# A New State Space Model for the NASA/JPL 70-Meter Antenna Servo Controls 

R. E. Hill<br>Ground Antenna and Facilities Engineering Section

#### Abstract

A control axis referenced model of the NASA/JPL 70-m antenna structure is combined with the dynamic equations of the servo components to produce a comprehensive state variable (matrix) model of the coupled system. An interactive Fortran program for generating the linear system model and computing its salient parameters is described. Results are produced in a state variable, block diagram, and in factored transfer function forms to facilitate design and analysis by classical as well as modern control methods.

## I. Introduction

The upgrade of the NASA/JPL $64-\mathrm{m}$ antennas to $70-\mathrm{m}$ apertures has added considerable mass and inertia moment on top of the existing alidade with resultant decreases in the natural frequencies of the structure. Because the combined compliances of the alidade and gear reducers separate the autocollimator from the antenna servo motors and tachometers, the increased inertia can affect the dynamics of autocollimator based pointing control. A study was undertaken to assess the impact on the axis servos of the increased inertia and decreased frequencies and to provide a more complete model for the new servo design. This article describes the methodology of combining the dynamics of the structure with those of the servo and cites results for both the $64-\mathrm{m}$ and $70-\mathrm{m}$ antennas.

The development of a condensed antenna structural model [1] provides a control axis referenced representation of the structure dynamics in a compact form. When integrated with the dynamic properties of the hydraulic actuators and the control electronics, the result is a more comprehensive model for
design, analysis, and simulation of the axis servos. The composite model is derived by coupling the linear differential equations describing the structure with those of the control components to produce a state variable model.

The structure model consists of a relatively large residual inertia to which are coupled individual modal inertias. For the elevation axis, two modes of the alidade structure are added. The elasticity of the control actuators, the compliance and inertia of the hydraulic system, the drive motors, and the characteristics of the servo compensation networks are also superimposed. In the most inclusive of the optional forms available, the elevation model representing five modal inertias and two alidade modes results in a nineteenth order linear system model.

The antenna pointing system employs two modes of position feedback derived from either a shaft angle encoder driven through a precision gear reducer from the bullgear, or an optical autocollimator mounted at the rear of the apex of the main reflector. The autocollimator mirror is attached to an hour
angle-declination mount on a pedestal isolated from that of the antenna. The structure model includes the transformation coefficients relating the displacement at the autocollimator reference structure to the arbitrary coordinates of the individual inertias. These coefficients enable system modeling of displacements at the autocollimator as well as at the encoder and tachometers, all of which are connected by nonzero flexibilities.

The state variable representation has one limitation in that system response properties are not evident by inspection when large system matrices are involved. For example, the existence of a pole in the right-half $s$ plane, evident in a root locus display, is not recognizable by inspection of a linear system matrix unless the matrix happens to be in a form where the eigenvalues are recognizable. The matrix form of system representation does, however, provide great flexibility to accommodate various computer processing methods. Thus, both transfer function and block diagram representations are readily derived from the open loop as well as the closed rate loop system matrices. The results are available in a variety of forms suitable for classical as well as modern control system design and analysis.

An interactive Fortran program was developed for generating the model in state variable (matrix) form. Operating on an IBM PC, the program provides options for adjustment of the complexity of the model and of various parameter values. It displays the resultant linear system matrix and computes the corresponding system poles from the eigenvalues of the system matrix. Zeros of each of the tachometer, encoder, and autocollimator responses are determined from the eigenvalues of partitioned matrices formed according to the Mason gain formula [2]. Zeros of the autocollimator response are computed from the weighted sum of encoder and individual mode zeros where the weighting factors are the transformation coefficients mentioned earlier. This indirect method was used as an expedient to avoid coding an algorithm for the more general solution of zeros of the transformed matrix.

## II. Structure Dynamics Model

The form of the condensed structure mode for the elevation axis is shown schematically in Fig. 1. In Fig. $1 \theta_{A 1}, \theta_{M}$, and $\theta_{B}$ correspond, respectively, to the angular rates of motion at the gear reducer attachment, the reducer output pinion (normalized with respect to the pinion to bullgear ratio), and the twin bullgears. The combined stiffness of the four gear reducers (two driving each bullgear) is represented by a single spring, $K_{G}$, shown connected between the pinion and the "single" bullgear. The angular rates of the individual modal inertias $\theta_{1}$ through $\theta_{N}$ have an indirect correspondence to the motion of the physical antenna. A set of dimensionless
coefficients, alpha, relate the motion of the Intermediate Reference Structure to $\theta_{1}$ through $\theta_{N}$.

While the azimuth axis of the antenna employs a single, stationary bullgear and moving gear reducers, its dynamic motion can be described using the same model as in the elevation axis. A small error results, however, because in azimuth, the reducer housing rotates with the alidade, such that in 360 degrees of azimuth motion each azimuth drive motor shaft makes $N-1$ revolutions relative to the pedestal and only $N$ revolutions relative to the alidade. The error arises because the motor torque-speed characteristic is referenced to alidade coordinates, while acceleration torque is proportional to motion in inertial coordinates. However, since the gear ratio, $N$, is large, the resulting error is negligible.

Using the coordinate definitions of Fig. 1, the equations of motion for the individual inertias, $J_{i}$, are derived. In general, a small damping, $D_{i}$, is associated with each spring, $K_{i}$.

$$
\begin{equation*}
J_{i} \ddot{\theta}_{i}+D_{i}\left(\dot{\theta}_{i}-\dot{\theta}_{B}\right)+K_{i}\left(\theta_{i}-\theta_{B}\right)=0 \quad \text { for } i=1 \text { to } N \tag{1}
\end{equation*}
$$

$$
\begin{gather*}
J_{B} \ddot{\theta}_{B}+\left(K_{G}+\sum_{1}^{N} K_{i}\right) \theta_{B}-\sum_{1}^{N}\left(D_{i}\left(\dot{\theta}_{i}-\dot{\theta}_{B}\right)+K_{i} \theta_{i}\right)=K_{G} \theta_{M}  \tag{2}\\
J_{A 1} \ddot{\theta}_{A 1}+K_{A 1} \theta_{A 1}-K_{A 1} \theta_{A 2}+K_{G}\left(\theta_{M}-\theta_{B}\right)=0  \tag{3}\\
J_{A 2} \ddot{\theta}_{A 2}+\left(K_{A 1}+K_{A 2}\right) \theta_{A 2}-K_{A 1} \theta_{A 1}=0 \tag{4}
\end{gather*}
$$

## III. Hydraulic Motor Model

A schematic representation of the hydraulic system and gear reducers is shown in Fig. 2. Each gear reducer includes two fixed displacement, axial piston hydraulic motors driving a spur gear reducer. One motor provides control and the other produces a constant value countertorque. The countertorque motors are coupled to a regulated hydraulic pressure supply and connected so as to produce opposite torque outputs from two of the four reducers. This arrangement eliminates backlash in all gear meshes except the single mesh between each control motor and the first intermediate gear. The countertorque has the added benefit of increasing the incremental torque stiffness of the reducer geartrains. Control motor modulation is provided by a four-port hydraulic servovalve interconnecting a regulated high pressure hydraulic source and return with the motors.

The dynamic model of the drive motors and hydraulic system is derived according to established practices. Because the high gain of the rate servo loop diminishes the overall effects of friction, leakage, and valve pressure variations, a comparatively simple, second order, linearized model can be justified. Neglecting leakage, the oil flow, $Q_{m}$, through the hydraulic motor is given by

$$
Q_{m}=V \dot{\theta}_{m}
$$

where $V$ is the volumetric displacement of the motor and $\dot{\theta}_{m}$ is the rotational speed at the output shaft.

Equating the fluid input power and the mechanical output power yields the relationship between motor torque, $T_{m}$, and hydraulic pressure, $P$

$$
T_{m}=P V
$$

The oil flow through the hydraulic servo valve is described by the equation of flow through a sharp edge orifice of variable size

$$
\begin{equation*}
Q_{v}=K_{v} I_{v} P_{v}^{1 / 2} \tag{5}
\end{equation*}
$$

where $P_{v}$ is the pressure drop across the valve, $K_{v}$ is the flow constant of the valve, and $I_{V}$ is the valve coil current.

The valve pressure drop equals the pressure difference between the regulated supply and the motor. Since both analytic and field test results show the steady state pressure drop is relatively constant in the range of 2000 to 2500 psi (13790 to 17238 kPa ), a piecewise linear approximation of the above orifice equation is sufficient. Transient pressure drops caused by large acceleration or high wind torque will effectively decrease the rate loop gain and increase valve damping relative to the values represented by the linear approximation. With the aid of a root locus diagram, it can be shown that the net effect on the rate loop stability is negligible.

The linearized valve equation combined with the motor and compressible flow equations is illustrated in block diagram form in Fig. 3 where $C$ and $J_{m}$ represent the hydraulic compliance and motor inertia, respectively. The valve gain and damping constants $K_{p}$ and $D$, respectively, are derived by partial differentiation of the valve flow Eq. (5) with values of $P_{v}$ and $Q_{v}$ that represent mean operating conditions. The damping parameter $D$ may be increased to include motor leakage and other equivalent sources of damping.

In rearranging the above equations to a form compatible with the structure equations, a provision for the motion of the flexible structure supporting the reducer is required. This
is accomplished by equating the motor rotation to the difference between $\theta_{m}$ and $\theta_{A 1}$ in Fig. 1. Thus by application of the Mason gain rule to the diagram of Fig. 3 and with the definition of the reducer natural frequency

$$
\omega_{m}=\left(\frac{V^{2}}{J_{m} C}\right)^{1 / 2}
$$

the gear reducer equation is obtained as:

$$
\begin{equation*}
N_{r}\left(s^{2}+\frac{D}{C} s+\omega_{m}^{2}\right)\left(\dot{\theta}_{m}-\dot{\theta}_{A}\right)+\frac{T_{x}}{N_{r} J_{m}}\left(s+\frac{D}{C}\right)=\frac{Q}{V} \omega_{m}^{2} \tag{6}
\end{equation*}
$$

where $Q=K_{p} I_{v}$ is the effective no-load valve flow and $N_{r}$ is the overall motor-to-axis gear ratio.

The large value of gear ratio $N_{r}(28700)$ permits the omission of the acceleration torque term that arises from the difference between reducer and inertial coordinates, with a small error resulting.

## IV. System Equations

Equating the reducer shaft torque, $T_{x}$, to the torque transmitted by the reducer stiffness, $K_{G}$ completes the equations defining the coupled actuation-structure system as follows:

$$
\begin{equation*}
T_{x}=K_{G}\left(\theta_{m}-\theta_{B}\right) \tag{7}
\end{equation*}
$$

To accommodate analyses of the servo rate loops as well as the position loops, and also to facilitate computation of transfer function parameters, the system equations are developed in two steps. First, the open loop linear system matrix and associated input and output vectors are derived from Eqs. (1) through (7) above. Subsequently, the closed loop system matrix is formed by augmentation of the open loop matrix by inclusion of the rate feedback and compensation gains. The system state equations are derived from Eqs. (1) through (7). above using the state variable definitions in Table 1. The variable definitions are generalized to accommodate either the azimuth or elevation axis and a variable number of structure modes, $N$. Because the azimuth structure model is based upon the assumption of a rigid pedestal, state variables corresponding to $\dot{\theta}_{A 1}$ and $\dot{\theta}_{A 2}$ are absent from the azimuth model.

It will be seen that with the exception of the third, $(2 N+5)$ th, and $(2 N+9)$ th variables, all rates and accelerations are relative to stationary coordinates. The third variable corresponds to the effective rotor-stator rotation of the hydraulic motor and of the tachometer. The $(2 N+5)$ and $(2 N+9)$ variables corre-
spond to the effective extension of the gear reducer torsional stiffness for the azimuth/elevation axes, respectively. This torsional extension is related to the reducer output torque through the stiffness parameter $K_{G}$.

The resulting state equations for the elevation axis are listed in generalized form in Table 2. Using

$$
\begin{gather*}
\dot{\mathbf{X}}=[F] X+[G] U  \tag{8a}\\
\mathbf{Y}=[H] X \tag{8b}
\end{gather*}
$$

with $\mathbf{X}$ the state vector, $\dot{X}$ the time derivative of $\mathbf{X}, U$ the system input, and $Y$ the output, the corresponding linear system matrices are listed in Table 3. The system block diagram is shown in Fig. 4. The azimuth equations, matrices, and block diagram are similar to their elevation counterparts, except the four alidade states are omitted.

## V. Derivation of Transfer Functions

The linear transfer functions relating the inputs and outputs are expressed as ratios of factored polynomials in the Laplace operator, $s$. The respective numerator and denominator factors are of the form ( $s$ - zero) and ( $s$ - pole) and are related to the system matrices through the traditional equations expressing the conditions for the poles and zeros of the response.

For system poles (denominator factors):

$$
\begin{equation*}
[s I-F]=[0] \tag{9}
\end{equation*}
$$

For system zeros (numerator factors):

$$
\left[\begin{array}{cc}
(s I-F) & -G  \tag{10a}\\
H & 0
\end{array}\right]\left[\begin{array}{l}
X(s) \\
U(s)
\end{array}\right]=[0]
$$

Equation (9) is an eigenvalue equation and the system poles are the eigenvalues of the linear system matrix. Software for eigenvalue evaluation is available for DOS microcomputers. For the more complicated case of Eq. (10) for evaluating the zeros, a more convenient method based on the Mason gain rule was employed. An advantage of this alternate method is that it reduces the dimensions of the matrices to be processed, thus improving numerical accuracy.

The method is based upon an adaptation of Mason's [2] signal flow graph gain (transfer function) determination, to state variable representations. Mason relates transfer function denominator and numerator to "determinants" of flow graphs and of certain subgraphs. It can be shown that these determinants of flow graphs are identical to the determinants of
corresponding matrices representing the equations of the graphs. Using this equivalence, the transfer function numerator thus becomes the determinant of the partitioned matrix formed by deleting from the system equations those state variables included along the forward path in a flow graph representation of the equations. Since forward paths are recognizable in system equations, this partitioning can be accomplished without actually constructing the graph. The numerator factors are thus determined from the eigenvalues of the partitioned matrix formed above.

The zeros for the autocollimator and elevation encoder output responses are computed by superposition of individual components of the respective responses. This superposition avoids both a coordinate transformation of the system matrix and also the relatively complicated application of the Mason rule to a transformed matrix. Because it involves weighted summations of characteristic polynomials with subsequent factoring, this method is subject to numerical inaccuracy as matrix size increases. Good accuracy has resulted for models including three structure modes. The accuracy of this method could be improved and its usefulness extended to more modes by frequency scaling in such a way as to reduce the numeric range of the polynomials. Using superposition, the general case for the encoder response characteristic polynomial, $P_{E}$, is given by

$$
\begin{equation*}
P_{E}=\frac{K_{G}}{J_{B}} P_{B}-\frac{K_{G}}{J_{A 1}} P_{A} \tag{10~b}
\end{equation*}
$$

where the response zeros are the roots of $P_{E} ; P_{B}$ and $P_{A}$ are the characteristic polynomials of the bullgear and alidade responses, respectively. They are the characteristic polynomials of submatrices formed according to the method described above. Equation (10b) can be applied to the azimuth axis by equating $P_{A}$ to zero.

The complexity of the elevation autocollimator response is reduced by partitioning into two smaller systems with the results combined so as to avoid processing polynomials of high order. The validity of this simplification is evident from the bullgear response submatrix formed by deleting the state variables included in the forward path between input and the bullgear rate. This submatrix is formed from the $\mathbf{F}$ matrix of Table 3 by deletion of rows and columns 1 through 4 . Since this submatrix consists of two diagonal blocks, with one block representing the alidade and the other representing the tipping structure, the eigenvalues are simply the combination of those of the individual blocks. The complete solution of the autocollimator response is the weighted superposition of the responses of the bullgear and of the individual inertias, all of which are derived from this block diagonal matrix. The zeros of the
autocollimator response are thus the roots of characteristic polynomial $P_{A C}$ defined by Eqs. (10c) and (10d):

$$
\begin{gather*}
P_{A C}=\left(P_{A}\right)\left(a_{0} P_{B B}+\sum_{1}^{N} a_{i} \omega_{i}^{2} P_{i}\right)  \tag{10c}\\
\mathbf{F}_{\mathrm{B}}=\left[\begin{array}{cc}
\mathrm{F}_{B B} & 0 \\
0 . & \mathbf{F}_{A}
\end{array}\right] \tag{10d}
\end{gather*}
$$

where polynomials $P$ are derived from their corresponding $\mathbf{F}$ matrices having the same subscripts, $\mathrm{F}_{B}$ is the bullgear response submatrix described above, and the $F_{i}$ matrices are derived from $F_{B B}$ by row, column deletion by the aforementioned principle. Coefficients $a_{0} \cdots a_{N}$ in Eq. (10c) are the transformation coefficients provided in the structure model.

The physical significance of this partitioning is explained by considering the individual uncoupled responses of the alidade and the tipping structure to a torque input applied at the elevation gear reducer. The frequencies of infinite compliance (i.e., zero stiffness) of the alidade are frequencies of bullgear response zeros and are not influenced by the tipping structure. Additional frequencies of zero bullgear response are the natural frequencies of the individual tipping structure modes and are not influenced by the presence of the alidade. The partitioning is thus valid and no loss of generality results from its use.

## VI. Closed Rate Loop Model

Modeling of the closed rate loop configuration is accomplished by extending the open loop equations and matrices to include the rate feedback and loop compensation. In both the $64-\mathrm{m}$ and $70-\mathrm{m}$ rate loops, tachometer based feedback, a lag/ lead network, and a lead/lag network are employed to obtain a high degree of stiffness at low frequency and a comparatively narrow noise bandwidth. Since the 50 Hz servovalve bandwidth is sufficiently wide to have negligible effect on loop dynamics, the rate feedback can be modeled by the two phase compensation networks and a gain parameter.

The transfer function of the tachometer-network-amplifier, servovalve cascade is:

$$
\begin{equation*}
\frac{Q(s)}{\dot{\theta}_{M}(s)}=\frac{K_{r} V}{\omega_{m}^{2}} \frac{\left(s+Z_{1}\right)}{\left(s+P_{1}\right)} \frac{\left(s+Z_{z}\right)}{\left(s+P_{2}\right)} \tag{11}
\end{equation*}
$$

The two real poles of Eq. (11) result in two additional states with the following additional state equations:

$$
\begin{gather*}
\dot{x}_{M}=-K_{r}\left(Z_{1}-P_{1}\right) x_{3}-P_{1} x_{M}  \tag{12}\\
\dot{x}_{M+1}=-K_{r}\left(Z_{2}-P_{2}\right) x_{3}+\left(Z_{2}-P_{2}\right) x_{M}-P_{2} x_{M+1} \tag{13}
\end{gather*}
$$

where

$$
\begin{aligned}
& M=2 N+6 \text { for azimuth and } \\
& M=2 N+10 \text { for elevation }
\end{aligned}
$$

For the closed loop case the equation for $\dot{x}_{4}$ becomes

$$
\begin{equation*}
\dot{x}_{4}=-\left(\omega_{m}^{2}+K_{r}\right) x_{3}-\frac{D}{C} x_{4}+x_{m}+x_{m+1} \tag{14}
\end{equation*}
$$

The closed rate loop linear system matrix is obtained by augmenting the open loop matrix of Table 3 according to Eqs. (12), (13), and (14) and is shown in Table 4.

The various transfer functions for the open and closed loop systems are compiled according to the following properties of linear systems:
(1) all transfer functions in a given system have identical poles.
(2) the zeros in any given transfer function are invariant with respect to gain changes in other parts of the system not touching the forward path under consideration.

Property (1) implies that the tachometer, encoder, and autocollimator transfer functions all have identical poles, thus eliminating a need for repeated computations. Because the loop closing gain is in a feedback path, property (2) allows the use of zeros computed for the open loop case in the closed loop transfer functions. The real zero at -2.2 , appearing in the closed loop functions, results from an electronic compensation network in the forward path.

## VII. Numerical Results

A generalized Fortran program for generating the linear system matrix and computing the corresponding poles and zeros was developed and executed on an IBM PC. The program provides options for selection of axis, display and adjustment of parameter values, and adjustment of the number of structure modes included. As the number of modes is adjusted downward, the inertia of the rejected modes is added to the residual inertia, thus maintaining accuracy of the total inertia. Results are written to disk-files in a format compatible with postprocessing programs.

The Fortran program was used to derive models for the azimuth and elevation axes of both $64-\mathrm{m}$ and $70-\mathrm{m}$ configurations. Hardware parameter values available for the four configurations are listed in Table 5. In some cases the number of structure modes modeled was reduced from the number available in order to reduce computation and data space. For the $64-\mathrm{m}$ azimuth case the 4 th mode was eliminated, for $70-\mathrm{m}$ azimuth the 5 th mode was eliminated, and for $70-\mathrm{m}$ elevation the 3 rd , 4th, and 5 th modes were merged into a weighted composite. The best estimate of structure damping ratio available is 0.003 , which was observed in factory tests of the $70-\mathrm{m}$ quadripod. Because of computation error in some of the zeros computations resulting from nonzero damping, all computations were run with zero structure damping. The introduction of appropriate damping would displace the complex zeros from the imaginary axis and cause a similar displacement of the complex poles. However, since the poles are already damped by the rate loop, the introduction of structure damping would have small effect on the overall results.

The poles and zeros of the open and closed rate loop transfer functions are listed in Table 6. In cases where inertia values other than those of Table 5 were used, the actual values are included in Table 6. Frequency response plots of amplitude vs. radian frequency for the $70-\mathrm{m}$ azimuth and elevation axes are shown in Figs. 5 and 6.

The differences between the tachometer, encoder, and autocollimator responses are due to the flexibility of the gear reducers and structure between the respective devices. In the elevation autocollimator responses, the low frequency $(2 \mathrm{~Hz}$
for $64-\mathrm{m}, 1.5 \mathrm{~Hz}$ for $70-\mathrm{m}$ ) resonant peak and subsequent rolloff result from the flexibility of the alidade. It occurs because alidade deflections in elevation are sensed by the autocollimator but not by the encoder. Both the encoder and autocollimator responses for both $64-\mathrm{m}$ axes show a high fiequency roll-off beginning at 6.7 to 7.2 Hz . For the $70-\mathrm{m}$ configuration the roll-off frequencies are nearly identical, 6.5 to 6.8 Hz . This result is explained by the fact that most of the inertia increase resulting from the upgrade is associated with the first three modes while the residual inertias are relatively unchanged.

## VIII. Conclusions

The models described have enabled the design of the rate and position servos for the $70-\mathrm{m}$ configuration with a minimum of on-site adjustment. The azimuth axis structure model, see Table 5, includes three low frequency modes at 1.27 to 1.42 Hz , a frequency roughly half that of the lowest mode in the $64-\mathrm{m}$ configuration. These modes are a cause for concern because of their low frequencies, close spacing, and relatively large associated inertias which make damping by the servo loop difficult to achieve. The presence of these modes necessitated an increase of the motor shaft mounted inertia wheels as a means of diminishing their effect on the control system.

The results summarized in Table 6 provide improved definition of the encoder and autocollimator response characteristics as compared with those based on the assumption of a "rigid" alidade structure. These results will be useful in future efforts to improve autocollimator based pointing. They do not necessitate immediate changes as a result of the upgrade.

## NOTES:

All input and output vectors have lengths equal to the dimension of the corresponding linear system matrix, $\mathbf{F}$.
The -1 in the Elevation Encoder response is in column $2 N+5$, where $N$ is the number of structure modes modeled.
Coefficients a 1. . a5 are defined as a part of the structure model. When fewer than five structure modes are modeled the a's corresponding to unmodeled modes are replaced with zero and a0 is increased an equal amount such that the sum of a $0+\mathrm{al}+\ldots \mathrm{a} N=1$ where $N$ is the number of structure modes modeled.

$$

## NOTES:

$64-\mathrm{m}$ and $70-\mathrm{m}$ azimuth models are for 90 degree elevation.
Inertia values are $\mathrm{ft}-\mathrm{lb}-\mathrm{s}^{2},\left(\mathbf{k g}-\mathrm{M}^{2}\right)$ and are referred to motor shaft.
Natural frequencies are in radians/s.
Coefficient $\mathrm{a} 0=1.0000-\mathrm{a} 1-\mathrm{a} 2-\mathrm{a} 3-\mathrm{a} 4-\mathrm{a} 5$.
