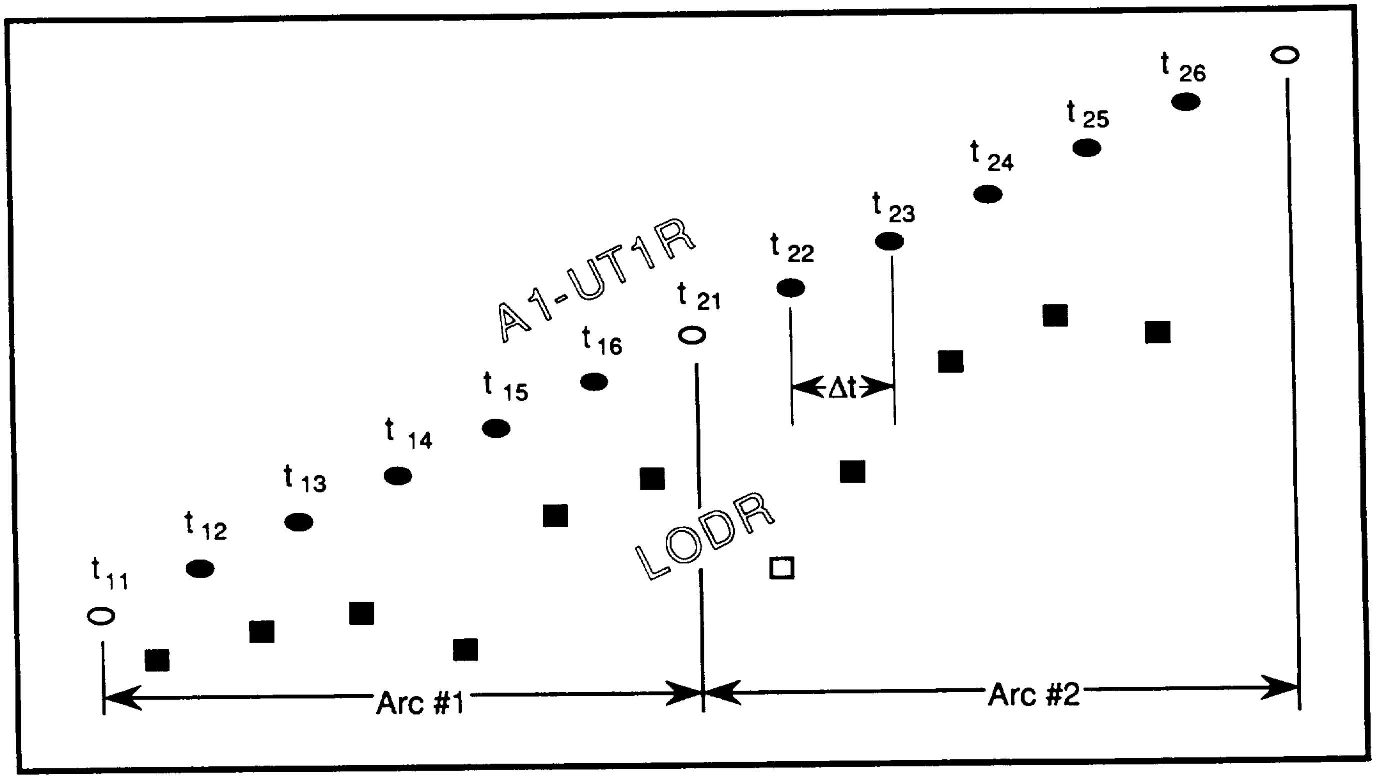

Figure 5.25 Method for uniformization of the estimated Earth orientation parameters. Two arcs are shown. The A1-UT1R series is depicted as ovals and the LODR series is depicted as rectangles. The open ovals indicate that A1-UT1R is constrained to BIH values. In the case of t_{11}, the BIH value is adopted to reference the uniform series. The solid ovals indicate values of A1-UT1R estimated in the solution. The solid rectangles indicate values of LODR determined from forward differencing of adjacent A1-UT1R values. The open rectangle indicates that LODR has been interpolated by cubic splines.

constrain the initial value of A1-UT1R in each of our independent arcs to its *a priori* value. If the constrained values are not consistent with the ensemble of values estimated, then the series will exhibit severe discontinuities at these nodal points.

Similar discontinuities exist in the derivative of the A1-UT1R parameter, the variation of the length of day, ΔLODR. Despite the fact that absolute orientation angles are not estimable from the data, their relative variations are. What we have done therefore, is to determine the ΔLODR series from the estimated A1-UT1R series and then determine, through spline interpolation, the missing values of ΔLODR at the nodes between arcs. Figure 5.25 illustrates these concepts. Once the ΔLODR series is rectified and complete, one only needs a starting value of A1-UT1R to reverse the forward difference procedure and integrate the ΔLODR series into a continuous A1-UT1R series

$$(A1-UT1R)_{unified}(t)=(A1-UT1R)_{unified}(t-\Delta t)+(\Delta t)\Delta LODR\left(t-\frac{\Delta t}{2}\right) \quad (5.13)$$

In applying this procedure we also smooth the final series using the Vondrák filter [*Vondrák*, 1977] with a weak smoothing parameter $\varepsilon = 10^{-4}$ which effectively suppresses the periods below 20-30 days. It is the rectified and smoothed series that was shown in the figures discussed above. This series is then in a form which can be used in comparison and time domain studies [cf. *Pavlis*, 1991].

The secular nature of the smoothed pole series was reported by *Pavlis* [1990] in which the secular trend of the pole was calculated from an 8-year span of polar motion data to be 3.3 mas/yr in x and 2.6 mas/yr in y giving a direction of approximately 38° E longitude with respect to the CIO.

5.5 Elastic Earth Parameters

In addition to the Earth orientation parameters, the global elastic parameters h_2 and l_2 (Love numbers) associated with the station tidal variations were estimated. The adjusted h_2 is 0.627 ± 0.004 as compared with the Wahr *a priori* of 0.609 and the adjusted l_2 is 0.0986 ± 0.002 as compared with the Wahr *a priori* of 0.0852. The standard deviations given are three times the formal standard deviation of the global solution. The differences from the *a priori* are formally significant: however, they represent variations in station positioning at the 1- to 5-mm level which could well be due to neglecting a model for the site dependent ocean loading. The discrepancies are at the 4% level for h_2 and the 16% level for l_2.

Previous recoveries of these parameters provide similar values for h_2 and l_2 : *Christodoulidis et al.* [1985] presented 0.608 ± 0.003 for h_2 and 0.0934 ± 0.002 for l_2 from analyses of the 1980-1983 LAGEOS tracking data. *Carter et al.* [1985], using VLBI data taken 1980-1984 determined values of 0.6135 ± 0.0054 and 0.0768 ± 0.0191 for h_2 and l_2, respectively. *Gendt and Dietrich* [1988] estimated h_2 and l_2 to have values of 0.610 ± 0.003 and 0.099 ± 0.002, respectively, based on their analysis of September 1983 to May 1985 LAGEOS tracking data. While none of these results are clearly inconsistent with the others, the values disagree by more than would be expected from their uncertainties; this behavior is more typical of model errors than geophysics.

C-2

Gendt and Dietrich [1988] have shed some light on this: they also evaluated h_2 and l_2 from their data on a station- by-station basis, recovering 0.598 ± 0.012 for h_2 and 0.092 ± 0.009 for l_2 as the respective means of their independent local determinations. The range of well-determined values was between 0.4 and 0.7 for h_2 and between 0.02 and 0.24 for l_2. The individual station recoveries provide estimates of h_2 and l_2 which are formally distinct from the global mean estimate by significant multiples of the formal error of determination. They are observing the same type of behavior we see in comparing the solutions of different investigators, and the implication is that the data do not fully conform to the model. We suspect that unmodeled ocean loading effects are strong candidates for being the major source of the model error here. This will be considered in future analyses.

6. The Estimation of Station Coordinates and Reference Frame Realization

In Section 3.1, reference systems were described and reference frames, as applied to the analysis of laser range data, were considered. One of the ultimate goals of the SL7.1 solution is to simultaneously realize the CTRS and determine the individual motions of the tracking stations. Ideally, the solution should be completely robust and all estimable quantities of interest (including those that vary with time) should be solved for in a singular, massive inversion. Due to software restrictions, the estimation of the station motions could only be achieved through a series of individual station position determinations spanning the tracking history of the network. In other words, the GEODYN/SOLVE analysis system was limited in its capability to directly estimate epoch positions while simultaneously estimating tracking site velocities.

Given the limitations of the software system, the procedure which was used can be outlined as follows. Within each solution period, the motion of each station was modeled according to the adopted tectonic model (AM0-2). It is important to try to keep the time span of each solution as short as possible so that the resulting station positions are not contaminated by errors in the underlying tectonic model. Additionally, if the solution period was made too long, the detection of episodic events and station hardware problems may become overly averaged and possibly go undetected. Once the series of station positions are available, their time histories of latitude, longitude, and height can be determined by weighted least-squares line fits to these quantities or, better, they can be estimated via a combined adjustment of the ensemble of interstation distance variations. A graphical outline of the data reduction process which was followed to estimate tracking site velocities is shown in Figure 6.1. The remaining sections of the chapter will describe the details of this process.

6.1 Requirements for High Temporal Resolution Analysis

The analysis of variations in the length of the distance between tracking sites provides the basis for the inference of station motions in SL7.1. Given the aforementioned software limitations, we chose to determine the motion of the stations based on the interstation distance rates. This approach was taken for primarily two reasons. The first is that interstation

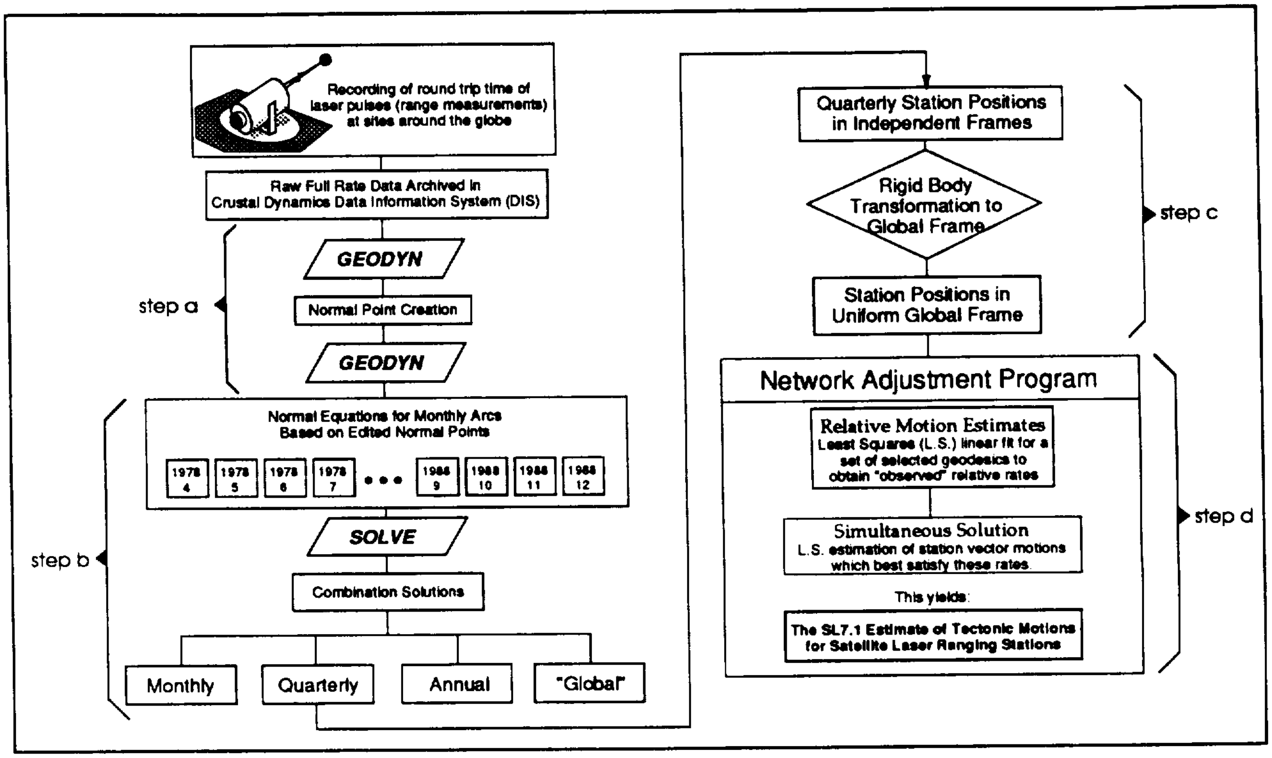

Figure 6.1 SL7.1 solution design. Step "a" on normal points was discussed in Section 4.2. The software system was described in Section 2.2. The various solution types were described in Section 2.3. The remainder of the present chapter will focus on steps "c" and "d."

distances are by and large uncorrelated, which then allows for the removal of off-diagonal terms within the covariance matrix without appreciable loss of accuracy. The second reason is due to the fact that the estimated station positions are directly dependent on the underlying reference frame. Since the reference frame from one estimation period (quarter) to the next is linked only through an *a priori* constraint, the stability of the reference frame is data dependent and therefore does not yield completely consistent station motion estimates based exclusively from the time histories of the geodetic coordinates themselves (this is discussed further in the next section).

Since the horizontal motion of the stations is of primary interest in assessing global tectonic behavior, it is required that all station positions be reduced to a common surface upon which distance computations are performed. A natural choice for the reference surface is an ellipsoid of revolution, such as is typically used for continental geodetic networks. The network computations are made with respect to the internationally accepted GRS-80 ellipsoid having a semi-major axis of 6378137m and a flattening of 1/298.257 [*Moritz*, 1988]. The last decision to be made is the "type" of interstation distance to be analyzed. Given the fact that the reference surface is an ellipsoid, there are two choices for a unique definition of interstation distance. These include the *spatial chord* connecting the projections of the two station positions on the ellipsoid, and the *geodesic line,* the curve on the ellipsoid's surface with the shortest length between the two projected positions.

The geodesic line, or shorter, the geodesic (sometimes called the geodetic line in some texts), was chosen since it can directly determine the horizontal components of the vector of motion which most closely approximates the natural one. This obviates the need to project the resulting motion vector components to the surface, since they are already determined directly with respect to it. Additionally, analysis of surface curves versus baselines or chord lengths overcomes the ill-conditioned case regarding motion between pairs of stations which are nearly antipodal (i.e., opposite sides of the world). Since the Earth's shape departs very little from that of an ellipsoid, the interstation chord or baseline between antipodal stations will contain only minimal information about the horizontal motion of the stations since it is essentially orthogonal to the local horizontal at each station. In these antipodal cases, baseline or chord rates, having typically a low signal-to-noise ratio, reduce the likelihood that one can derive any meaningful results regarding horizontal motion.

The disadvantage of using geodesic lines lies in the fact that unlike the spatial chords, geodesics are not independent of the reference frame realized by the estimated station positions. This stems from the fact that the reference surface, the ellipsoid, is attached to the coordinate axes of the reference frame centered at its origin. Any misalignment of the axes between solutions or any translations of the origin will directly affect the computed geodesic lengths and thereby their rate of variation. This in turn will propagate into the station position motion and result in biased estimates for them.

Without loss of generality, one can examine the special case of two stations lying on the same meridian. The situation is illustrated in Figure 6.2 for the case of an origin shift along the Z axis, and for that of a rotation $\Delta\psi$ about either the X or Y axis. As can be seen from these figures, the geodesic is less sensitive to rotations about X and Y (no changes for rotations about Z) but very sensitive to Z-axis translations. One can show that the sensitivity contrast between translations and rotations reaches a maximum when the ellipsoid degenerates to a sphere. At that point the geodesics degenerate into great circles and their length is, of course, independent of the orientation of the coordinate axes. For the spherical case, a change in a spherical

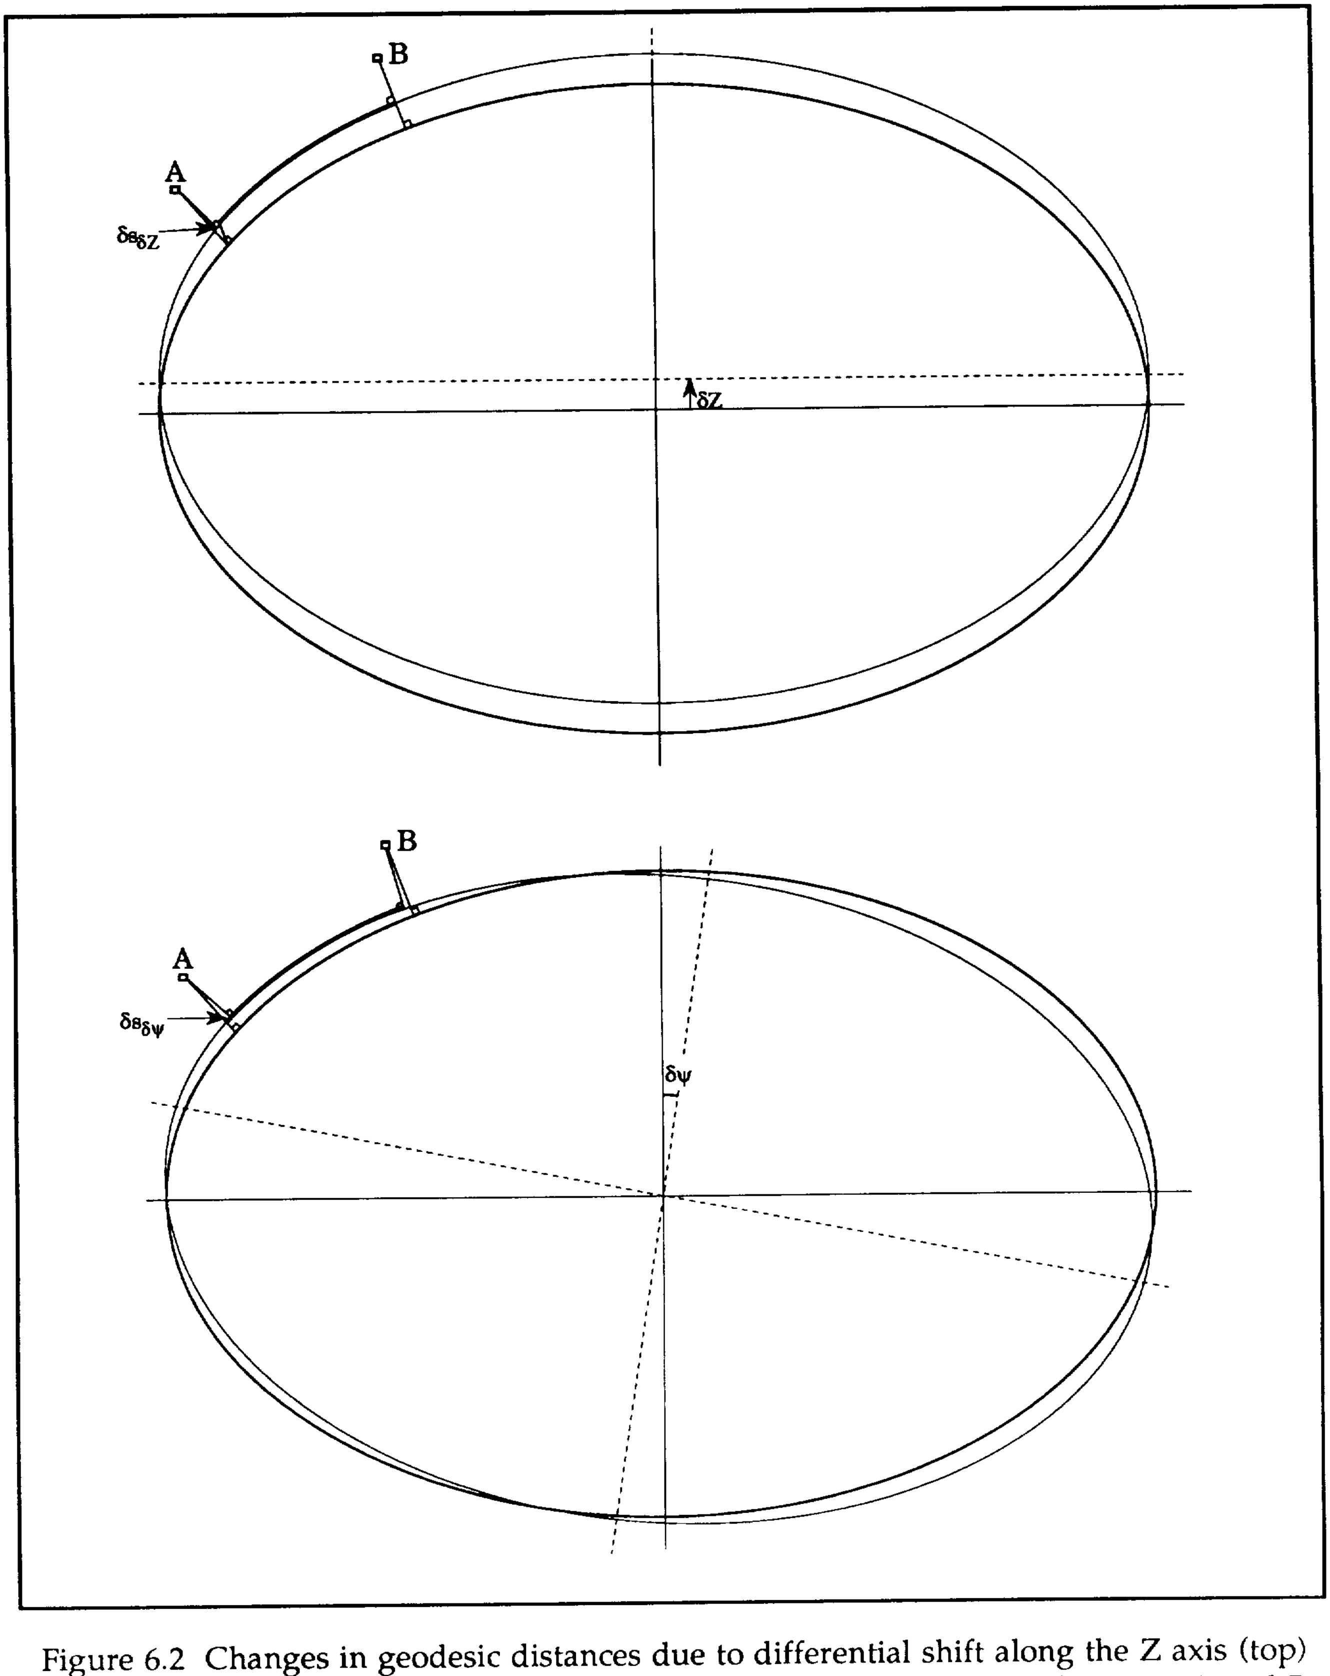

Figure 6.2 Changes in geodesic distances due to differential shift along the Z axis (top) and due to rotation about an axis lying in the equatorial plane (bottom). Points A and B represent tracking station locations which are projected to the ellipsoid for the purposes of computing geodesic distances. In both figures, the flattening of the ellipsoid is highly exaggerated compared to that of the real Earth.

distance (δs) between points projected onto the sphere at A and B due to a differential shift along the Z axis (δz) is given by

$$\delta s = -r_e\left(\frac{1}{\sqrt{1-u^2}}\right)\frac{du}{dz}\delta z \tag{6.1}$$

where

$$u = \sin\varphi_a \sin\varphi_b + \cos\varphi_a \cos\varphi_b \cos\Delta\lambda$$

$$\frac{du}{dz} = \sin\varphi_b \cos\varphi_a \frac{d\varphi_a}{dz} + \sin\varphi_a \cos\varphi_b \frac{d\varphi_b}{dz} - \cos\Delta\lambda\left\{\cos\varphi_b \sin\varphi_a \frac{d\varphi_a}{dz} + \cos\varphi_a \sin\varphi_b \frac{d\varphi_b}{dz}\right\}$$

$$\frac{d\varphi_i}{dz} = \frac{\sqrt{x_i^2 + y_i^2}}{r_i^2}$$

For the meridonal case as illustrated in Figure 6.2, the spherical approximation, formulated above, yields a family of curves describing the behavior of equation (6.1) which are illustrated in Figure 6.3. Shifts along the Z axis can cause variations of the spherical distance to have a ratio with respect to the Z shift as large as 2:1. The ellipsoidal case is not much different since the flattening of the ellipsoid departs from a sphere only by a small amount (~ 0.3 %).

6.2 Controlling the Stability of the Reference Frame

The results of the above analysis indicate that specific geodesics can attain magnification factors from Z axis translations as high as two. This means that to obtain geodesic rates free of any such biases and still claim accuracies of some millimeters per year, the reference frame must demonstrate comparable stability. This stability is a function of four major factors:

- the geometric strength of the network of observing stations,
- the variability of the station configuration between solutions,
- the time interval over which the stations define the reference frame, and,
- the orbital dynamics of the satellite(s) being tracked.

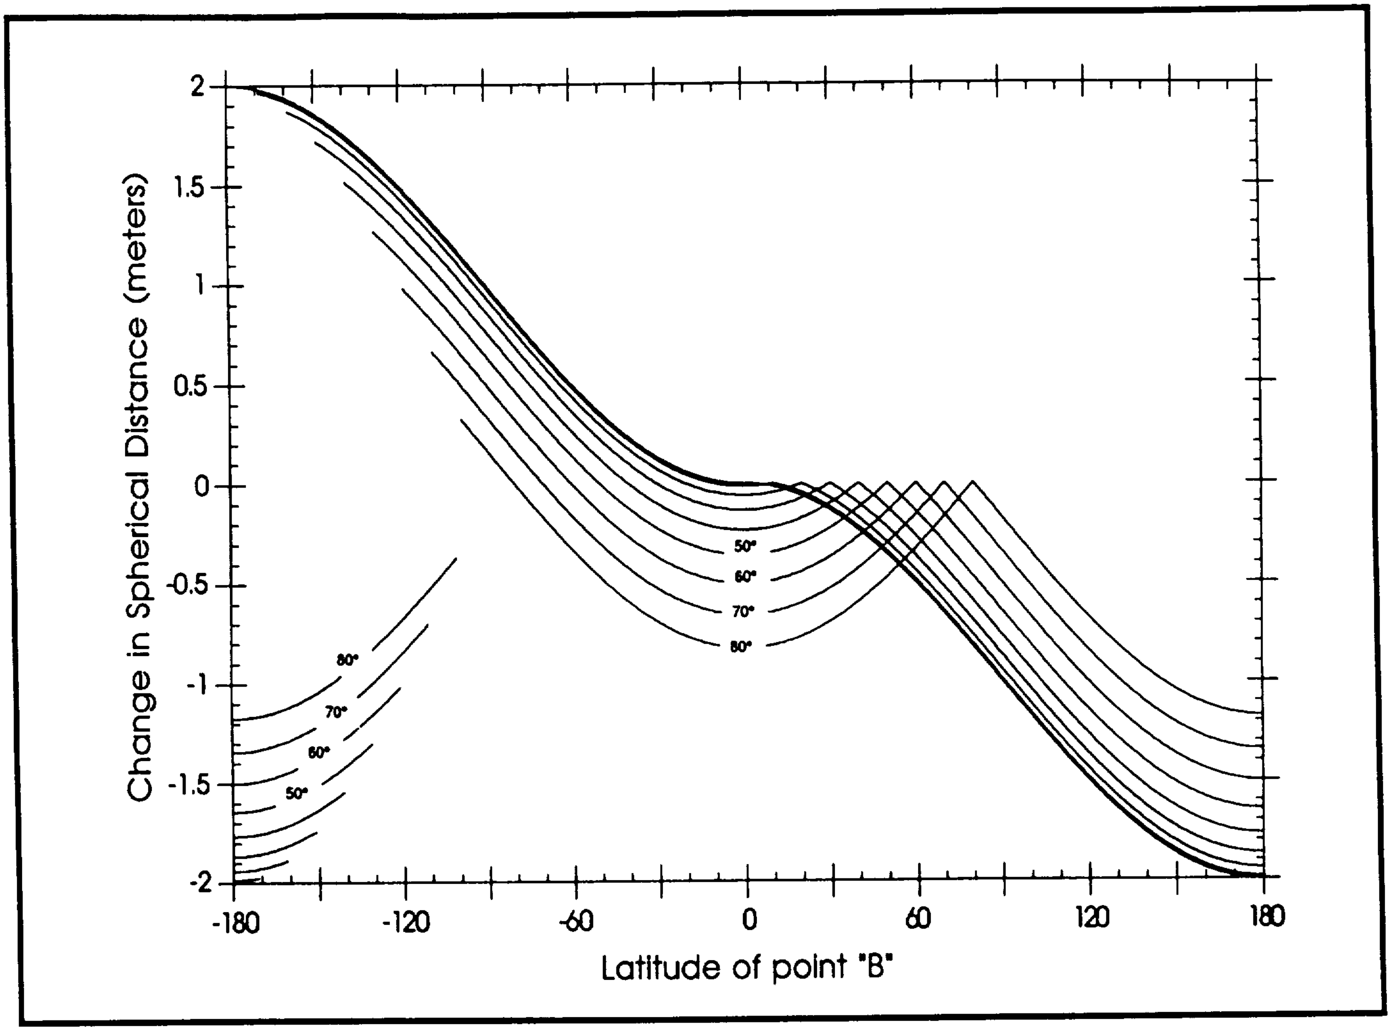

Figure 6.3 Behavior of meridonal spherical distances due to a 1-meter downward shift of the origin along the Z axis. Each curve represents the behavior of the spherical distance from point "A" to point "B". The latitude of point "A" is listed on each curve in 10° increments. The latitude of "B" goes beyond ±90° when "B" is in the opposite hemisphere. The curves are discontinuous at the antipodal point at which a singularity exists. Along meridonal sections, the largest spherical distance change occurs when points "A" and "B" lie near the Equator and can approach as much as twice the amount of the Z shift.

There is not much that can be done with respect to the first point, since in the case of SL7.1 the network is given de facto. As for the last point, the orbital evolution studies (Section 5.3) have not indicated any significant stability problems. LAGEOS constrains the origin of the coordinate system to an effective center of the Earth's attracting mass with great stability. Due to the extremely accurate force modeling possible for LAGEOS, the origin should be, to a very high degree of approximation, equivalent to the center of mass of the Earth.

The stability of the network configuration turns out to be very important because the tracking problems of particular stations and the effect of residual unmodeled forces on the orbit propagate through the highly accurate ranging data into the recovered station positions, Earth orientation, etc., in considerably different ways from one solution to the next. The solution time interval is very closely related to the network stability. The longer the interval which the solution spans, the more stable the frame it realizes. This is not only because of the increase in the collected observations, but also because of the natural averaging in the tracking configurations encountered. As the interval is lengthened, the impact of station drop-outs or new stations joining the network is minimized. It is extremely difficult to control this last factor since in most cases, drop-outs are to be blamed on unpredictable station malfunctions or prevailing climate conditions that are beyond our control. Nevertheless, one needs to develop a measure that reflects these changes in the network so that one can appropriately correct for them.

6.2.1 *Network Geometric Stability*

One way to quantify the two factors mentioned above is to monitor the changes in the geometric center of the tracking stations ensemble. We have done this for the case of the shortest span over which a set of data has been reduced (one month nominally) and for the station distribution over the triplets of the monthly subsets which define our basic solutions, the quarterlies, as presented herein.

We define the geometric center of the network as the point whose Cartesian coordinates are the average of those of the stations in the network:

$$\overline{X} = \frac{1}{N}\sum_{i=1}^{N} X_i \qquad \overline{Y} = \frac{1}{N}\sum_{i=1}^{N} Y_i \qquad \overline{Z} = \frac{1}{N}\sum_{i=1}^{N} Z_i \tag{6.2}$$

where N is the number of stations in the network. If the station configuration were to remain the same over the entire period of time, then the evaluation of the above would show no variations. On the other hand, the actual values would indicate how symmetrical the current station distribution is or, for that matter, how biased it is with respect to any one particular region. The results in Cartesian and spherical coordinates are shown in Figures 6.4 and 6.5.

The initial observation is that the geometric center of the network is located in the Northern Hemisphere as depicted in the graphs of the variation in Z (bottom of Figure 6.4) or in latitude

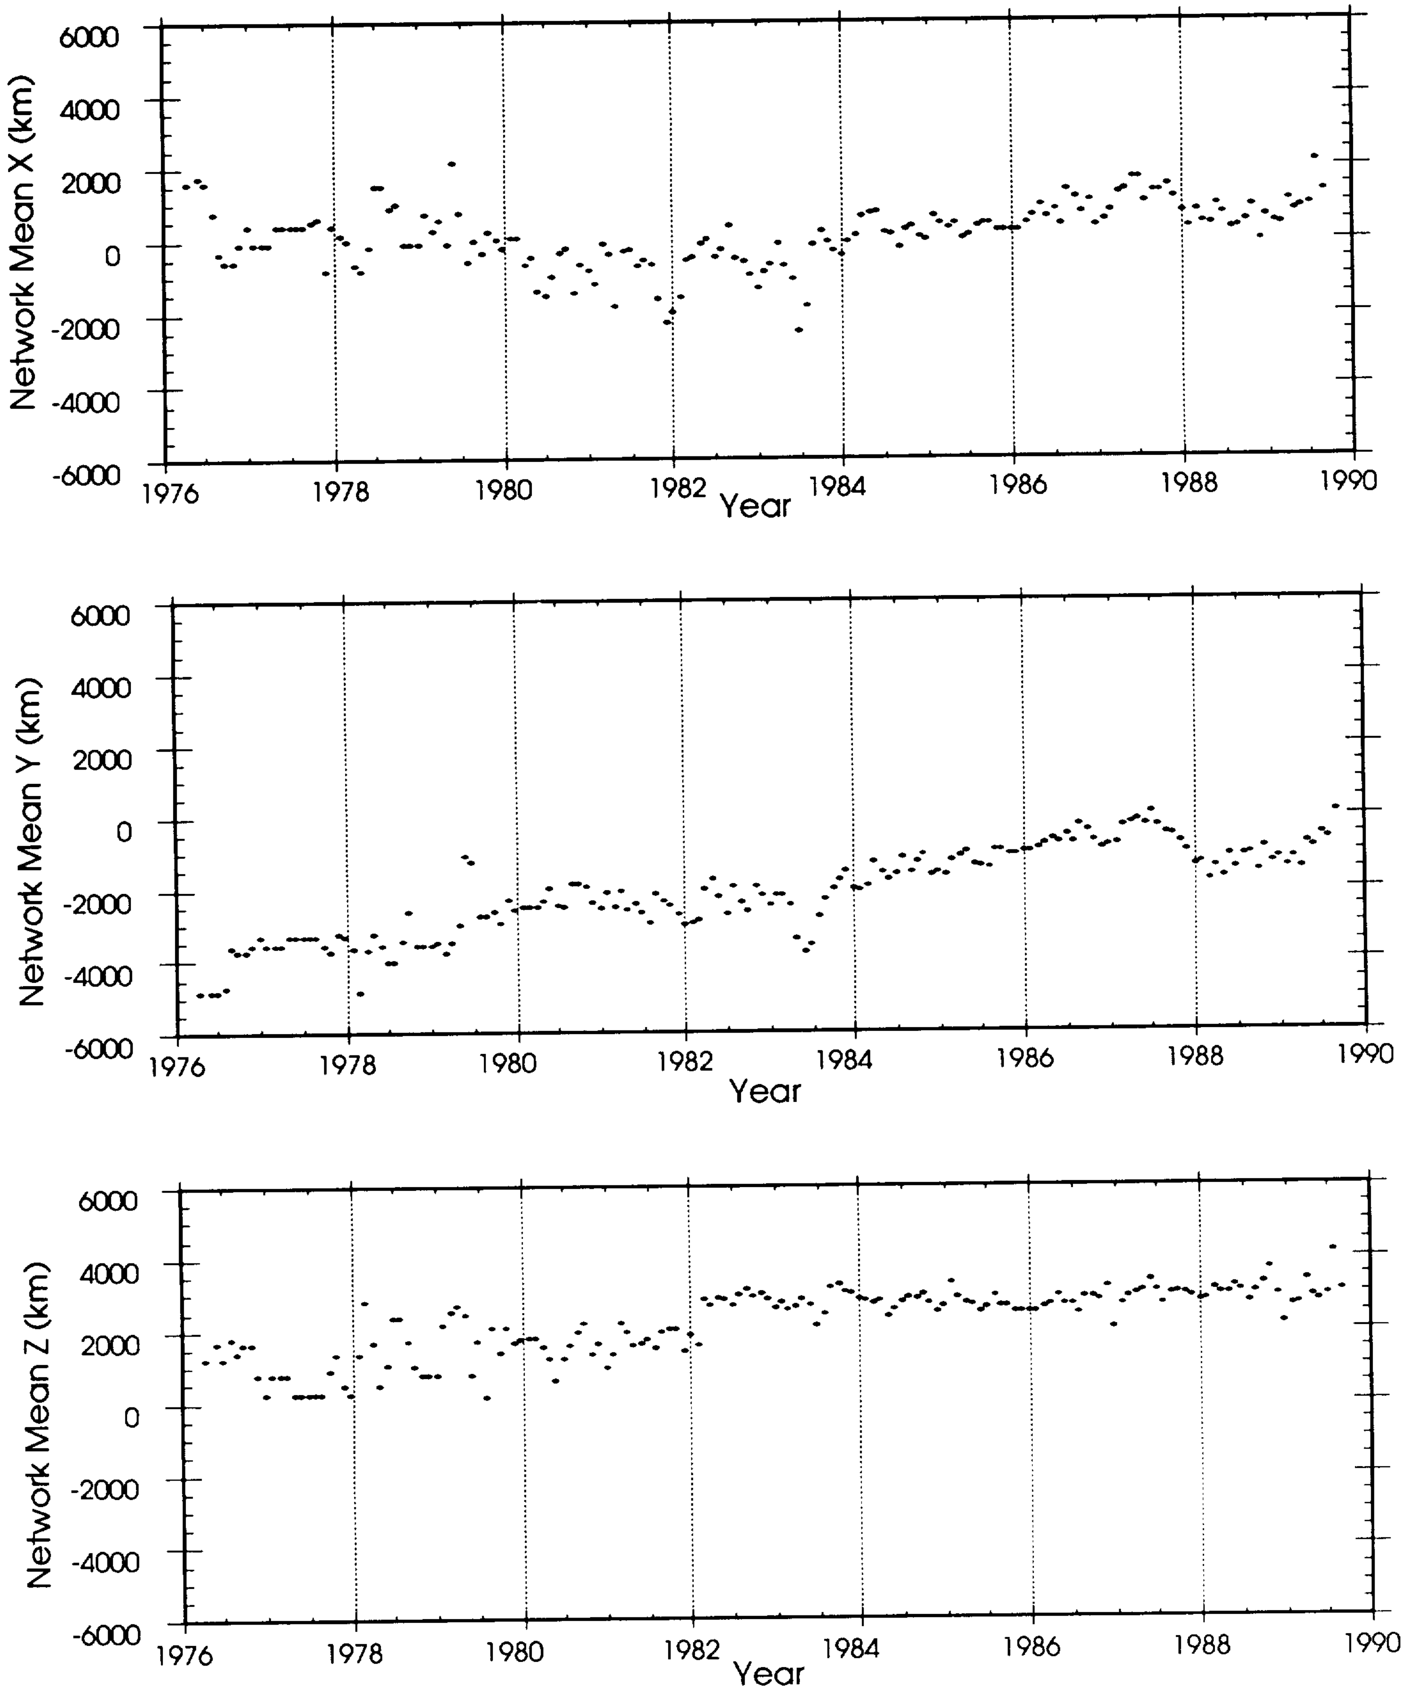

Figure 6.4 Monthly variations of the mean geometric center for the SLR network in terms of Cartesian coordinates.

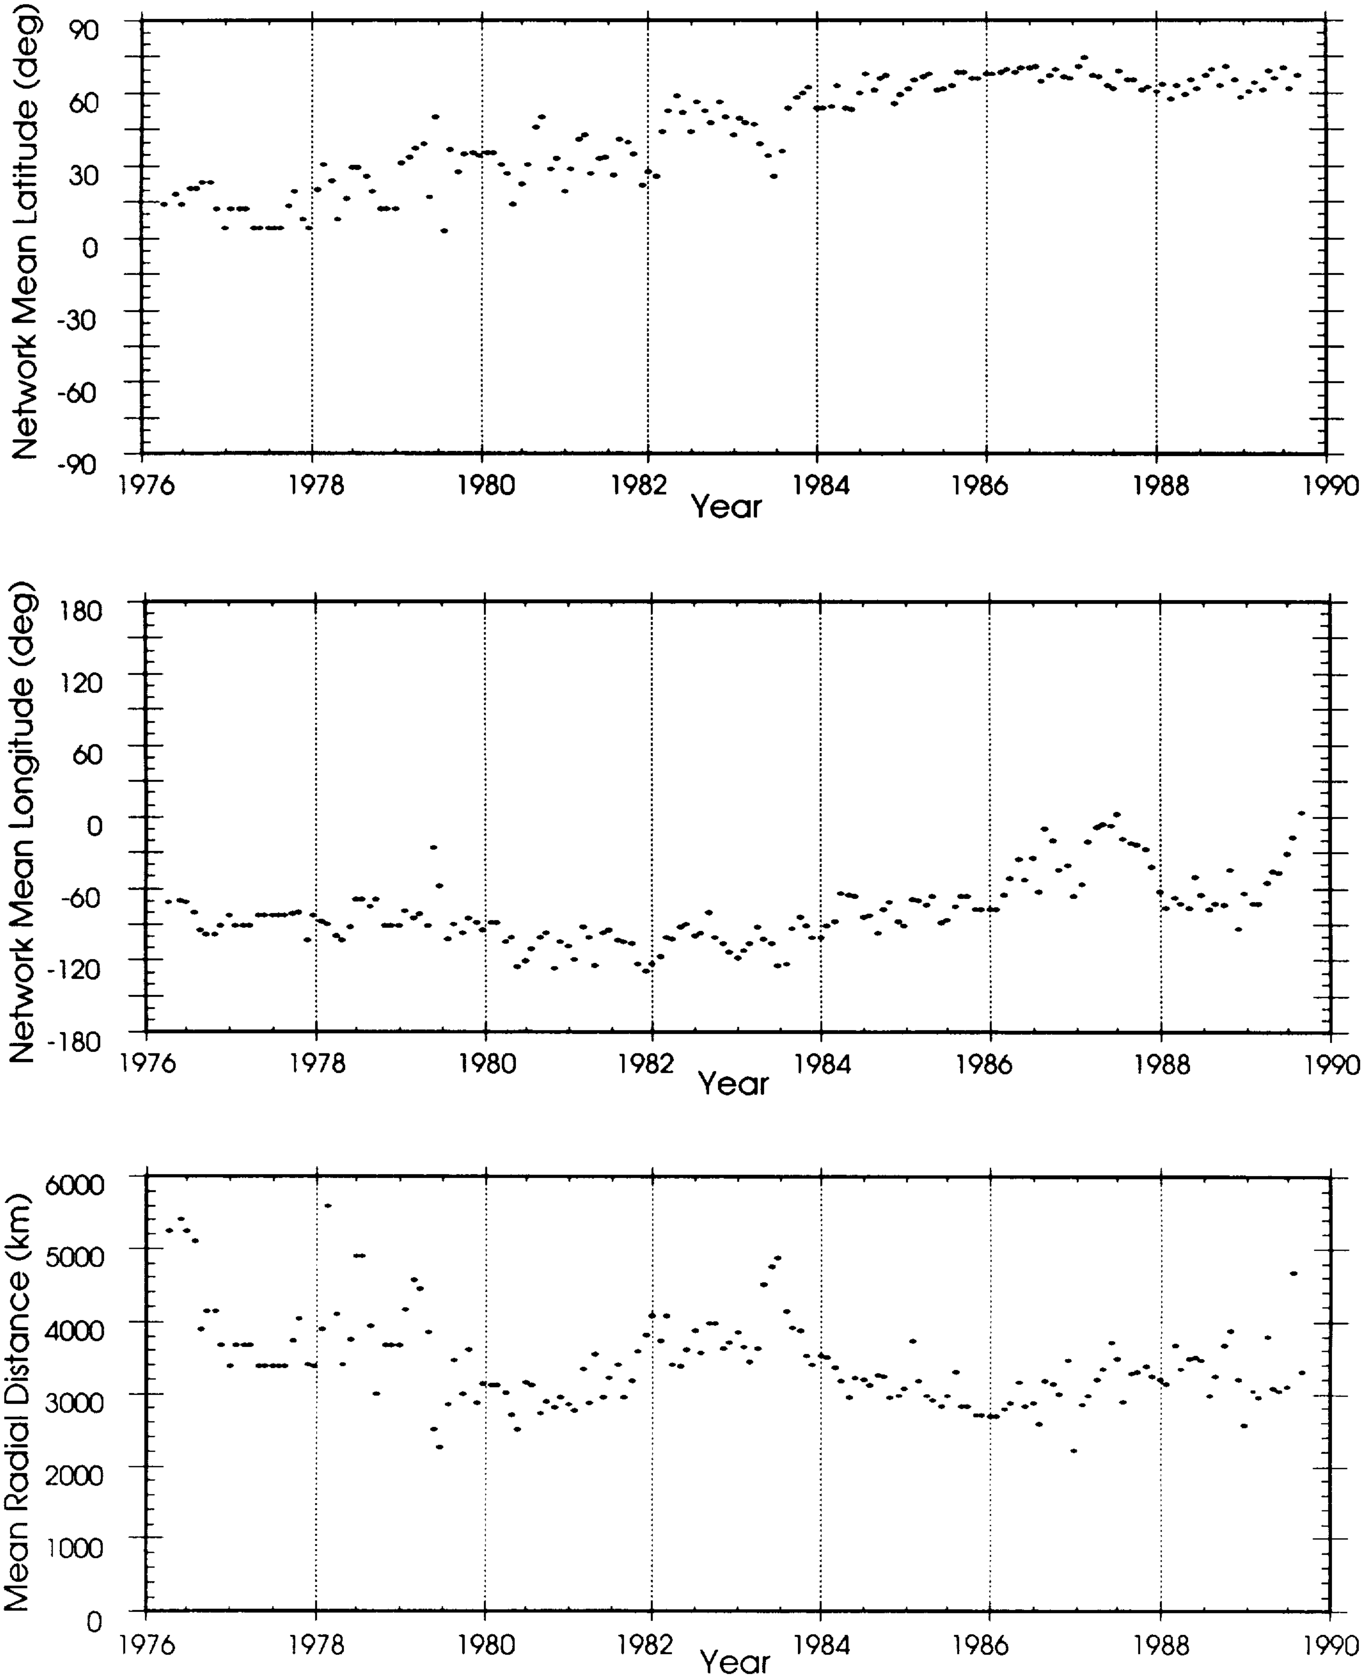

Figure 6.5 Monthly variations of the mean geometric center for the SLR network in terms of spherical coordinates.

(top of Figure 6.5). Secondly, the longitude of the mean geometric center is consistently close to 270 degrees indicating the strong influence of the stations located in the continental U.S. (middle graph of Figure 6.5). In terms of variations, one should note that the network center undergoes significant changes from one month to the next and, due to averaging, one can anticipate the variation across quarterly solutions to be smaller than that of the monthly ones.

The results of this analysis indicate that even with the extended solution period of 3 months, the network will continue to exhibit instabilities which may hinder the solution in achieving the accuracies required for answering geodynamically relevant questions. What therefore needs to be done is to devise a technique that would allow an increase in the resolution of the results without forcing a trade-off in their accuracy.

6.2.2 *The Global Solution as a Reference Standard*

If the length of the interval of analysis plays an important role in determining the stability of the reference frame, then the global solution should provide the most stable frame that can be established. As previously described, one of the main concerns in this "global" definition is the fact that the station motions are modeled through the adopted tectonic model rather than being estimated from the data. This, however, should not matter too much since the majority of the stations follow very closely the modeled motion anyway. What has been done, is to refer the estimated station positions from each quarter we analyzed to the frame realized by the globally estimated positions. To accomplish this, similarity (or rigid-body) transformation parameters (scale excluded) between each quarterly solution and the corresponding global positions from the global solution are determined. In order to avoid biases in the recovered transformation parameters, a time correction is made to bring the global positions from their reference epoch (January 1983) to the mid-epoch of each quarter. The geometry of the transformation is shown in Figure 6.6. Mathematically, the transformation can be written as

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix}_{Global} = \begin{bmatrix} \Delta X \\ \Delta Y \\ \Delta Z \end{bmatrix} + \begin{bmatrix} 0 & \omega & -\psi \\ -\omega & 0 & \varepsilon \\ \psi & -\varepsilon & 0 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}_{Quarterly} \qquad (6.3)$$

where the translational and rotational quantities are as shown in Figure 6.6. These parameters are estimated via a weighted least-squares inversion scheme. The results of this procedure are

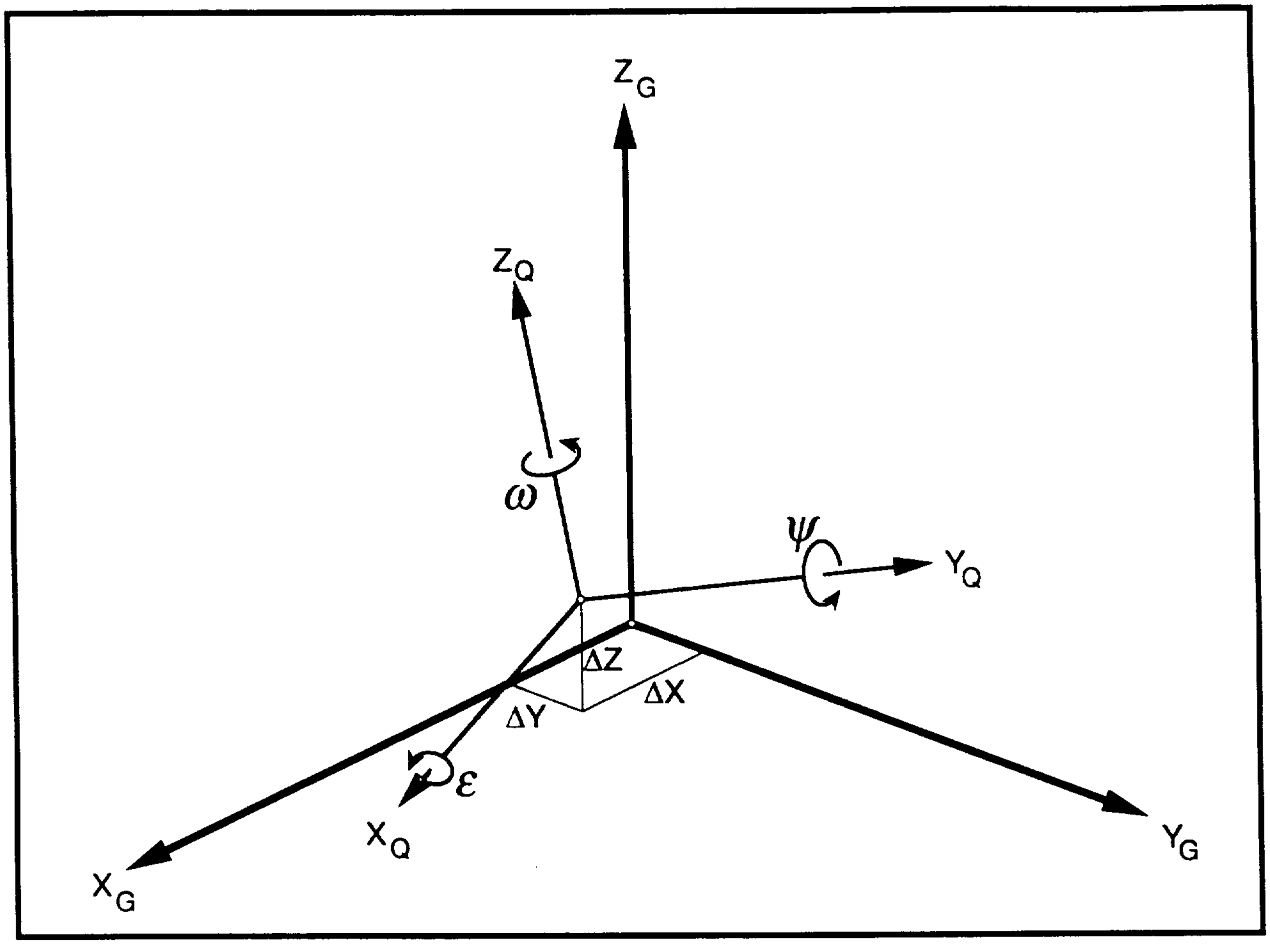

Figure 6.6 Similarity or rigid-body transformations. Nomenclature and geometry used to unify the quarterly realized reference frames into a more consistent "global" frame. The subscripts G and Q refer to the reference frames defined by the "Global" and "Quarterly" solutions, respectively.

summarized in Table 6.1 and are graphically displayed in Figure 6.7 for the translations and in Figure 6.8 for the rotations.

The poor station distribution in the tracking network prior to 1980 is quite evident in the magnitude as well as the quality of the estimates for those early years. In terms of translations, it seems that the Z-axis shift is the one which is consistently more significant than the other two. Yet, its root-mean-square variation for the quarters after 1980 is only 5.5 centimeters. The rotations are of even less significance, with rms variations of about one milliarcsecond in any one of them. What is more of interest here is the fact that the rotation about the Z-axis is very correlated with that about the X-axis, which in turn, is negatively correlated (strongly) with the rotation about the Y-axis. These estimates are based on the weighted estimates of the

positions, so that the strongly determined stations dominate the solution, while the effect of the poorly determined ones is insignificant. The peculiarities of the recovered transformation parameters are therefore the result of an unbalanced distribution of quality tracking data rather than anything else. Despite the small magnitude of these individual constituents of the transformation, one should keep in mind that first it is the sum total that affects the solution, and second, in certain cases, as already shown, a geodesic can be affected by as much as twice that amount.

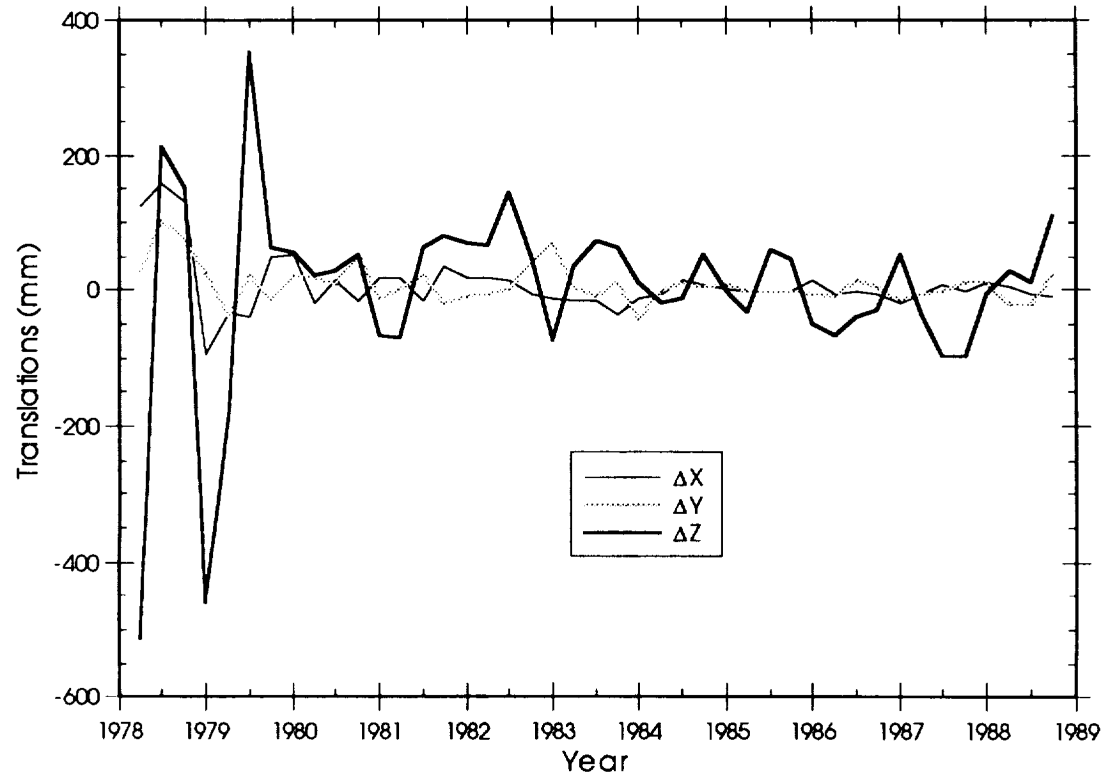

Figure 6.7 Rigid-body Transformations: Translations of the origin.

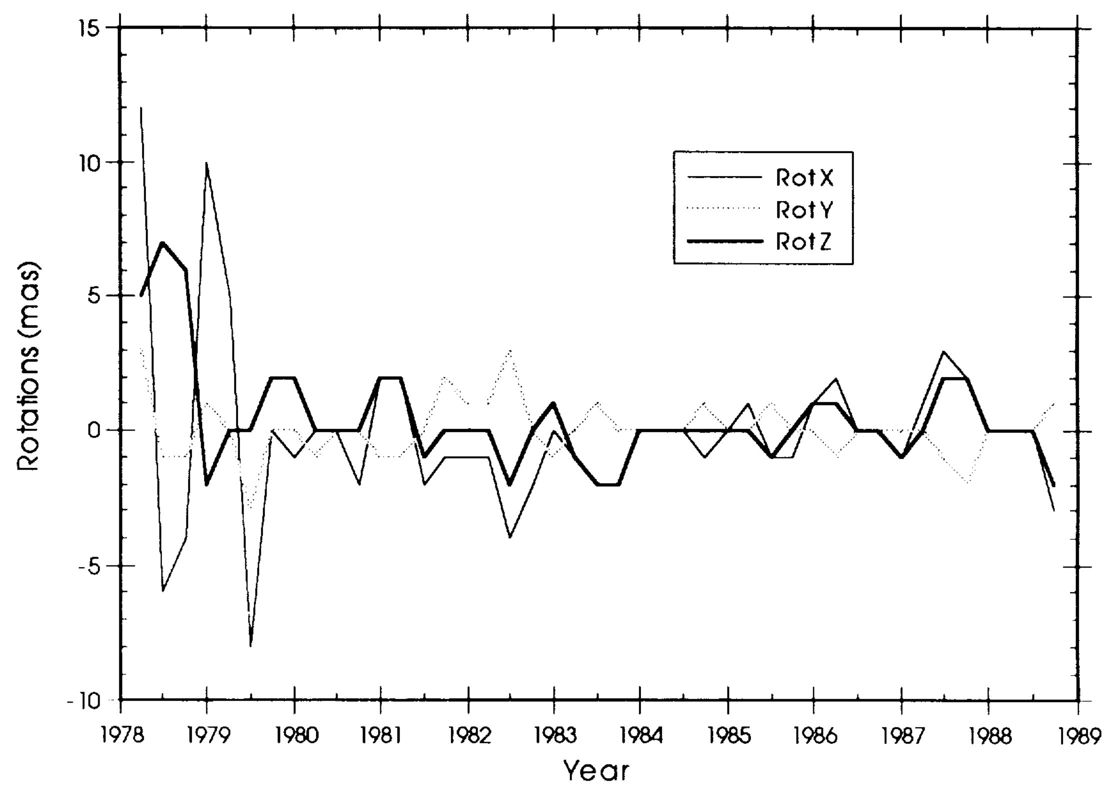

Figure 6.8 Rigid-body Transformations: Rotations about the origin.

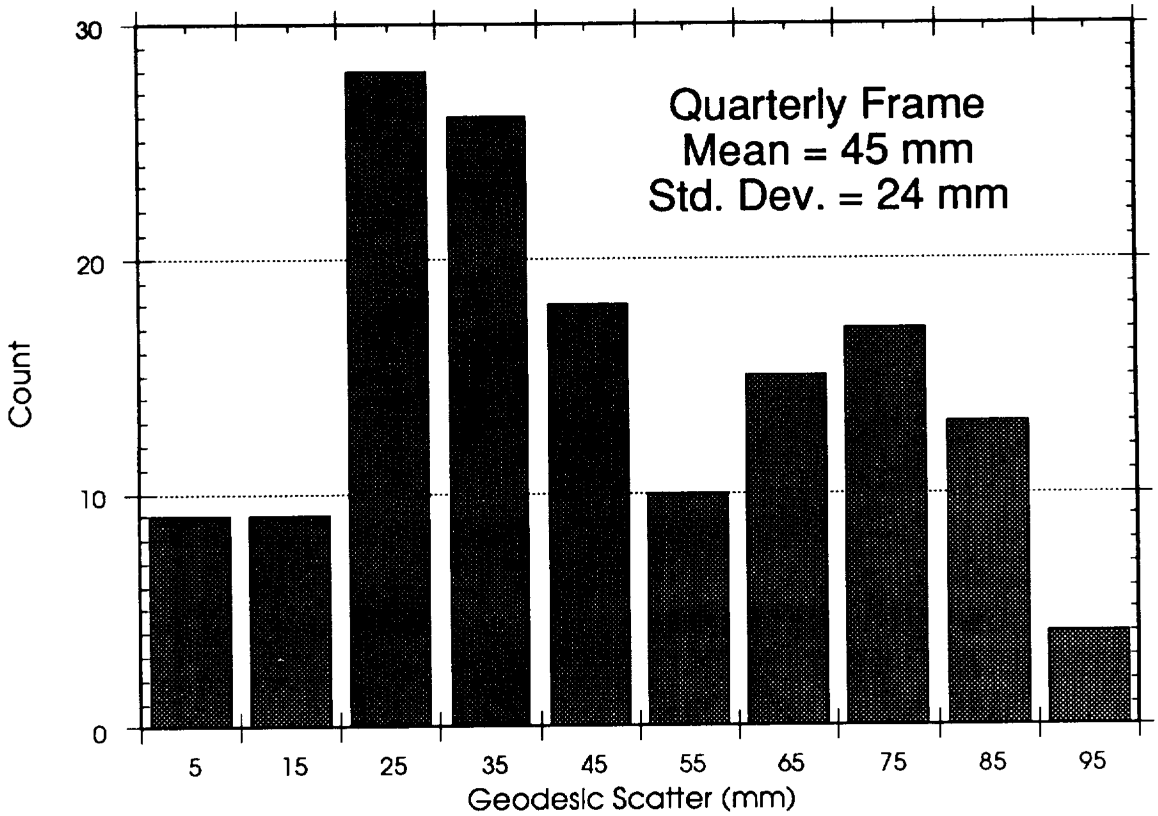
The transformation parameters, as listed in Table 6.1, have been applied to all station positions within each quarter to produce a set of quarterly station positions in a globally consistent frame of reference. The resulting station positions used in the network adjustment are listed quarter-by-quarter in Appendix 6.

6.3 Geodesic Lines from the Transformed Quarterly Solution

The behavior of the recovered transformation parameters indicates a possible periodicity, perhaps varying with an annual period. The source of this effect may possibly be due to the seasonal nature of weather impediments thereby reducing the amount of tracking. However, such behavior is likely to introduce excessive variation in the behavior of the geodesics for reasons previously described. Our conjecture is that this variation should be grossly eliminated once we have accounted for the instability in the reference frame. Additionally, the reduction in the variation should be more prominent in the case of lines with greater extent, since short lines depart only slightly from their respective chords. This conjecture was tested by means of a comparison of the geodesic line lengths based on the station coordinates before having been transformed and those after applying the transformations. Weighted least squares estimates of best fitting lines were determined to yield the slopes of the observed geodesics between a set of twenty stations. We limited ourselves to this subset of stations, since they are the only ones with a significant number of determinations to recover meaningful estimates. The scatter about each line was the statistic under scrutiny. Histograms of the scatter were made for both sets of geodesics and for various subsets according to criteria based on the number of contributing determinations per line. The results for all cases examined are shown in Figure 6.9, for the lines with more than four determinations in Figure 6.10, and for our extremely robust lines with more than twelve determinations in Figure 6.11.

The obvious conclusion from these histograms is that the imposition of the global reference frame has resulted in a 30 - 40% decrease in the scatter of the line fits. That is to say the geodesic estimates are far more consistent between quarters after transforming the sites to a common origin. The original conjecture proves to be true then, and the increase in resolution is supported through this technique with a parallel increase in the consistency of the estimates.

Another way of examining the effect of the transformation is in the temporal stability of the quality of the line fits. Naturally, one expects that these quantities should follow the curve that describes the improvement in the quality of the ranging data on which they are based. We have computed the root mean square line fit scatter for each quarter in the solution and for the station subset which is nominally analyzed for the determination of the tectonic model implied by our geodesic rates between stations. The results for the pre- and after-transformation geodesic sets are shown in Figure 6.12. Even though the downward trend is expected, due to the improvement in the data, it is not nearly as clear in the case of the line fits determined on the



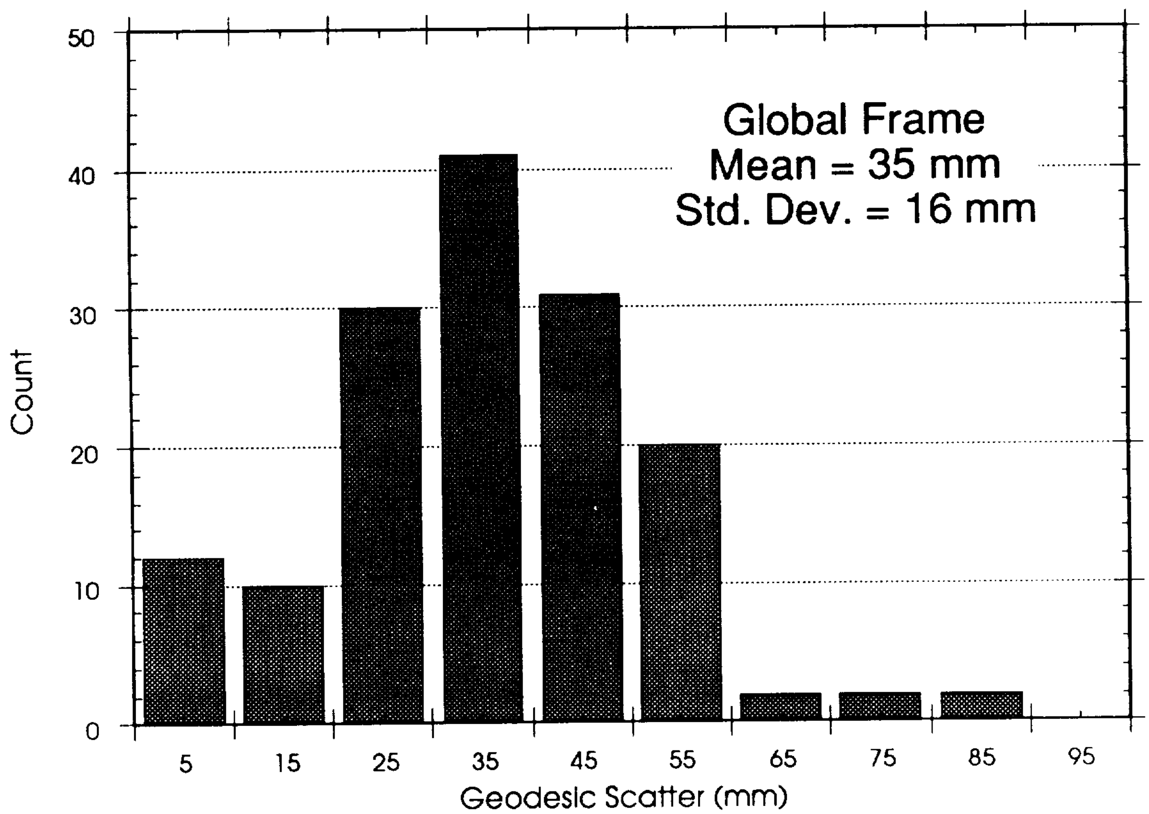


Figure 6.9 Geodesic line fit scatter distribution: Using all observed lines between 20 stations. Quarterly frame at top, global frame at bottom.

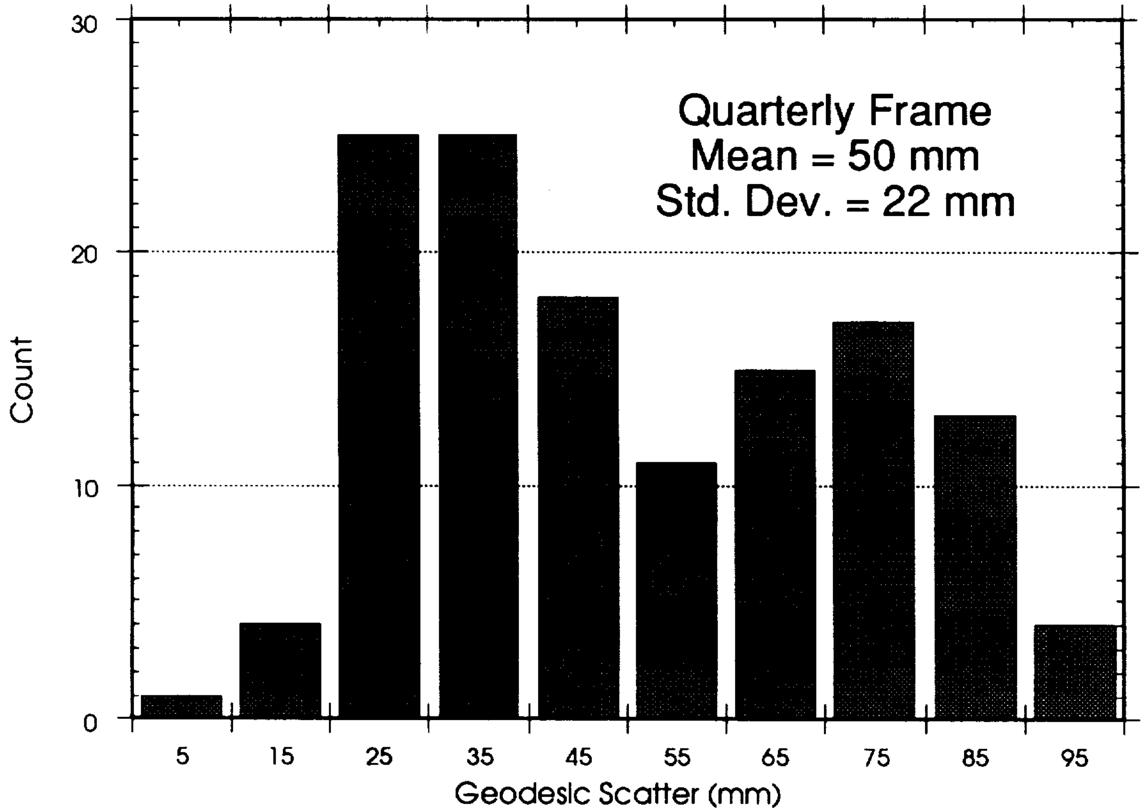

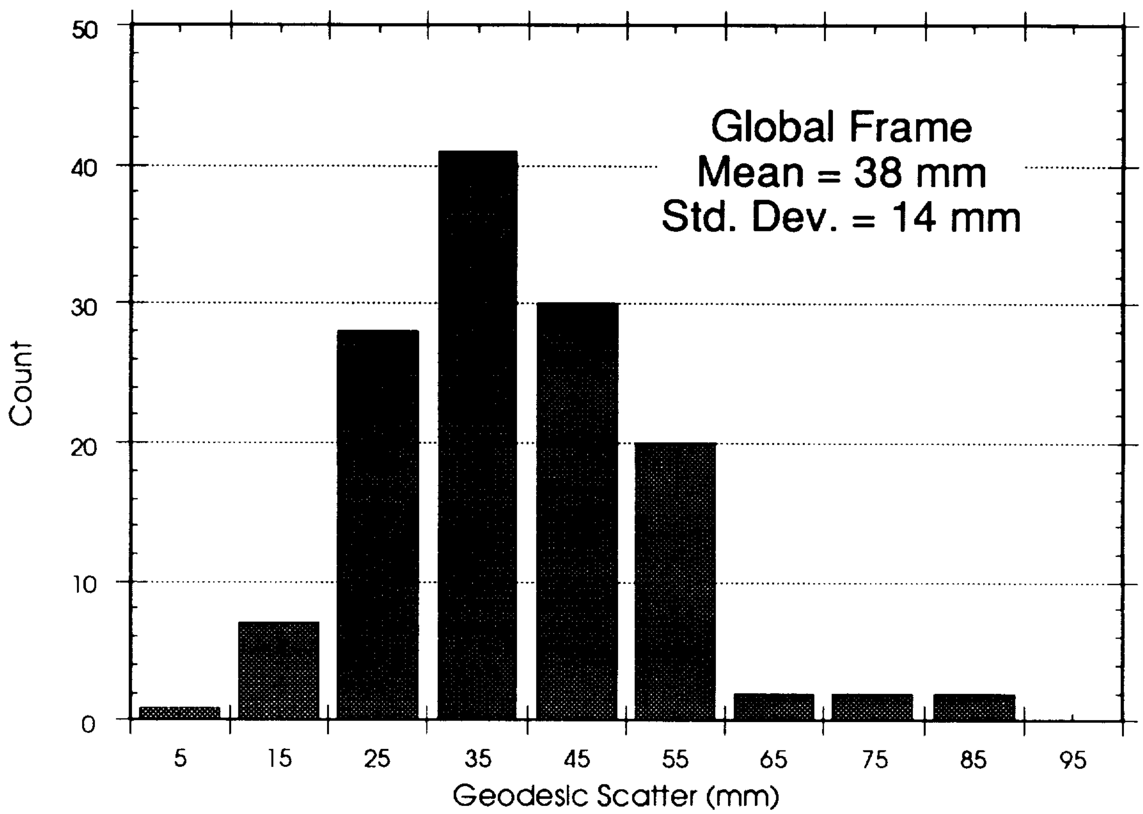

Figure 6.10 Geodesic line fit scatter distribution: Using lines with more than four determinations. Quarterly frame at top, global frame at bottom.

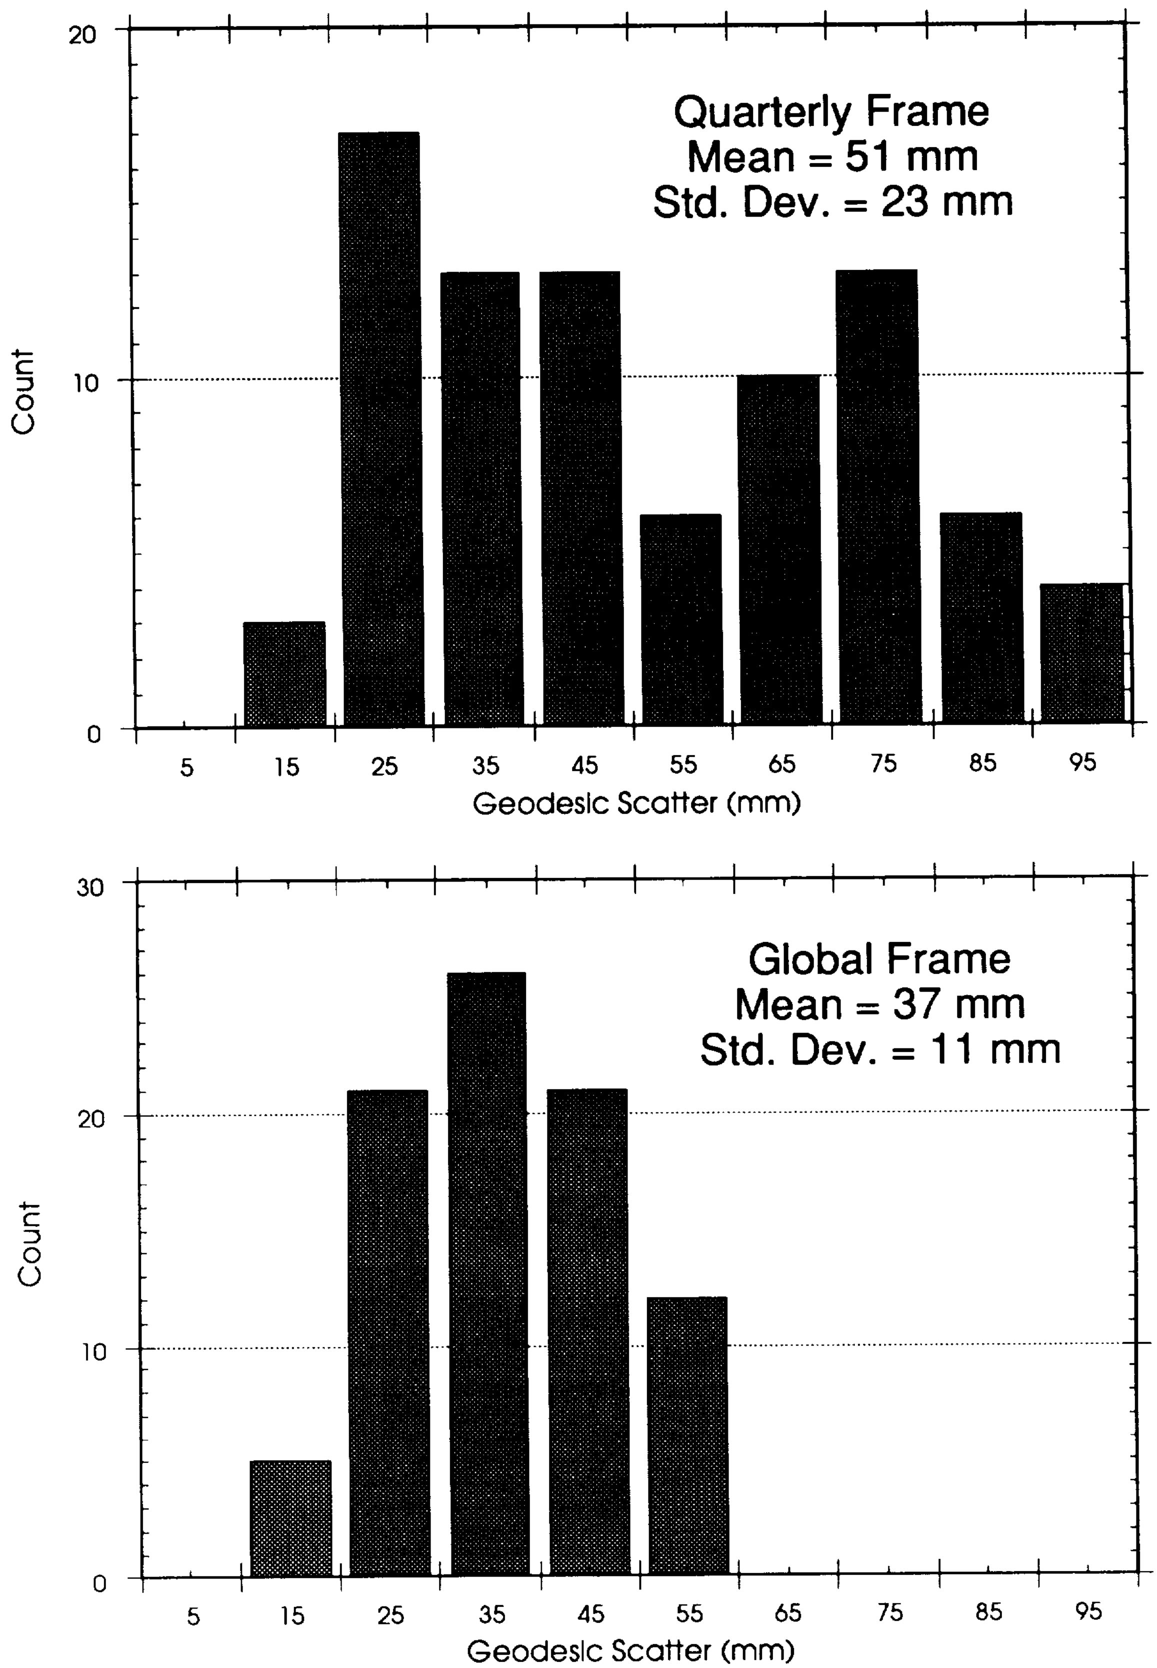

Figure 6.11 Geodesic line fit scatter distribution: Using lines with more than twelve determinations. Quarterly frame at top, global frame at bottom.

basis of quarterly determined stations in an independent frame. Not only does the trend become clearer, the rms of these scatters is now much more consistent for the entire period of time.

Finally, perhaps the best demonstration of the benefits resulting from the reference frame stabilization process is through the line fits themselves. Several examples of lines with typical fits as derived from station positions before and after the application of the transformation are shown in Figures 6.13 - 6.19. As expected, there is little to be gained in the case of short lines (e.g., Monument Peak to Quincy, Figure 6.13), but for long lines, the improved results are remarkable (e.g., Yaragadee to Arequipa (6.18) and Quincy to Matera (6.16)). An added benefit of this procedure is the fact that outliers are easier to detect, as is seen, for example, in the second and third quarter of 1983 determinations of the Quincy-to-Wettzell line (Figure 6.14).

6.4 Summary

In conclusion, the technique we have adopted allows for an increase in the temporal resolution of our estimates while still maintaining the same or even improved integrity of the results. It should be stressed here that this is an interim solution of the problem which we had to adopt due to software limitations. The results of the next cycle of analysis will be based on direct estimates of the station motions recovered in the global estimation procedure rather than through post-processing efforts.

7. Site Motion Estimation via Network Adjustment

7.1 Kinematic Reference Frames - Concepts

According to plate tectonic theory, all points on the Earth's surface are located on a continuously moving crust. To more easily understand the global tectonics determined by SLR and to understand regional deficiencies between the SLR results and the geologically based tectonic models (which assume rigid plate behavior), it is desirable to adopt a kinematic reference frame with respect to which we can define the linear horizontal motions of the individual SLR stations. We have elected to use the NUVEL-1 NNR (No Net Rotation) model of *Argus and Gordon* [1991] in the definition of the kinematic frame. NUVEL-1 NNR is based on the NUVEL-1 relative plate motion model published by *DeMets et al.* [1990]. This model updates the AM0-2 model of *Minster and Jordan* [1978], used throughout most of the SLR data reduction process. To determine the kinematic behavior of the SLR sites within this frame, standard network adjustment concepts have been applied. These concepts and the results thereof are described in the remainder of this chapter.

7.2 Interstation Geodesic Rates and Network Definitions

The transformed SL7.1 quarterly station coordinates are used in this, the final portion of the analysis. Geodesic distances between all possible tracking sites that have tracked LAGEOS in each quarter are computed via an algorithm derived by *Vincenty* [1975]. The uncertainty for each quarterly geodesic distance is calculated by propagating the formal station position uncertainty. The variation across time of the geodesic distances connecting pairs of stations provides the base information used to determine the north and east velocity components of the SLR sites. Linear changes in geodesic distances are computed using a weighted least-squares estimator. The uncertainty of each quarterly geodesic distance provides the weights used in the estimate of the slope. The algorithm yields a formal estimate of the uncertainty in the determined geodesic rate which is additionally scaled to reflect the fit of the geodesic distances to the linear model (i.e., χ^2=1 criteria is assumed yielding an uncertainty of unit weight). These slopes, or geodesic rates, are used as the "observables" to determine the station motions in a least squares network adjustment described in the following section. Although for short interstation distances there is no significant difference between changes in the length of geodesics and the chord lengths, for long distances, changes in geodesics give a more meaningful description of the relative horizontal motion between stations. The geodesic rates are used to describe the relative changes in the positions of the stations along the ellipsoidal surface which is taken to be approximately equivalent to the Earth's surface. These rates are therefore independent of all station vertical motions and their associated height uncertainties. Thus, horizontal motions within the SLR network are effectively isolated.

Two networks of stations are defined in the adjustment procedure; an "external" network of strong stations which are used for the realization of a kinematic reference system and whose motions are assumed to be known; and an "internal" network of stations whose motions are to be determined. The motions of the internal stations are estimated within a kinematic reference frame defined by the motions of the external sites within the least-squares estimation procedure. Obviously, for satisfactory closure, the adopted motions for the external stations must be consistent relatively with that observed directly by SLR.

The definition of the kinematic reference frame within a geologically compatible context is provided by the NUVEL-1 NNR model. Two SLR sites are selected to define the external network which is constrained to move with NUVEL-1 NNR motions. As was used throughout the data reduction process, the tracking stations at Maui and Greenbelt were selected as the external reference stations. Use of these sites was viable, for the geologically predicted relative motion between these sites is consistent with that deduced by SLR (e.g., the SLR rate estimate between Greenbelt and Maui is 16 ± 2 mm/yr compared to the rate predicted by NUVEL-1 of 14 mm/yr). These two stations were also chosen for additional reasons, mainly having to do with the strength of the quality and quantity of laser data collected at these sites as well as both having been in continuous operation for at least 7 years and that each station is centrally located on a major tectonic plate. The motion constraint adopted in the network adjustment differs from that used in the laser data reduction in that both the north and east components of Maui's motion are constrained.

The tracking sites which make up the internal network are listed in Table 7.1 and shown in map form in Figure 7.1. These sites are distributed globally and represent the strongest stations with the longest tracking histories presently available from CDP SLR tracking campaigns. More importantly, each internal site has a resolvable geodesic rate with respect to almost all other internal and external stations used in the adjustment. A total of 230 geodesics can be constructed between the 22 tracking sites considered here. Of these, 214 actual geodesic rates can actually be calculated based on the available data. Two subsets of the geodesic rates are defined in the

adjustment procedure. One subset contains the geodesic rates between internal and external sites, and the other subset is made up of rates between the internal sites themselves.

7.3 Mathematical Description of the Network Adjustment

The algorithm used to estimate the velocities of the tracking sites is based on similar algorithms used to determine static positions based on distance measurements. In classical terrestrial surveying, the problem falls into the class of trilateration problems. In our application, we essentially solve the problem in the same manner, whereby we have substituted geodesic rates for distances and components of motion for components of location. In

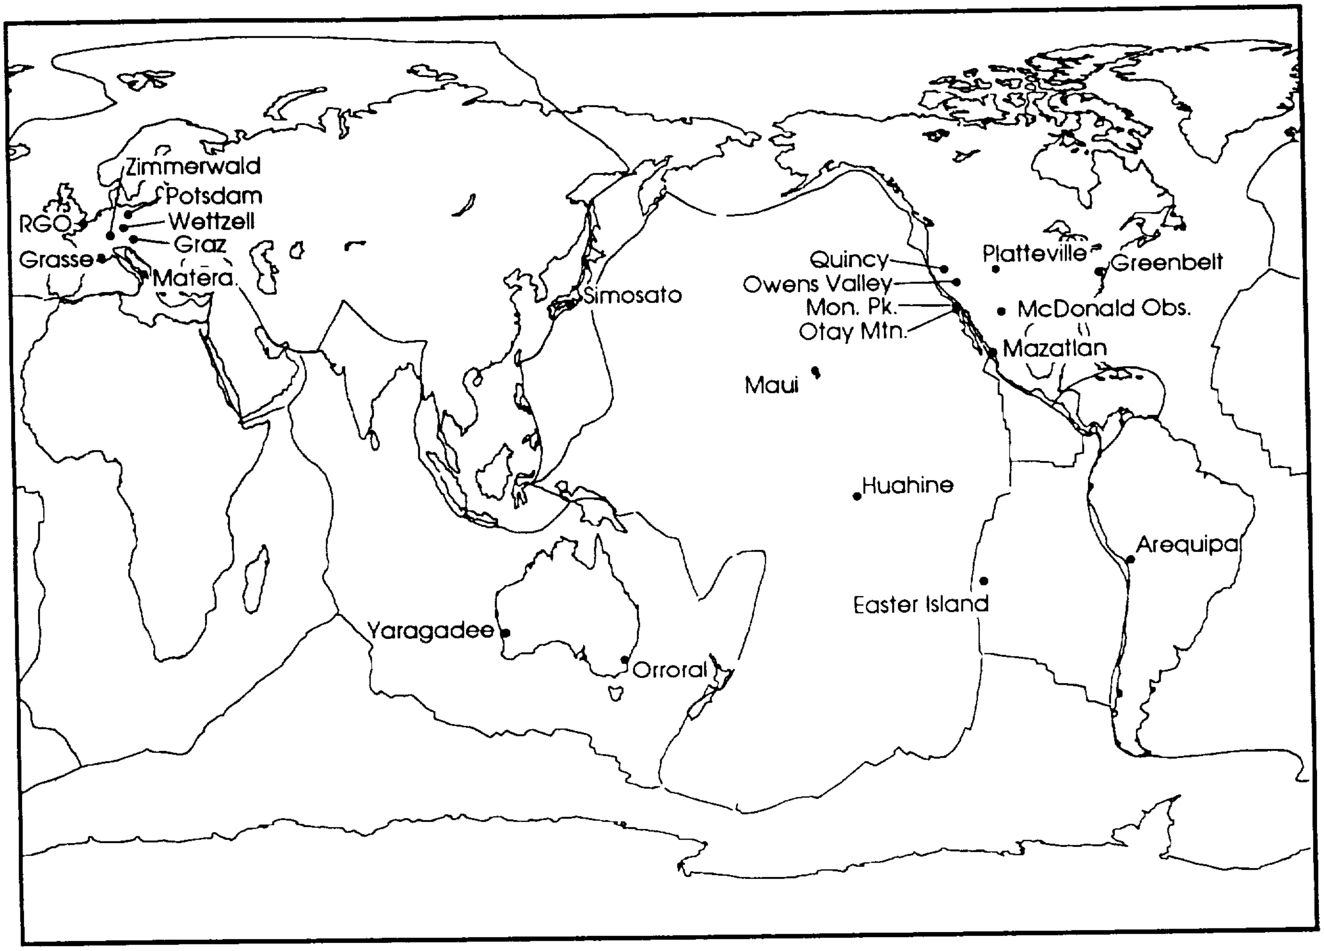

Figure 7.1 Locations of tracking sites contributing to the SL7.1 solution.

trilateration problems, the reference system is typically established by adopting a position of one of the nodes of the network and a direction toward one of the other nodes. In the same manner as described in the previous section, we have adopted the motion of two of the tracking sites. This is actually over-constraining the solution, but as mentioned above, as long as the SLR-determined motion between the constrained sites matches (to at least one standard deviation) that implied by the constraining model, the effects on the overall solution become negligible.

All geodesic rates between internal sites as well as those between internal to external sites are combined in a weighted least-squares solution which ultimately yields the unique motion vectors for each internal tracking site. Two kinds of observation equations can be written. For the external-to-internal lines the equation is written as:

$$C_{ij} = \left|\dot{X}_j\right|\cos\left(A_{xj} - A_{ji}\right) \tag{7.1}$$

where:

C_{ij} is the "observed" relative motion of the j^{th} internal site towards the i^{th} external station after the modeled motion of the external station has been removed, i.e., $C_{ij} = \dot{r}_{ij} - \dot{X}_i \cdot e_{ij}$ where $\dot{r}_{ij}$ is "observed" relative motion between external site i and internal site j, $\dot{X}_i$ is the constrained motion of the external site i, and e_{ij} is the unit vector at i toward j.

A_{xj} is the azimuth of the unknown motion vector $\dot{X}_j$.

A_{ji} is the azimuth from the internal site toward the external site.

These quantities are illustrated in Figure 7.2. The internal-to-internal lines have a somewhat similar observation equation of the form:

$$\dot{r}_{jk} = \left|\dot{X}_j\right|\cos\left(A_{xj} - A_{jk}\right) + \left|\dot{X}_k\right|\cos\left(A_{xk} - A_{kj}\right) \tag{7.2}$$

where:

$\dot{r}_{jk}$ is the observed relative geodesic rate between internal sites j and k

$\dot{X}_j, \dot{X}_k$ are the motion vectors being solved for at internal sites j and k

A_{xj}, A_{xk} are the azimuths of X_j and X_k, respectively, and

A_{jk}, A_{kj} are the azimuths of station j to k and k to j, respectively.

These terms are also illustrated in Figure 7.2.

7.4 Results from the Network Adjustment

The network adjustment is performed for 20 internal sites whereby estimates of their horizontal motions are relative to the constrained motions of the two external sites. In total, 214 geodesic distance rates (out of a possible 230) were used to determine the internal site velocities. The input geodesic rates between all pairs of stations are tabulated in Table 7.2 as well as those

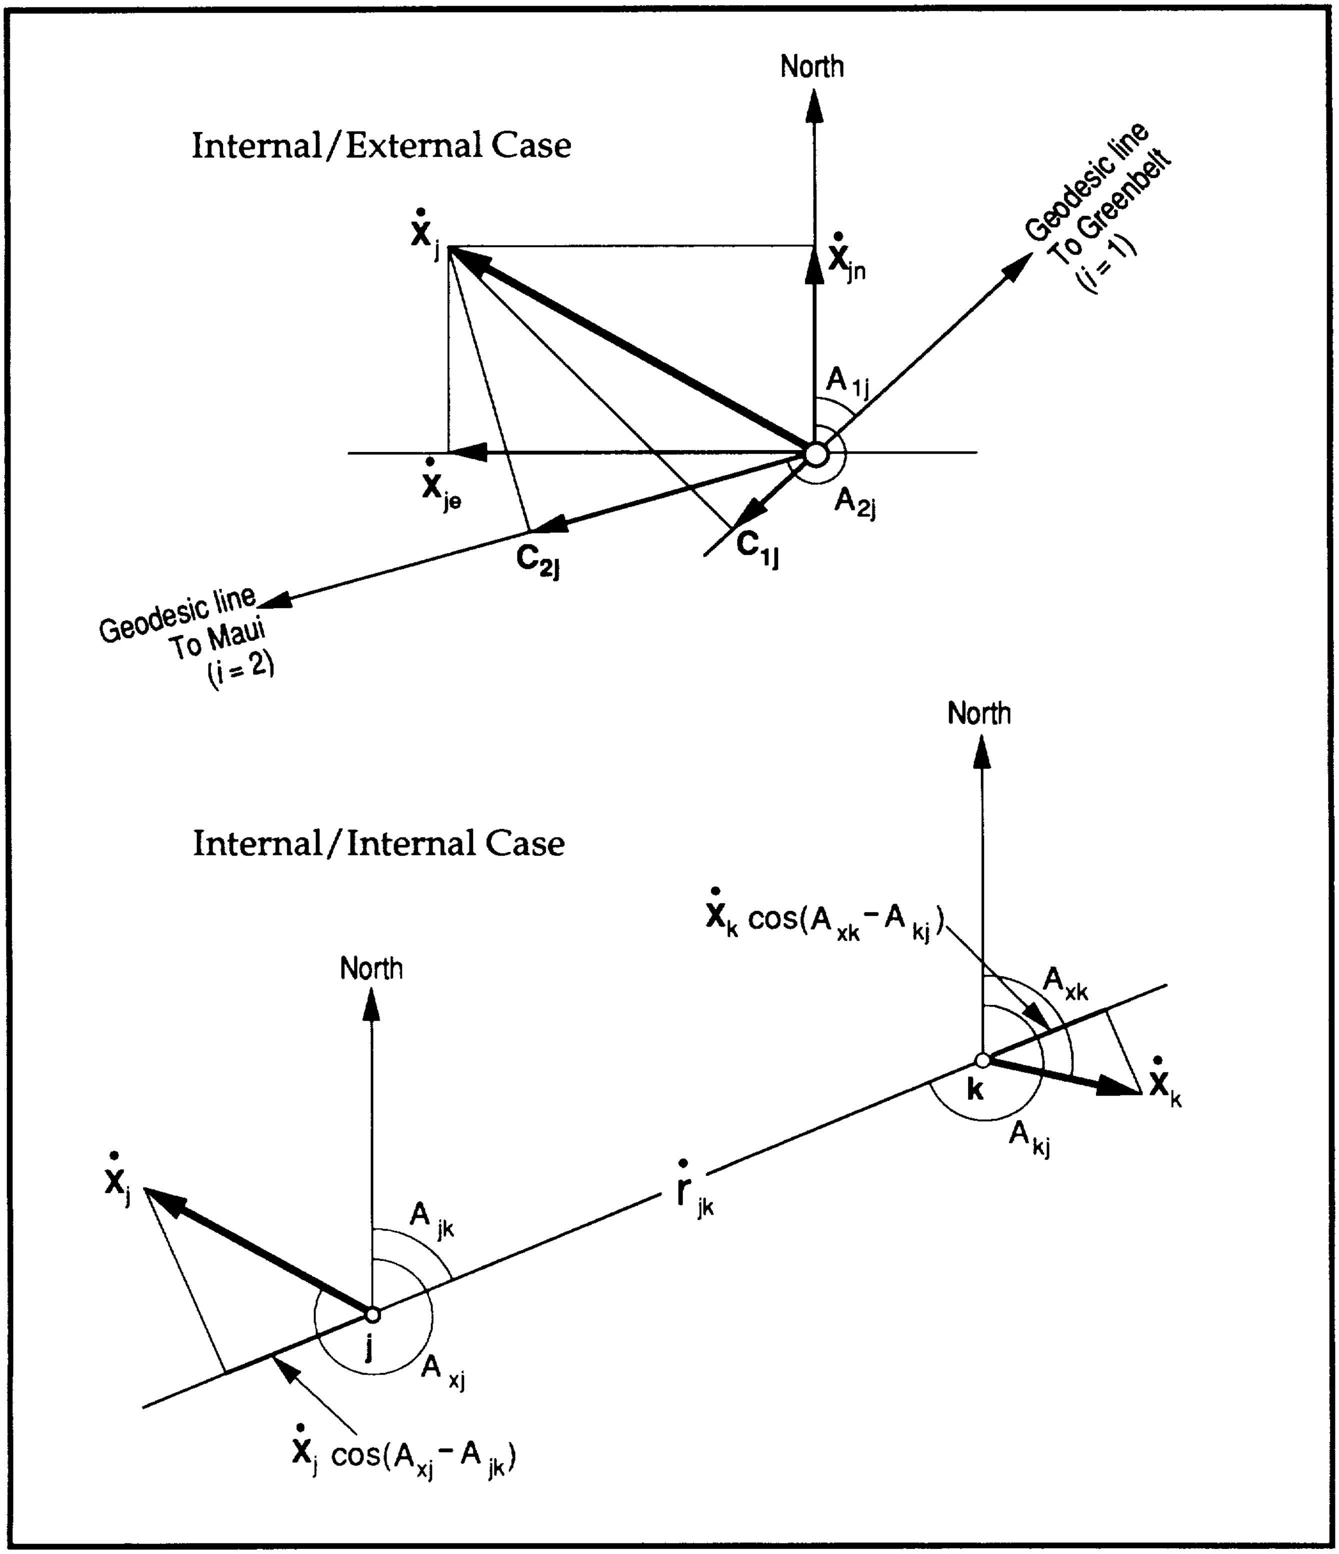

Figure 7.2 Network adjustment nomenclature used in equations (7.1) and (7.2). Top diagram illustrates the case between internal site *j* and the two external sites at Maui and Greenbelt. The bottom diagram illustrates the case between two internal sites, *j* and *k*.

inferred by the SL7.1 solved-for site velocities. Also shown on this table for reference, are the geodesic rates inferred by the geologic models NUVEL-1 and AM0-2.

The network adjustment provides estimates for the motions of the tracking sites as shown in Table 7.3. Actually, the estimated quantities are the site's northward and eastward velocity components, although in Table 7.3 we have elected to only show the direction and rate of the motions. Estimates of their errors in each component are also computed in the inversion and the error ellipse parameters are also given in the table. The overall weighted RMS of fit (or χ -squared statistic) for the complete solution is

$$WRMS = \left\{ \frac{\sum \left[\left(\dot{r}_{observed} - \dot{r}_{model} \right) / \sigma_{obs} \right]^2}{214} \right\}^{1/2} = 0.85 \qquad (7.3)$$

which indicates that the uncertainties quoted from the solution are optimistic (i.e., too large) and that good network closure has been achieved.

Geophysical interpretation of these results was the main focus of a companion paper of the present volume. The reader is advised to consult *Smith et al.* [1990b] for a comprehensive discussion of the tectonic results as well as regional anomalies and their implications with respect to current geophysical theories. Another recent global analysis of SLR-derived motions has been published by *Biancale et al.* [1991].

1. Report No. NASA TM-104549	2. Government Accession No.	3. Recipient's Catalog No.
4. Title and Subtitle LAGEOS Geodetic Analysis - SL7.1		5. Report Date September 1991
		6. Performing Organization Code 921
7. Author(s) D. E. Smith, R. Kolenkiewicz, P. J. Dunn, S . M. Klosko J. W. Robbins, M. H. Torrence, R. G. Williamson, E. C. Pavlis, N. B. Douglas, and S. K. Fricke		8. Performing Organization Report No. 91B00153
		10. Work Unit No.
9. Performing Organization Name and Address Laboratory for Terrestrial Physics Goddard Space Flight Center Greenbelt, MD 20771		11. Contract or Grant No.
		13. Type of Report and Period Covered Technical Memorandum
12. Sponsoring Agency Name and Address National Aeronautics and Space Administration Washington, D.C. 20546-0001		14. Sponsoring Agency Code

15. Supplementary Notes

D. E. Smith and R. Kolenkiewicz: NASA/GSFC, Greenbelt, MD
P. J. Dunn, S. M. Klosko, J. W. Robbins, M. H. Torrence, and R. G. Williamson: ST Systems Corp., Lanham, MD
E. C. Pavlis and N. B. Douglas: Astronomy Program, Univ. of Maryland, College Park, MD
S. K. Fricke: RMS Technologies Inc., Landover, MD

16. Abstract

Laser ranging measurements to the LAGEOS satellite from 1976 through 1989 are related via geodetic and orbital theories to a variety of geodetic and geodynamic parameters. This document explains the SL7.1 analyses of this data set including the estimation process for geodetic parameters such as the Earth's gravitational constant (GM), those describing the Earth's elasticity properties (Love numbers), and the temporally varying geodetic parameters such as Earth orientation (polar motion and ΔUT1) and tracking site horizontal tectonic motions. Descriptions of the reference systems, tectonic models, and adopted geodetic constants are provided; these are the framework within which the SL7.1 solution takes place. Estimates of temporal variations in non-conservative force parameters are included in these SL7.1 analyses as well as parameters describing the orbital states at monthly epochs. This information is useful in further refining models used to describe close-Earth satellite behavior. Estimates of intersite motions and individual tracking site motions computed through a network adjustment scheme are given. Tabulations of tracking site eccentricities, data summaries, estimated monthly orbital and force model parameters, polar motion, Earth rotation, and tracking station coordinate results are provided as appendices.

17. Key Words (Suggested by Author(s)) Geodesy, Earth Rotation, Tectonics, Crustal Dynamics	18. Distribution Statement Unclassified - Unlimited Subject Category 46
