## ABSTRACT

Successful IUE observations of the equatorial sunlit atmosphere of Jupiter and Saturn have been obtained. Spectra containing atomic and molecular hydrogen and solar reflection continuum emissions have been analyzed, with the purpose of determining the long term temporal behavior of the electrolow process. Quantitative estimates have been established for the first time using a model analysis of the short wavelength region of the spectrum. Both systems show varying degrees of long term variability in hydrogen emission rate, but the time scale is too short to determine whether there is a dependence on solar cycle activity. As part of the emission modeling program, a preliminary point source spreading function for the IUE SWP instrument has been established, suggesting a wavelength dependence in spectral line width different from previous analyses. Further IUE observations are planned for both Jupiter and Saturn.

## INTRODUCTION; OBJECTIVES

### JUPITER

A question of recognized importance to the understanding of the source and flow of energy in Jupiter's atmosphere, is the long term behavior of the EUV emissions. The initial epoch for usable observations relevant to this question is ~1970. The principle reference points are rocket observations in 1968-72, Pioneer 10 (P10) and Voyager (V) spacecraft encounters in 1973 and 1979 near the times of solar minimum and maximum activity respectively, and IUE measurements beginning in 1978. Recent reanalysis of rocket observations obtained originally by Giles et al. (1976), together with the P10, Voyager, and IUE data indicate that the H<sub>2</sub> band emissions have remained relatively constant, while the H Ly $\alpha$  emission has varied in intensity by an order of magnitude (Shemansky and Judge 1986; Appendix A). The more recent IUE measurements in this series (1985-1986) which have now provided a measure of both H Ly $\alpha$  and H<sub>2</sub> emissions, with the application of spectral models, suggest that the H<sub>2</sub> bands may have increased in brightness at solar minimum whereas the H

Ly $\alpha$  values decreased. This result contrasts with H Ly $\alpha$  measurements of Uranus over the 1982-1985 period in which there is no long term variation (Clarke et al. 1986). Table 1 shows a summary of results. On this basis Jupiter exhibits a substantially larger variation at the H Ly $\alpha$  emission rate than the solar source between minimum and maximum activity. The H Ly $\alpha$  bulge phenomenon showing longitudinal variation in emission rate is unique to Jupiter. The proposed bulge mechanism (Shemansky 1985) requires particle energy deposition in the exosphere, a symptom of which is the observed equatorial H<sub>2</sub> Rydberg bands. The apparent strong variability of the H Ly $\alpha$  emission both in absolute terms and in relation to the H<sub>2</sub> Rydberg systems, is basically not understood, but it appears to imply a changing abundance of H forced primarily by variations in loss rate rather than production rate.

The April 1985 and November 1986 IUE results obtained in this program show a reduced absolute H Ly $\alpha$  intensity, but not to the extent obtained from the equivalent results near solar minimum in 1974. The analysis of the 1985, 1986 measurements also have obtained a measure of H<sub>2</sub> Rydberg brightness which may have increased relative to 1979. The reason for an apparent decreased abundance of atomic hydrogen in the face of an increase in the major dissociation source is an interesting mystery. Further investigation is required to determine the extent of the dependence on the solar cycle.

It should be emphasized that although the brightness of the strong Jovian H Ly $\alpha$  line has been monitored since shortly after the launch of IUE, little of this data can be used to establish the corresponding intensities of the H<sub>2</sub> band emissions. These emissions are complementary to the H Ly $\alpha$  intensity, providing a spectroscopic diagnostic of the dissociation and energy deposition rates. Understanding the role played by solar EUV radiation in catalyzing this emission will require knowledge of the behavior of the Ly $\alpha$  and H<sub>2</sub> band components throughout the solar cycle.

### SATURN

We propose to obtain further observations of Saturn's sunlit atmospheric emissions, on the basis of preliminary analysis of very recent measurements obtained in the 9th year IUE program on 1986

DOY 252 and 254. These results show a mean H Ly $\alpha$  brightness a factor of 5 below the value measured by Voyager 1 in November 1980. The details of the analysis indicate that the IUE and Voyager results can be directly compared as discussed below, and we conclude that the apparent change in emission brightness is real. The present result is remarkable because the disk averaged brightness of Saturn in H Ly $\alpha$  ( $0.88 \pm 0.2$  kR) is less than the mean value obtained for Uranus by Clarke et al. (1986). The Saturn disk averaged brightness in H Ly $\alpha$  radiation has not been monitored on a frequent basis so that the time scale of the variation is not well defined. Since the launch of the IUE observatory and the Voyager encounters with the outer planets it has become apparent that, contrary to our expectations, the solar UV flux contributes only a small fraction of the energy deposited in the upper atmospheres of Saturn and Jupiter (Broadfoot, et al, 1981a, Broadfoot et al., 1981b; Shemansky, 1985; Yelle, et al., 1986. Evidence for this is the high exospheric temperatures (1000 K for Jupiter, 420 K for Saturn and 800 K for Uranus), the intense, non-auroral, H<sub>2</sub> band emissions (3 kR from Jupiter and 1 kR from Saturn) and the H Ly $\alpha$  to H<sub>2</sub> band brightness ratio which indicates a high altitude, collisional source for both emissions. These developments imply that the measured solar UV flux can no longer be used as the sole input for calculations of the physical state of Saturnian and Jovian upper atmospheres. Rather, we must rely on the H<sub>2</sub> band brightness to measure the energy deposition and infer the exospheric temperature, ionization rate and atomic H mixing ratio in the upper atmospheres (Table 2 shows estimates of dissociation rates based on Voyager data). Fortunately our understanding of the properties of the H<sub>2</sub> molecule, and consequently synthetic spectra, have advanced sufficiently to allow the accurate determination of total emission brightness, energy deposition and electron temperature (given a sufficient signal to noise ratio) from the measured H<sub>2</sub> band spectrum (Shemansky et al., 1985; Shemansky, 1985). Similarly, the H Ly $\alpha$  line is produced predominantly by collisional excitation rather than resonant scattering of solar Ly $\alpha$ . The resonant scattered contribution is less than 50% on both Saturn and Jupiter [Shemansky, 1985; Yelle et al., 1986]. For this reason the H Ly $\alpha$  to H<sub>2</sub> band brightness ratio directly reflects the atomic H mixing ratio and hence the altitude of the excitation source. The H Ly $\alpha$  to H<sub>2</sub> band brightness ratio provides an important clue to the nature of the

underlying energy source and the physical state of the upper atmosphere.

The relative instability of Jupiter and Saturn in apparent abundance of atomic hydrogen must carry clues to the source process if the nature of the variability can be identified. It is not clear what the relationship to solar cycle is, because all three outer planets, Jupiter, Saturn, and Uranus according to available data show different behaviors in relation to solar activity.

## RESULTS; DISCUSSION

### JUPITER

We now have an IUE point of reference in August 1984, April 1985, and November 1986. The analysis of this data (Table 1, Figure 1) shows a moderately reduced H Ly $\alpha$  intensity, but a relative bulge amplitude roughly the same as that observed by Voyager. This appears to imply that the H Ly $\alpha$  is excited at about the same atmospheric and ionospheric density levels as in 1979. The solar reflection continuum is at the same level as that obtained by both Voyager and IUE observations in 1979 with the exception of the 1986 result which shows a value 16% larger (Table 1). H<sub>2</sub> band intensities obtained from model calculations compared to the April 1985 IUE data indicate values that are basically the same as an analysis of the Clarke, Moos and Feldman (1982) results,  $I_S (H_2 Ly\alpha+W_R) = 4.4 \pm 1.6$  kR. This value is ~45% larger than the Voyager measurement in 1979. Analysis of the November 1986 spectrum (Figure 2) gives a value  $5.4 \pm 1.7$  kR, moderately higher, than the 1985 and earlier value, but about a factor of ~ 2 larger than the Voyager value of  $I_S (H_2 Ly\alpha+W_R) = 3.0$  kR. We have proposed further IUE observations of Jupiter to extend the data base further into the solar minimum period. The additional data we are proposing to obtain here would be composed of a series of bracketed SWP exposures designed to measure H Ly $\alpha$  as well as the fainter H<sub>2</sub> features. These data would characterize the Jovian equatorial emission under solar minimum conditions. The importance of obtaining an equatorial H<sub>2</sub> emission spectrum lies in the fact that the emission is clearly unaffected by hydrocarbon absorption, and provides a direct measure of energy deposition rates.

## SATURN

We have obtained measurements of the Saturn electroglow spectrum on 1986 DOY 252 and 254 in this program. Observing conditions were remarkably good. Analysis of the data requires relatively more model analysis than is the case for Jupiter, in order to account for extinction effects, geocorona, and non uniformity of the source in the field of view.

Table 3 shows a comparison of earlier results. The corrections for foreground and background LISM contributions and foreground geocorona require model calculations that have not yet been made for the Clarke et al.(1981) observations. Moreover at the time of these observations, Saturn was not in a favorable position in respect to extinction effects in the intervening LISM. Crudely estimated extinction coefficients are given in Table 3. The measured H Ly $\alpha$  brightness from IUE is substantially lower than the V1 result, which we attribute mostly to extinction, by the interplanetary medium (ISM/IPM) partly to the analysis method, and possibly partly to variability in the source. The 1980 IUE observations are close enough to solar maximum to constitute a solar maximum reference. Observations in 1986 and 1987 will provide measurements near solar minimum, under much more favorable conditions (see Table 3 for extinction estimate in 1986).

It should be emphasized that although the brightness of the H Ly $\alpha$  line on Saturn has been monitored over much of the lifetime of IUE, little of this data can be used to establish the corresponding intensities of the H<sub>2</sub> band emissions. As we have pointed out H<sub>2</sub> emissions are complementary to the intensity of the H Ly $\alpha$  line, providing a spectroscopic diagnostic of the excitation process. Understanding the role played by solar EUV radiation in stimulating this Saturnian EUV emission will require knowledge of the behavior of both components at conditions of solar maximum and minimum. Unfortunately the observations designed to provide H<sub>2</sub> band intensities in this program have not been reduced to this extent for lack of available time (1986 DOY 252, 254) for analysis. We therefore do not have a measure of how accurately the band emissions can be measured.

The observational sequence in the last program (1986 DOY 252, 254) is shown in Table 4. The Table includes the reduction of the H Ly $\alpha$  brightness. We regard this as the best combination of

exposures required to obtain both H<sub>2</sub> band H Ly $\alpha$  and solar reflection continuum. The reflection continuum albedo is low enough that moderate changes in eddy diffusion coefficient may be detectable.

We require models of the LISM as well as the geocorona in order to properly reduce the data. We have developed a model of the geocorona for this purpose, and we have used the recent Ajello, et al. (1987) model of the LISM to take complete account of the extraneous H Ly $\alpha$  signal in the data. The result of the application of the models is shown in Table 4. This is the only IUE observational data from Saturn that has been analyzed in this way, and it will be necessary for comparative purposes to reanalyze the earlier data obtained by Clarke et al. (1981). Table 4 shows the sequence of observations with the measured H Ly $\alpha$  intensity in Col. 4. Interspersed with the Saturn observations are background data obtained 60" north of the planet. The background is composed of geocoronal and LISM components as estimated in Col. 5 and 6 of Table 4. The component of the LISM in the foreground to the planet is estimated to be 0.463 kR as given in Table 3, using the Ajello, et al. (1987) LISM model. The total LISM intensity in the look direction was 0.622 kR. Although the observed emission brightness varied from ~3.1 kR to ~1.8 kR during the sequence, most of the variation appears to be caused by the geocoronal component, and the derived Saturn emission brightness is basically constant during the sequence with an estimated mean value of  $I_{H Ly\alpha} = 0.88 \pm .2$  kR. The geometry for the 1986 DOY 252, 254 observations is ideal in the sense that the planet is essentially directly upstream from the earth relative to the bulk inflow of the LISM, so that extinction of the planetary signal is at a minimum. However, the observing geometry at the time of the Clarke et al. (1981) observations indicates a substantially larger extinction factor (Table 3). If these estimates are correct the evidence indicates that the Saturn emission brightness in H Ly $\alpha$  has varied by a factor of 5. The inference is that the abundance of atomic hydrogen on the planet must have changed significantly.

The analysis of the 1986 DOY 252, 254 data is incomplete, because there has been insufficient time to reduce line by line data to obtain estimates of the H<sub>2</sub> equatorial emission. We therefore do not have a good assessment of the uncertainties in determining H<sub>2</sub> band intensities. In contrast to

the H Ly $\alpha$  analysis described above, auroral and ring reflection components must be removed from the data in order to analyse the H<sub>2</sub> band electroglow emissions.

### DEVELOPMENT OF EMISSION MODELS

We use an H<sub>2</sub> emission model that has been employed extensively in the analysis of both Voyager observations of H<sub>2</sub> emission from Jupiter and Saturn (Shemansky and Ajello, 1983; Shemansky 1985) as well as interpretation of electron excited H<sub>2</sub> emissions in the laboratory (Ajello et al., 1984, Shemansky et al. 1985). We have developed and applied an accurate model of the IUE instrument transmission function for use with our calculations of the emission structure of the H<sub>2</sub> Rydberg systems (see accompanying report). It is composed of a convolution of a gaussian (point source) and a trapezoidal function. The FWHM of the trapezoidal function is constant as a function of wavelength. However on the basis of our analysis of a point source H Ly $\alpha$  line, and results reported by Cassatella et al. (1983), we apply a gaussian function with a linear FWHM dependence on wavelength, ranging from 3.44A at 1216A to 6.40 A at 1900 A. This analysis differs from that of Cassatella et al. at short wavelengths (see accompanying report). The instrument transmission function is clearly an important factor in the analysis of discrete structure, and the variation of the gaussian point source function measurably affects results. We use an H<sub>2</sub> emission model that has been employed extensively in the analysis of both Voyager observations of H<sub>2</sub> emission from Jupiter and Saturn (Shemansky and Ajello, 1983; Shemansky 1985) as well as the interpretation of electron excited H<sub>2</sub> emissions in the laboratory (Shemansky et al., 1985). As far as we are aware it is the most comprehensive model of H<sub>2</sub> emission employed so far.

Figure 2 shows the analysis of the November 1986 spectrum. All of the spectral components are modeled, including solar reflection continuum.

## Abstract

Analysis of the Pioneer 10 and rocket observations of disk averaged emission from the sunlit atmosphere of Jupiter indicates that the spectrally integrated EUV brightness was reduced by at least a factor of 2 relative to Voyager spacecraft observations in 1979. Most of the variation is caused by the H Ly  $\alpha$  component in the spectrum, which was reduced  $\sim 1$  order of magnitude near the time of solar minimum in 1972-1973. Although the analysis of the data does not produce entirely consistent results, the weight of evidence points to a factor of order  $\sim 2$  lower abundance of HI in Jupiter's atmosphere in 1972-1973 relative to 1979. The low emission rate in H Ly  $\alpha$  near the time of solar minimum in this proposed scenario is caused by an electroglow energy deposition rate reduced by a factor of  $\sim 3$ . The apparent reduced abundance of HI implies a reduced thermospheric temperature, even under the assumption of a constant electroglow deposition rate.

## Spectral Transmission Function

D. E. Shemansky, J. B. Holberg, and D. T. Hall

Lunar and Planetary Laboratory

University of Arizona, Tucson, AZ 85721

In the analysis of discrete emission spectra obtained with IUE, we have found that it is important to apply an accurate spectral transmission function. In the course of applying model calculations to emission spectra of the outer planets using the SWP camera we have established what we believe to be a more accurate function particularly at the shortest wavelengths. Cassatella et al. (1985) have provided a valuable analysis of the system in both the dispersive and non dispersive coordinates. Figure 6 of the Cassatella et al. (1985) paper shows a plot of the FWHM for the SWP based on point source observations in the large and small apertures, showing variation in the FWHM width of emission lines as a function of wavelength, using extracted spectra as given by the IUESIPS. Cassatella et al. suggested that resolution was at a peak in the 1300-1400 Å region, although uncertainty in the measured widths increased at the shorter wavelengths due to the poor quality of the available sources. Many of the features of major interest in outer planet atmospheric observations occur in the vicinity of the H Ly $\alpha$  line. In order to produce a better measure of the point source spreading function, we obtained a measurement of the H Ly $\alpha$  line in emission from the geocoronal background, using the small aperture. This spectrum in flux numbers is shown in Figure 1. Although the source fills the field of the small aperture, the line is assumed to be equivalent to a point source function, because

the ultimate instrumental resolution is the limiting factor at the solid angle defined by the aperture. A model calculation using a Gaussian function with  $\text{FWHM} = 3.44 \text{ \AA}$  provides an optimum fit to the line. Figure 1 shows the Gaussian curve integrated over the mean channel interval of the instrument in comparison to the observed line. The fit clearly appears to be exceptionally good. If one applies the data plotted by Cassatella et al. a value  $\text{FWHM} \sim 5.3 \text{ \AA}$  would be obtained, approximately 50% larger than the present result. On this basis with the trend shown in the Cassatella et al. data we recommend that a linear function be applied to the calculation of the FWHM values of the Gaussian shape as a function of wavelength,

$$\text{FWHM} = a \lambda + b, \quad (\text{\AA}) \quad (1)$$

$$1150 \text{ \AA} \leq \lambda \leq 2000 \text{ \AA},$$

where

$$a = 4.444 \times 10^{-3},$$

$$b = -1.984.$$

The quantity FWHM varies from  $3.44 \text{ \AA}$  (@ $1216\text{\AA}$ ) to  $6.9 \text{ \AA}$  (@ $2000\text{\AA}$ ). Figure 2 shows a plot of the proposed linear FWHM function against the data provided by Cassatella et al., and the present result at  $1216 \text{ \AA}$ . In model calculations for spectra of sources filling the SWP large aperture, we have applied a convolution of the point source function given above with a constant trapezoidal shape function having a full width at the peak of

$$\text{FWP} = 7.24 \quad (\text{\AA}), \quad (2)$$

with a value

$$\text{FWHM} = 9.96 \quad (\text{\AA}) \quad (3)$$

The parameters for the trapezoidal function have been designed to provide a best fit to the H Ly $\alpha$  line of uniform intensity filling the large aperture. Figure 3

shows a direct comparison of 1216 Å and 1800 Å monochromatic lines modeled for a uniform spatially diffuse source, illustrating the effect of the variational point source function. The spectra in this case are given in absolute units, using the IUE photometric calibration curve as it would be applied to real data. Each line is fixed at a brightness of 1R. The Figure 3 plot of differential (R/Å) brightness indicates differences in peak value of the order of 10%, the 1216 Å line being significantly narrower. Another effect that should be noted in Figure 3 is that the 1216 Å line shows a noticeable asymmetry in its shape. This is caused by the fact that the IUE calibration curve is not flat in the 1150-1300 Å region of the spectrum; the application of the calibration curve to the instrumental transmission function distorts the shape of the resultant calibrated spectrum. At 1216 Å this causes very little error in the integrated line intensity (< 1%), but model analysis should follow the procedure described here in order to accurately describe the calibrated spectrum at and below 1216 Å. The FWHM value of the 1216 Å feature in this calculation is 10.5 Å. Note that the calibration curve distorts the shape of the 1216 Å line in Figure 3 sufficiently to cause the peak in the line profile to occur ~ 1 Å shortward of the position of the source line. Attempts to adjust the wavelength scale using calibrated spectra may therefore introduce errors; such adjustments should be made to the flux number spectra prior to application of the calibration curve. From this point of view spectral analysis with or without the use of models should be done using flux number spectra, with a subsequent conversion to absolute quantities; in effect, the calibration process applies conversion factors to photons that do not match the wavelength of the conversion factor, causing distortion of the true instrumental transmission function.

We recommend that model calculations be carried out in a two stage process in which point source gaussian lines are first placed in a buffer with integration channel widths of  $\lambda \leq 0.1 \text{ \AA}$ . The buffered data is then treated as a monochromatic line source for the trapezoidal transmission function. The resultant convoluted spectrum can then be integrated to match the mean channel width of the IUESIPS data. A code for a normalized trapezoidal function integrated over user selected channel widths is given below.

## Figures

Fig. 1 A comparison of the observed and modeled profile of the Ly  $\alpha$  line in the SWP small aperture. The observed profile represents the net flux number spectrum from a 335 m exposure (SWP25630) of the geocoronal Ly $\alpha$  background.

Observed data; oooo.

Model calculation;-----.

An optimal fit to the observed data is shown calculated using a Gaussian profile with FWHM = 3.44 Å integrated over channel widths corresponding to the IUE data interval.

Fig. 2 Point Source Gaussian FWHM as a function of wavelength, recommended for use in the analysis of IUE SWP data. The formula for the linear function is given in the text.

□ - FWHM determined from Figure 1.

○ - Small aperture data from Cassatella et al.; 2-3 measurements

● - Small aperture data from Cassatella et al.; 4-9 measurements

Fig. 3 Model calculations of IUE SWP monochromatic lines at 1216Å and 1800Å, from a spatially diffuse source. The data is calibrated (R/A) using the IUE SIPS calibration function. Each line has an integrated brightness of 1 R. The line shapes are calculated using the convolution of Gaussian point source and Trapezoidal aperture function with parameters given by Eqs. (1) - (3). Distortion and shifting of the peak position of the 1216Å line is caused by the strong wavelength dependence of the calibration curve in that region of the spectrum.
