### ACKNOWLEDGEMENTS

The authors would like to thank Dr. James B. Abshire for his invaluable suggestions and assistance throughout the experiment. Many thanks are also owed to Mrs. Jan McGarry for her help in developing software and Mr. H. E. Rowe for his help in collecting the data.

This work was supported by the National Aeronautics and Space Administration Goddard Space Flight Center, under Contract NASA NSG-5049.

## 1. INTRODUCTION

The technique of using atmospheric dispersion to estimate atmospheric delay was first proposed by Bender and Owens<sup>1</sup> in 1965. Since then, many researchers have used this technique for applications in global surveying, geophysical research, and positioning.<sup>2,3,4</sup> More recently, there has been considerable interest in developing remote sensing techniques for the global measurements of temperature and pressure based on the theory of atmospheric dispersion. Gardner<sup>5</sup> has proposed a pressure measurement technique which uses a pulsed two-color laser altimeter for ranging over the ocean. The success of this technique depends on the accuracy in measuring the differential propagation time. In general, picosecond accuracy in differential arrival-time measurement is required in order to achieve millibar-level pressure measurements. In a recent paper, we have expanded the theory on differential arrival-time estimation to include speckle noise.<sup>6</sup> To demonstrate the feasibility of this technique, Abshire et al.<sup>7,8</sup> have conducted preliminary experimental studies by ranging to retro-reflectors over horizontal paths. The experimental timing accuracy was about 6 picoseconds. This corresponds to a pressure measurement accuracy of 3 millibars at nadir. In this report, we describe recent pulsed measurements of atmospheric delay obtained by ranging to the more realistic targets including a simulated-ocean target and an extended plate target. These measurements are used to estimate the expected timing accuracy of a correlation receiver system. The experimental work reported here was conducted using a pulsed two-color laser altimeter developed at NASA-GSFC.

## 2. TARGET CONFIGURATIONS

Abshire et al.<sup>7,8</sup> have done extensive experimental studies on the differential arrival time and the atmospheric delay of optical returns by ranging to retro-reflectors over the horizontal paths using the 355- and 1064-nm wavelengths. They have also performed experiments on single-color returns from an adjustable extended target over the horizontal paths to test various receiver processing algorithms as well as to identify error sources.<sup>8</sup> The experiment involved a "V"-shaped target which consisted of 14 plastic bicycle reflectors on adjustable mounts to simulate the depth-distributed specular returns from the ocean surface. The test results indicated that it is possible to resolve the returns from individual bicycle reflectors. The fluctuation of the strengths between shots in the return was believed to be caused by the combination of shot noise and speckle-induced fluctuations introduced by the target.

In an attempt to identify the different noise sources, we conducted additional experiments in March, 1983. The main objectives of these new experiments were to further study the speckle-noise effect on the received pulses and to investigate the timing performance of a correlation receiver based on the measurements which we obtained for the various target configurations. In this chapter, the detailed descriptions of the ranging path and the target configurations are furnished.

The experiment took place at NASA-GSFC during the last week of March, 1983. During the experiment, the laser pulses were transmitted over a horizontal path using a periscope mirror (Fig. 1) mounted permanently on the

roof of the laboratory. The ranging targets were located on the roof of another building at approximately the same altitude. The round-trip distance between the targets and the ranging system was 753 m.

The first target that was used in the experiment was a 36" by 1.5" flat plate covered by reflective tape. A single retro-reflector was mounted 9" in front of the plate. It was used for comparison and alignment purposes. The front view of this target is shown in Fig. 2. It should be noted that the radius of the laser footprint was on the order of one centimeter. Since the length of the plate target was 36", the amount of pulse broadening could be controlled by tilting the target surface at the appropriate angle. This configuration is a typical example of a continuous range-spread target. The amount of range spread (S) is given by

$$S = L \cos\phi , \quad (1)$$

where L is the length of the plate target, and  $\phi$  is the tilting angle between the plate target and the ray of incidence.

After a few sets of raw data for this target configuration were collected, we discovered that some of the received pulses on each data set contained only minimal energy from both the retro-reflector and the plate target. We later concluded that the plate target of 1.5" width was simply too narrow to compensate for the effect of vertical laser beam wandering. During some measurements, the turbulence steered the beam off target, which accounted for the small return energy. In order to correct this problem, a

36" by 6" flat plate was used to replace the old target. The new target is shown in Fig. 3.

The return pulses from these targets have widths of about twice the amount of range spread. Since each received pulse width is longer than the speckle correlation length, the target-induced speckle causes random small-scale fluctuation within an individual received pulse.<sup>9</sup>

The second target was a simplified version of the "V"-shaped, extended target in Abshire's experiment. In this configuration, one side of the "V" was covered by the non-reflective blanket so that the target became an array of seven bicycle reflectors with each reflector offset by 6" behind and 1" to the right of the previous reflector. Each individual reflector had a 2.5" dia. circular reflecting surface which consisted of a plastic shield on top of the numerous small cube-corner reflectors. Since the plastic shield had an optically rough surface, much of the reflected energy was scattered away from the receiving telescope so that the back-scattered signal was more difficult to detect. To overcome this difficulty, a retro-reflector was placed 9" in front of the first bicycle reflector. With this strong returned signal from the retro-reflector as a reference, it was relatively easy to locate the target return. The picture of this target is shown in Fig. 4.

In this configuration, the target array as a whole is a range-spread target, but each bicycle reflector consists of numerous non-dispersive cube-corner reflectors. As a result, the target-induced speckle will cause random fluctuations in the total received energy as well as small-scale fluctuation within each received pulse.

### 3. SYSTEM HARDWARE

A pulsed laser ranging system was constructed and developed at NASA-GSFC for the experimental two-color laser altimetry research. The objectives for building this system were both to verify the theoretical instrument performance and to determine the technical limits in measuring the atmospheric delay. This system has gone through many modifications in order to improve its performance. The block diagram of an older version of this system is shown in Fig. 5, and summaries of the nominal specifications of the laser, optical, and receiver subsystems are given in Tables 1, 2, and 3, respectively. In the new ranging system that we used throughout our experiments, the bias error in measuring the atmospheric delay was reduced by using a single detector for both the 355- and 1064-nm pulses and by reducing the magnification in the receiver optics. Both of these changes have been incorporated into the receiver design shown in Fig. 6. This subsystem has replaced the subsystem within the dashed lines in Fig. 5. Airborne experiments using this system are also planned for measurements over the ocean later this year. In the future, a dual-channel streak tube camera-based receiver system will be employed to replace the waveform digitizer which will yield a much higher time resolution. This chapter outlines the operation of the ranging system for the horizontal path experiment. Detailed descriptions of the subsystems and their performance limitations can be found in [7].

During the experiment, the mode-locked frequency-tripled ND:YAG laser transmitter produced optical pulses at 1064 nm. A small fraction (about 4%)

Table 3. Receiver Electronics

Figure 6. New receiver configuration.

of the transmitted energy was reflected by a beam splitter into the reference path to trigger the timing circuit. The remainder of the energy passed through a beam splitter and was directed over the atmospheric path to the target reflector(s). The reflected energy was collected by the telescope and was directed through a shutter into the receiver assembly. The amount of collected energy was varied from one set of data to the next by carefully controlling the effective collection area of the receiver telescope.

This system was operated in the ranging mode to measure the system delays and the atmospheric delay. The photomultiplier outputs were recorded by the Tektronix R7912 waveform digitizer. In these measurements, the time biases caused by digitizer sweep speed nonlinearities and time-walk were minimized by using specially developed calibration procedures. Normally, 200 individual measurements were recorded in this mode. The mean pulse separation time between the returns from the retro-reflector and the target and the mean flight-time reading were then computed from these data.

The waveforms of the received pulses are of principal interest in this experiment because of their applications to remote pressure measurements. In the following chapters, the detailed description of the waveform processing and the analysis of the timing performance of a correlation receiver using these waveforms are given.

#### 4. DATA PROCESSING

Several sets of returned pulses from both the plate target and the bicycle reflector array were collected. Different data sets of the same target configuration correspond to measurements taken with different receiving aperture sizes and/or at different times.

There are 200 individual waveforms of the received signals recorded in each data set. Due to the photomultiplier and digitizer time jitter, the waveforms appear to shift temporally from pulse to pulse in a random fashion. This time jitter would contribute additional error to the timing accuracy of the receiver if left uncorrected. Since we are only interested in the differential arrival time between the retro-reflector returns and the target returns, we can correct the time-jitter problems by using the peak returns from the retro-reflector as the time reference. Specifically, the time positions of the retro-reflector peak returns are first determined by using a center-of-mass algorithm. A mean peak position is then computed, and all the waveforms are aligned with respect to this mean peak position. After the waveforms in a data set are aligned, the corresponding mean, standard deviation, and the signal-to-noise ratio for that set of data are computed.

If an individual received signal is denoted by  $S(t)$ , and the mean received signal by  $\bar{S}(t)$ , then the correlation receiver estimates the arrival time according to

$$\hat{\tau}_c = \arg \max_{\tau} \left\{ \int_{-\infty}^{\infty} dt S(t) \bar{S}(t + \tau) \right\} . \quad (2)$$

In this experiment, the arrival times of the returned pulses from the plate and the bicycle reflector targets are the principal interests. Because each aligned waveform in every data set also includes the retro-reflector return of 1000 psec FWHM width which contaminates a portion of the extended target return, it is necessary to eliminate the retro-reflector returns from the waveforms before correlating. This problem of cross-over is particularly severe in the bicycle reflector returns where the separation times between the peak retro-reflector returns and the peak returns from the first bicycle reflector are only about 750 psec. In order to recover the net extended target returns, the first halves of the retro-reflector returns and their mirror images are subtracted from the return waveforms. A typical return waveform which included both the returns from the bicycle reflectors and the retro-reflector is shown in Fig. 7(a), and the same waveform after subtracting the retro-reflector return is shown in Fig. 7(b). We can see that the tail of the return from the first bicycle reflector is recovered very nicely. The pulse subtraction routine has been incorporated into the correlation algorithm. The first part of this algorithm finds the mirror image and performs the subtraction. The second part performs the correlation between the resultant mean waveform of the data and each individual resultant waveform, and locates the peak of the correlation function. This peak corresponds to the estimate of the time of arrival. The last part of the algorithm calculates the mean and the standard deviation of the arrival time. The results obtained using this algorithm are then presented in the forms of a history plot and a histogram.

The results are shown in Fig. 8 through Fig. 85. A list of different

Figure 7(a). A typical return waveform which contains both the returns from the bicycle reflector array and the retro-reflector.

## 5. DATA ANALYSIS

From the experimental results, we observe considerable fluctuations both in time and amplitude in the received signal waveforms. The main sources which contributed to random amplitude fluctuations are fluctuations in laser output energy, shot noise, speckle noise, turbulence, and random gain of the photomultiplier. The main sources of temporal fluctuations are the time jitter in the photomultiplier and waveform digitizer. As mentioned in Chapter 4, the problem of temporal fluctuation was corrected by properly aligning the waveforms using the retro-reflector returns. In this chapter, we concentrate on the problem of amplitude fluctuation and the timing performance of the correlation algorithm.

Due to the nature of the noise sources, there are different types of amplitude fluctuations presented in the laser ranging measurements. Fluctuations in laser output energy and photomultiplier's random gain contribute to fluctuations in the received energy level from pulse to pulse. The effects of turbulence and shot noise cause fluctuations in energy level and distortion of the received pulse shape. The effect of speckle noise on the extended target-returns causes both fluctuations in energy level and small-scale fluctuations within each received pulse.

The retro-reflector has an optically smooth surface, so its returns are free of speckle noise-induced fluctuations. Also, because it is a point target, the problem of pulse distortion is nonexistent. This fact is well-illustrated by referring to the recorded waveforms. In these waveforms, the retro-reflector returns have very smooth Gaussian shapes with widths

equal to the impulse response of the receiver. The variations in energy levels among them are due to other noise sources.

By comparing the returns from the extended targets with those from the retro-reflector, we find that the returns from the extended targets drop off much faster than those from the retro-reflector as the receiving aperture area decreases. This is because the optically rough surfaces of the extended targets cause the reflected beam to scatter. The portion of the scattered beam being intercepted by the receiving telescope also spreads over the entire aperture, and so any changes in the aperture area will cause the changes in the amount of received energy. On the other hand, the reflected beam from the nondispersive retro-reflector is directed right back to the receiver without much divergence, this means a total interception of the reflected beam and the spatial extent of this beam are much smaller than the area of the receiving aperture. Consequently, the returns from the retro-reflector are much less sensitive to the changes in the receiving aperture.

In the plate target configuration, the widths of the returned pulses are broadened by both range spread and curvature effects. Due to the physical size of the receiving aperture, a large number of speckle correlation cells are intercepted by the receiving telescope, or equivalently, the spatial granularity of the returns is very fine with respect to the receiving aperture diameter.<sup>10</sup> This, in turn, implies that the effects of the speckle noise-induced fluctuations are negligible. Also, because of the larger target area, the return energy from the plate target is much less sensitive to the turbulence-induced horizontal beam wandering than that from the retro-reflector. That is the reason for the higher SNR's in the plate target

returns than those in the retro-reflector returns.

The waveforms of the received pulses from the bicycle reflector array indicate very fine Gaussian-shaped structures. These correspond to the returns from the first few bicycle reflectors within the laser footprint. In addition to the distortions from overlapping, the shapes of these structures are very similar to the returns from the retro-reflector, and it is not clear if there are any speckle noise-induced fluctuations. In order to proceed with the analysis, we hypothetically assume each bicycle reflector to be a retro-reflector (speckle noise-free situation) and try to express the statistics of its returns in a form that we can compare with the experimental results. The analytical result shows that the signal-to-noise ratio of a returned signal from a retro-reflector is given by

$$\text{SNR} = \frac{1}{1/\langle N \rangle + \text{var}(\alpha)} \quad (3)$$

where  $\langle N \rangle$  is the mean received energy, and  $\alpha$  is a random proportionality factor which includes the fluctuations due to turbulence, laser output, and photomultiplier's gain. In the shot-noise limiting case, the SNR is proportional to the mean received energy. This means that, if there is no speckle noise-induced fluctuation, we expect each SNR plot to be identical to the mean pulse shape. But as the actual SNR plots indicate, the SNR's of the bicycle reflector returns drop off to a negligible level relative to the SNR's of the retro-reflector returns. From the above reasoning, we conclude that there are speckle noise-induced fluctuations in the returns from the bicycle reflector array, and these fluctuations cause the reductions in SNR.

Theoretically, the performance of a correlation algorithm in arrival time estimation is related directly to the returned signal bandwidth, the signal strength, and the number of speckle correlation cells. Since the speckle noise does not have significant contributions to the returned signals in this experiment, we shall neglect its effect on the timing performance.

The returns from the bicycle reflector array contain sharp temporal structures which correspond to high-frequency signals, and the signal strengths are reasonably high due to the specular nature of the small cube-corner reflectors. As a result, we expect reasonably good estimates of arrival times for these returns. On the contrary, the returns from the plate target contain relatively low-frequency contents, and the signal strengths are not as high because of the diffused target surface. Therefore, we do not expect the correlation receiver to perform as well in estimating the arrival times for these returns. This fact is well-illustrated experimentally by referring to the histograms of the arrival-time estimation. The results indicate that the single shot accuracy is 40 to 120 psec for the bicycle reflector configuration, while the single shot accuracy is 90 to 140 psec for the plate target configuration. The timing accuracy of the bicycle reflector configuration is of considerable interest since this configuration simulates the actual ocean surface. By averaging over 100 shots, a timing accuracy of 4 psec is achievable. This corresponds to the pressure measurement accuracy of 2 mbar. Thus, the results show that the pulsed two-color laser altimeter technique in measuring pressure is promising. Further experiments have been planned to verify the feasibility of this

technique for airborne and satellite-based applications.

## 6. CONCLUSIONS

The horizontal path ranging experiment was conducted in March, 1983 to verify the feasibility of the remote pressure measurement technique for weather modeling. The waveforms of the received signals from both the ocean-simulated bicycle reflector array and the range-spread plate target were recorded, and their corresponding arrival times were estimated using the correlation algorithm. For the ocean-simulated bicycle reflector configuration, the atmospheric delay can be measured with an accuracy of 40 psec on each laser pulse. This accuracy permits 4 psec accuracy on 100-shot averages of the receiver data. For the plate target configuration, a timing accuracy of 90 psec on each laser firing is achievable. This corresponds to a 9-psec accuracy on 100-shot averages. In order to acquire higher accuracies which are essential to applications in barometric measurements, a receiver system with better time resolution is required. A streak tube camera-based receiver system of 5-psec time resolution is planned to replace the waveform digitizer-based receiver system. Subsequent airborne experiments using this system are planned in the spring of 1984.
