APPENDICES (Cont'd)

CHAPTER I

INTRODUCTION

## 1.1 GENERAL REMARKS

Spur gears have been utilized for many years and are of great importance in transmitting power from one rotating shaft to another. To affect power transmission, two or more gears are combined in a variety of arrangements. The most common and best understood configuration is the use of two external spur gears side-by-side as shown in Figure 1. This arrangement of the gears is used in single and multiple pairs or stages, and is referred to as a parallel shaft gear transmission or "gear box". Parallel shaft gear boxes are economic in the power range 0 to 1500 KW, but become large, heavy and less economic above these power levels.

More compact arrangements are achieved with the use of an external gear inside an internal gear as shown in Figure 2. This configuration is referred to as internal gear drive and is applied for the movement of turntables, tank turrets, radar systems, and the transmission of power in wind turbines, wheel drives of off-the-road vehicles, etc. The internal gear drives can be used either as speed reducers or speed increasers.

Because of their inherently higher cost, selection of internal gear drives is predicated on the need for compactness or the opportunity of sharing components with another function in the system. Examples

of either possibility are shown in Figures 3 and 4. The radar gear reduction unit of Figure 3 is actually a combination or hybrid of external and internal gear reduction stages. The compactness of the design is obvious.

Figure 4 is an example where two functions are combined in one component. In this application the rotor of a wind turbine is supported at the inner race of a large ball bearing. Also, the inner race is used as the first stage speed increaser for the wind turbine. As shown in Figure 4, internal gear teeth at the bore of the inner race engage with the external mating gear. The mating gear is mounted at the far side of the bearing. A long drive shaft connects the first stage speed increaser to the two-stage final speed increaser. Finally, the electric generator is connected to the final speed increaser and is shown at the far side of the drive shaft. The cost of a separate bearing support for the rotor and a three-stage speed increaser is higher than the arrangement shown in Figure 4.

Other examples of internal gear arrangements can be found in epicyclic gearing (Figure 5). As can be seen, an epicyclic gear train has a central "sun" gear, several "planets" meshing with the sun and spaced uniformly around the sun, and an internal gear or ring gear meshing with the planets. The name epicyclic is derived from the fact that points on planets trace out epicycloidal curves in space. Because of the multiple use of planet gears, epicyclic gearing is the most compact arrangement of all the spur gear systems.

At present, concerted efforts are being made to increase the power-to-transmission weight ratio. These efforts are not limited to the aerospace industry alone because of the high cost of material,

labor and energy. Savings in weight normally imply less material with some savings in cost of the transmission.

Consequently, extension of the state-of-the-art in spur gearing is a continuing requirement. Unfortunately, spur gearing investigations are concentrated almost exclusively to external gears as is evident from the literature review in the next section. For example, the latest investigations utilize large scale digital computer programs to analyze external spur gearing for both static and dynamic conditions. These sophisticated computer programs for external gears help to move the analytical simulation closer to the actual behavior. Prior to this research work, no such analytical tools were known to exist for internal spur gear (ISG) drives.

The design of ISG drives was based principally on extrapolations of external gearing procedures by the American Gear Manufacturer's Association (AGMA) and the International Standard Organization (ISO). In either case, these procedures represent the technology known in the 1950's. The basic drawback of these procedures is that they are based on highly idealized relationships, which in real applications hardly exist. Thus, a multitude of safety and application factors are imposed on the procedures which can result in considerable overdesign.

CHAPTER II

LITERATURE REVIEW

As mentioned earlier the study of spur gearing is concentrated to a great extent on investigations of external spur gears. Therefore, this literature review relies heavily on the information for external spur gears in showing the progress and current status of spur gear technology. The information is presented chronologically, and in separate sections for the external and internal spur gearing respectively.

## 2.1 EXTERNAL SPUR GEARS

In 1892 Lewis[1]* used the form of the gear tooth as one of the factors in a formula for the Strength of External Gear Teeth. He related the tooth load to the material working stress using simple beam theory and developed equation (1), known as the Lewis Equation

$$W = SPFY \qquad \qquad ...(1)$$

where

W = transmitted load, lb.

S = safe working stress in material, psi

P = circular pitch, in.

F = face width of gears, in.

Y = tooth-form factor

---

*Superscripts refer to entries in references.

Lewis also recognized that the instantaneous load of the teeth was affected by the velocity of the system. Barth[10] took note of this fact and developed a formula which resulted in an adjustment of the allowable stress as follows:

$$S_d = S \frac{600}{600 + V} \qquad \ldots (2)$$

where

S = safe static stress, psi

V = pitch line velocity, fpm

This modified design stress was then used as the design stress in the Lewis Equation. Today, the American Gear Manufacturer's Association (AGMA) recommended practice for bending strength uses the Lewis Equation in modified form.

In the 1920's and the early 1930's the American Society of Mechanical Engineers (ASME) Research Committee investigated gear tooth loads and available design criteria in order to develop a unified approach to gear design. Tests were conducted by Lewis and Buckingham to determine the effects of production errors and pitch line velocity on the load capacity of gears. The resulting report indicated a procedure to determine the so-called dynamic load increment due to dynamics of gears in mesh and the error of the gear teeth. Buckingham presented the dynamic load increment calculation in his text[1] as follows:

$$F_t = F + \sqrt{F_A [2 F_2 - F_A]} \qquad \ldots (3)$$

where

$$F_2 = F [(e/D) + 1]$$

$$F_A = \frac{F_1 F_2}{F_1 + F_2} \qquad \ldots (4)$$

$F_t$ = instantaneous load, lb.

$F$ = average transmitted load (calculated from the horse-
power to be transmitted and considering the force to
act tangential to the pitch circle)

$F_A$ = acceleration load on gear teeth, lb.

$F_2$ = force required to deform the teeth the amount of the
effective error, lb.

$e$ = measured error in action (maximum), in.

$D$ = displacement of gear tooth under load F, in.

$F_1$ = force required to accelerate the masses of the gear
and pinion as rigid bodies, lb.

The instantaneous load determined by equation (3) should be less
than the safe allowable load determined from the Lewis Equation.

Probably, the most important finding by the ASME Research
Committee testing program was that most gear failures were not due
to insufficient bending strength in gear teeth. In many cases teeth
failed in wear, primarily by progressive pitting. Again, Buckingham
developed the wear equation which is used today in modified form.

Tuplin was one of the first to publish a more refined method of
determining the dynamic loads in gear teeth.[2] He considered an
equivalent spring-mass system as shown in Figure 6 that represents
gears in mesh. He states that passage of a "high" tooth through the
meshing zone is equivalent to the rapid insertion of a thin wedge
between loaded teeth of stationary gears and that the model in Figure
6 represents this condition. The mass M is determined from equivalent
masses of gears concentrated at the gear pitch circles. Spring stiff-
ness K is that of two teeth acting together and is determined from the

M

K
(CONSTANT GEAR TOOTH
MESH STIFFNESS)

e

V
Figure 6 - Tuplin's Model

static load-deflection relationship. In this model, e and V represent

the maximum pitch error and rate of insertion of the wedge (average

pitch line velocity of gears), respectively.

Tuplin's results indicate the dynamic load increment to be

$$I = \frac{Ke}{1 + 6.6(t/T)^2} \qquad \text{for } t \leq 0.3 \qquad \qquad ...(5)$$

$$I = \frac{0.815 \times Ke}{[1 + 6.6(t/T)^2]^{\frac{1}{2}}} \qquad \text{for } t > 0.3 \qquad \qquad ...(6)$$

where

I = dynamic increment of load (the load above the average

load), lb.

K = spring constant of teeth in mesh, lb./in.

e = maximum pitch error, in.

T = natural period of vibration of equivalent spring-mass

system, sec.

t = time of insertion of wedge, sec.

It is especially interesting to note that the dynamic increment

determined by Tuplin's equation has no relation to the average load

being transmitted between gears. Also, the equations do not account

for multiple tooth contact or damping in the system.

Attia[3] performed experiments to determine the actual instantaneous

load. He found that Buckingham's equation gave high values of dynamic

increment while Tuplin's equation gave values nearer to those measured.

Also, Attia's measurements illustrated sudden rises and drops in the

load curves, indicating that gearing errors caused several impacts

throughout engagement rather than smooth load transmission, and that

the maximum load did not occur at a particular phase of engagement.

From the results he inferred that the simple analyses presented by

Buckingham and Tuplin were not adequate to describe the transmitted load behavior.

Reswick[4] conducted a more rigorous analyses by including the effects of multiple tooth engagement. He also considered the effects of heavily and lightly loaded gears.

Niemann and Rettig[5] found in their test program that larger masses caused higher dynamic loads, but that as the average load became larger the effect of larger masses became unimportant. They also found that "very heavily loaded" gears showed no appreciable dynamic load increment, whereas in "lightly" and "moderately loaded" gears dynamic load increments of considerable magnitude were observed.

Harris[6] carried out a photoelastic investigation concerning dynamic loads of gears. He concluded that when spur gears are isolated from external forcing functions, the dynamic load is caused by

1.  Error in the velocity ratio measured under the working load (gears can only approach a constant velocity ratio under one deflection which depends on the applied load and profile modification).

2.  Parametric excitation due to the stiffness variation of the teeth.

3.  Nonlinearity caused by tooth separation (backlash).

Munro's[7] work in gear dynamics indicated that transients do not decay as quickly as previously thought. Hence, he strongly suggests that single tooth studies are inadequate, since essential nonrepetitious errors are considered. He found that after a tooth with error had passed through an engagement cycle, subsequent engaging teeth were affected by the preceding tooth's error.

Richardson[8] completed an analyses of static load, stress and deflection cycles of gear teeth and substantiated his results with experimental measurements. He then developed a dynamic model to predict the instantaneous load by first considering two gears in mesh as shown in Figure 7. Newton's laws of motion were applied to this physical system and then the system of equations were transformed. The model shown in Figure 8 is the result of the transformed equations. Assumptions made in order to make the problem of determining the instantaneous transmitted loads tractable were:

1. Input and output torques remain constant and the output torque is inversely proportional to the velocity ratio.

2. The total mass M of the model is determined considering the equivalent mass of the gears concentrated at the base circles of the gears.

3. Coulomb friction is considered negligible.

4. The viscous friction force $W_f$ and all other friction are considered as a single damping term.

5. The stiffness of the gear teeth is assumed to be the same for all teeth and constant.

6. Error functions act as forcing functions on the system.

7. The cam moves at the pitch line velocity of the gears.

8. Curved ends of the cam result from a "no load separation analysis" as described by Richardson. (The attempt is to make the gears engage gradually, rather than abruptly).

Two modes of dynamic operation were considered:

1. Heavily loaded gears where the relative displacement or static displacement of gears is greater than the errors

involved.

2. Lightly loaded gears where the errors are much greater

   than the relative displacement, single tooth action

   predominating.

Richardson's work, for the most part, substantiated each mode of

operation. His equations are presented in such a manner that the only

forcing functions acting on the model are error functions; however,

his error function did not allow for the condition of tooth separation.

It is felt that tooth separation is important in lightly loaded systems.

Kasuba[9] analyzed heavily loaded gears, and developed a model

similar to Richardson, but rather than using a cam and an error to

impress displacement upon the spring, he used a simulated engagement

error, s(t). His model, after conversion to a spring-mass system, is

shown in Figure 9. He also considered a planetary system and used it

both for analytical and experimental investigation. For the planetary

system he employed the model shown in Figure 10. The model representing

the planetary system accounts for the reaction of the system to errors.

This is the first attempt to consider system effects. Dynamic load

factors found by Kasuba are generally smaller than those obtained pre-

viously. He recommended that the actual contact ratio under load

should be used. The entire system of gears should be considered when

attempting to determine the instantaneous load to which teeth are

subjected. Also, the tooth stiffness should be considered a variable

accounting for multiple tooth contact.

Bollinger[10] considered tooth stiffness as a trapezoidal

function. Results of the study correlated very well the experimental

and analytical work. He found that under different running conditions,

Corresponding to a Compound Differential Gear Train Model

the trapezoidal stiffness function for the same pair of gears changed.
He determined the stiffness function experimentally and used it in his
analytical investigations.

Many investigations have been made to determine the gear tooth
deflections. Baud and Peterson[11] proposed equations for the deflec-
tion of gear teeth, considering the tooth as a cantilever beam of
variable cross section. Walker[12] deduced a formula for the deflection
of the gear tooth following an experimental investigation carried out
on one tooth fixed to a frame. Both investigations assumed the tooth
to behave as a cantilever beam fixed to a rigid wheel. Weber[13]
considered the actual shape of the tooth profile in his analysis using
strain energy techniques. He accounts for normal, shear, and bending
energy in the tooth and a small surrounding area of the gear to which
the tooth is considered attached. He also considers Hertzian deforma-
tion assuming tooth profile radii of curvature as equivalent cylinders.
Attia[14] expanded Weber's model by including the circumferential
deformation of the gear rim, and the deflection of a tooth under the
effect of loaded neighboring teeth. Further improvements were made by
Cornell[15] in the treatment of the fillet/foundation deflection. He
defined the deflection of three different fillet configurations, whereas
previous studies assumed a given fillet angle of 75°. He evaluated the
resulting compliance analysis against available test, finite element
and exact transformation analyses, and found that the calculated
compliance results agreed well with measurements. Premilhat, Tordion
and Baronet[16] determined the elastic compliance through the use of
appropriate stress functions resulting from the complex transformation
of the tooth profile. Their analysis resulted in a slightly larger

compliance than Weber's analysis. Chabert, Tran and Matis[17] made yet a different evaluation of stresses and deflection of spur gear teeth by finite element methods. Formulas were developed for a simple calculation of the maximum stresses and compared the results with ISO and AGMA standard formulas for the strength of gear teeth.

Cornell and Westervelt[18] developed a time history, closed form solution of a dynamic model of spur gear systems. Their analysis determines the dynamic response of the gear system and the associated tooth loads and stresses. The dynamic model is based on Richardson's cam model but treats the teeth as a variable spring. Included in the analysis are the effects of the nonlinearity of the tooth pair stiffness during mesh, the tooth errors, and the profile modifications. The analysis showed that tooth profile modification, system inertia and damping, and system critical speeds can affect the dynamic gear tooth loads and stresses significantly.

Kasuba and Evans[19] concluded that the gear mesh stiffness in engagement is probably the key element in the analysis of gear train dynamics. Also, the gear mesh stiffness and contact ratio are affected by many factors such as the transmitted loads, load sharing, gear tooth errors, profile modifications, gear tooth deflections, and position of contacting points.

By introducing these aspects, the calculated gear mesh stiffness can be defined as being a variable - variable mesh stiffness (VVMS). The VVMS model is an improvement over the previous periodic varying mesh stiffness which the authors[19] called fixed - variable mesh stiffness (FVMS).

They developed a large scale digitized gear model including the

VVMS method which investigates in one uninterrupted sequence the static and dynamic conditions.

An iterative procedure was used to calculate the VVMS by solving the statically indeterminate problem of multi-pair contacts, changes in contact ratio, and mesh deflections. The developed method can be used to analyze both normal and high contact ratio gearing.

The associated computer program package calculates the VVMS, the static and dynamic loads, and variations in transmission ratios, sliding velocities, and the maximum contact pressures acting on the gear teeth as they move through the contact zone.

Their findings for typical single stage external spur gear systems are:

1. The gears and the adjacent drive and load systems can be matched for optimum performance in terms of minimum allowable dynamic loads for a wide range of operating speeds.

2. Torsionally flexible design of gear bodies/hubs/rims offers an excellent means of absorbing or minimizing the geometrical errors in mesh.

3. The gear mesh stiffness and its distribution are significantly affected by the transmitted loads and tooth profile imperfections.

4. The dynamic factors can be decreased by increasing the damping and/or contact ratio. Local damping appears to be the most efficient means for decreasing the dynamic load factors.

5. The high contact ratio (HCR) gearing has lower dynamic

loads and peak Hertz stresses than the normal contact

ratio (NCR) gearing.

The studies by Kasuba and Evans provide  one of the most detailed and advanced models available at this time.

## 2.2 INTERNAL SPUR GEARS

Buckingham[1] indicated that there are almost an infinite number of forms which can be used as gear tooth profiles. However, the most common profile for transmission of power is the involute form. He developed the kinematic formulations under which involute gears transmit uniform rotary motion. The constant velocity action between such teeth is called conjugate gear tooth action. Buckingham's formulations of the conjugate gear-tooth action and interference prediction for the internal spur gear are readily applicable for present day use.

Dudley[20] further pointed out that a comparison between the internal and external spur gear sets assuming the same number of teeth produced the following advantages of the internal spur gear set:

1. Greater length of action.

2. Relative sliding of the teeth at the start and end are less.

3. Center distance is smaller and thus leads to a more compact arrangement.

4. Contact area is larger because of the mating of a concave and convex surface. This increased contact area results in larger resistance to pitting and wear. Also, the distribution of the load among more teeth decreases the intensity of the stress.

An additional advantage is derived because the tooth strength of an internal gear is greater than that of an equivalent external gear.

Dudley acknowledges that there is no AGMA standard covering internal gears. He recommends that the methods of design for the external spur gear may be applied to the internal spur gear. In light

of the obvious advantages of the internal set, it is understandable

that the external spur gear design methods would lead to a satisfactory

internal gear design. Incidentally, the available methods for external

gears that Dudley refers to are primarily based on static analysis of

the system. In this study the internal spur gear set will be analyzed

from the dynamical point of view.

Dudley also lists several disadvantages to the internal gear set.

These disadvantages can be removed by introducing more accurate and,

consequently, more costly manufacturing operations.

The first of these disadvantages is tip interference. In this

type of interference, the external gear cannot be assembled radially

with the internal gear. Only axial assembly is possible. If a shaper

cutter having a number of teeth equal to or greater than the external

gear is used to cut the internal gear, then it will cut its way into

mesh but in so doing will remove some material from the flanks of a

few of the teeth that should have been left in place for good tooth

operation. This cutting action is also known as "trimming". Such

teeth will have poor contact and will tend to be noisy.

The second problem is sometimes known as "fouling". In this

case the internal gear teeth interfere with the flanks of the external

toothed gear if there is too small a difference in numbers of teeth

between the external and internal gears.

The third problem is in the manufacture of internal gears.[21]

The necessity for the generating tool to work within the gear body

restricts cutter and machine dimensions, which in turn limits tool

accuracy, rigidity and the resultant precision. Finish grinding of the

teeth is especially difficult because of the large size of the grinding

wheel. Generally, internal gear sets are not used for precision gear trains unless the applications must utilize their unique internal features as an advantage. Examples of such applications are indicated in Section 1.1, "General Remarks".

Clearly, any detailed investigation of the ISG drives, such as this thesis work, must consider the previously mentioned findings and recommendations by Buckingham and Dudley. However, the above findings must be used in conjunction with the modern thinking of gear behavior as was indicated in the literature search for external gears. This modern thinking must include consideration of the elastic deformation of the internal gear teeth and their supporting ring structure, and dynamic analysis of the system.

To date, the number of investigations related to the elastic analysis of the internal spur gear teeth and the supporting ring are limited. Karas[22] was the first to evaluate the deflection of the internal spur gear tooth due to bending, shearing and Hertzian contact deformation. He assumed a trapezoidal shape for the tooth profile and a rigid support at the root. He did not consider any deformation of the supporting ring. Ishikawa[23] regarded the root of the gear tooth as a semi-infinite body, and then calculated the deflection due to the tooth rotation at the root of the gear tooth. He also did not consider the deformation of the ring. Hidaka[24] superimposed the above four deflections into one final tooth deflection. He then compared this deflection against a finite element representation of the tooth and portions of the ring. The boundaries of the ring portions were then fixed against translation or rotation. He concluded that the results of his four deflection relations and the finite element analyses were

similar.  Thus, he decided to use the four relations for deflection due
to bending, shear, Hertzian contact stress and rotation at the root in
the analysis of planetary spur gear systems.

The first treatment of the ring gear deflection was by Sinkevich.[25]
He replaced the ring gear with a perfect ring having an equivalent stiff-
ness.  The equivalent thickness was expressed as a function of module/
diametral pitch, whole depth of the tooth, backlash and the number of
teeth.

Hidaka[24] later compared Sinkevich's relations against a finite
element representation of the ring.  He treated the deflection as a
plane stress problem using different finite element mesh sizes and
different thickness.  Having arrived at an optimum mesh size and thick-
ness he then modified Sinkevich's deflection relations based on the
equivalent thickness concept.  However, Hidaka's final relations for
ring deflection are not applicable to the present ISG ring gear deflec-
tion investigations due to the following reasons:

1.  His investigation is for a planetary gear system in
    which the loading is symmetric around the circum-
    ference.  The ISG drive has a single point loading.

2.  He assumed thin ring relations (i.e., thickness over
    radius ratio < 1/10).  In many cases the ring gear of
    the ISG drive is a thick ring.

Hidaka also points out that the finite element method of solution for
the deflection of gear teeth requires a finely meshed model.  This
approach can quickly exhaust the capacity of the computer.

Because of the limited available information for deflections of
the ISG drives, the author of this thesis decided to utilize the

applicable and proven methods for determining the stiffness of external

gearing systems to the ISG drive. The work by Weber[13] and Attia[14]

on external gear teeth and hubs will be adapted to the internal tooth

profile and then will be used as a basis for comparison of results.

CHAPTER III

ANALYTICAL INVESTIGATION

3.1 PROBLEM FORMULATION

A comprehensive analysis of the dynamic loading in internal spur gear (ISG) drives presents a difficult task even under ideal geometry conditions because of the continuously changing interactions as the gears move through the meshing cycle. Further complications arise when the gear tooth deflections, backlash, profile errors and multiple gear tooth pair loading are introduced. The complexity of the meshing process can be illustrated by following the action of the teeth through one complete mesh cycle. Figure 11 shows the two gears at the start of the cycle where the driver engages the driven tooth at its tip. Under load the teeth deform to a noninvolute shape which changes the line of action and, thus, the loading between the teeth. Other in-plane deformations, both tangential and radial, take place in the tooth support structure, the adjacent teeth and the remaining drive train. Figure 12 depicts this deformed condition. If the deflection continues, then contact will be made between another tooth pair and an indeterminate load sharing condition is entered. Backlash or a tooth that is too thin increases the deflection slightly but in general decreases the chance of multi-tooth contact. A tooth that is too thick leads to premature engagement and jamming between teeth. A pit in the profile can cause sudden disengagement and subsequent clashing between teeth.

As the driver pushes through the mesh cycle, the loading changes from root to tip contact and finally disengagement. The unloaded teeth will regain almost all of their original shape immediately, and then completely as additional teeth become unloaded. A typical combined stiffness pattern for error free teeth is shown in Figure 13. This periodically repeating pattern will be distorted by identical profile errors in the teeth. The nonlinear dynamic process leads to instantaneous load fluctuations in the teeth even in the presence of constant external load conditions. Also, the magnitude of the load and the fluctuations are influenced by the damping effect of the lubricant, and the proximity of component natural frequencies with any of the forcing frequencies. Figure 22 shows a practical internal gear drive system model used in this study.

Having thus identified the physical problems it can be stated here that adequate mathematical tools are available for their solution. However, the capacity of the present large scale digital computers and the scope of this investigation are such that certain limitations must be imposed on the treatment of the problem. These limitations or assumptions are treated next.

3.2  ASSUMPTIONS

The following simplifying assumptions and conventions are used to make the analysis manageable and still realistic:

1.  The dynamic process is defined in the rotating plane of the gears.  The torsional stiffness of the shafts and gears in engagement, and their masses are acting in the plane.  This assumption is considered realistic because of the symmetry of the rotating axes.  Also, the out-of-plane twisting and misalignment are prevented by proper design and careful assembly procedures.

2.  Damping due to lubrication of gears and bearings are expressed as constant damping coefficients.  Their effect on the load dynamics is investigated by parametric studies.

3.  The dynamic process is investigated through several complete engagement or mesh cycles.

4.  The differential equations of motion are expressed along the instantaneous rather than the theoretical line of action of the teeth which permits evaluation of noninvolute action.

5.  The deformations of the tooth support structure and shafting are determined from equations which were developed in solid mechanics for simple shapes. For more complicated shapes the deformations have to be determined experimentally or by finite element techniques.  The computer program is structured so that the deflection values from experiment or finite

element analysis can be entered into the analysis
process by means of data sets.

6. Multi-tooth contact is determined by analyzing five
   gear tooth pairs. The central or middle tooth is used
   to establish the instantaneous position of the teeth
   and monitor their progress through a complete mesh
   cycle.

7. The presence of backlash may lead to tooth separation
   under dynamic conditions which must be accounted for
   in the analysis methodology.

## 3.3 METHOD OF SOLUTION

The purpose of this investigation is to develop an analytical method for determining the static and dynamic behavior of the ISG drive. In order to obtain dynamic information, it is first necessary to get the static supporting data. For this reason, it has been convenient to divide the investigation into static and dynamic sections. In each section, the appropriate analytical model is comprised of relations available from references in gearing, strength of material, mathematics, vibration analysis, and the publications on deflections by Weber,[13] Attia,[14] etc. In the interest of timely solutions, an attempt was made to solve for the required information directly. Where this was not possible, iterative search techniques and numerical solutions, along with suitable acceptance criteria, were substituted.

The developed analytical methods were combined in a sequence of digital computer programs which can be used on a large scale computer like the IBM 370/158 at Cleveland State University (CSU). For parametric studies, the program can be used more efficiently in three parts (modules). The first module determines the static information and stores it on a tape. The second module uses the static data to initiate the dynamic solution and then solves for the dynamic information. The third module calculates the static or dynamic tooth bending stress at the critical fillet location. In a similar fashion, the program can be further subdivided for incorporation on a mini-computer like the Hewlett-Packard 1000.

The next three sections of this report present a detailed development of the static and dynamic analysis procedures as well as a summary description of the computer program. For reference purposes, Appendix A and B contain all of the standard equations which were utilized in this investigation. Appendix C contains the computer program listings.

## 3.4  STATIC ANALYSIS

The task of the Static Analysis Procedure is twofold.  First, it must provide all of the supporting and final information needed from a static analysis of a gear system.  The analysis procedure must be structured so that the desired information is obtained efficiently. Some of the structural requirements and the needed information can be identified as follows:

1.  A suitable nomenclature for documentation and computer use.

2.  Suitable local and global coordinate systems.

3.  External and internal gear tooth profiles.

4.  Contact points between gear tooth pairs.

5.  Line of action.

6.  Contact ratio.

7.  Interference conditions.

8.  Deflection and stiffness of the teeth and their supporting structure.

9.  Load sharing among neighboring teeth.

10.  Sliding action between mating teeth.

11.  Static load per tooth pair.

Second, the static analysis must file this information for use in the dynamic and stress analyses, and for printing of selected portions of this information.

### 3.4.1  Nomenclature

The nomenclature for the static and dynamic analysis has been selected from symbols used in gearing, strength of materials, mathematics and publications by Weber, Attia, etc.  When the required

symbols were not available from these sources, special symbols were introduced to describe the particular parameters in short form.

### 3.4.2  Local and Global Coordinate Systems

Three Cartesian coordinate systems are employed in the static analysis. The first is a local system using the symbols X and Y. It has its origin at the root of each tooth. The Y-axis coincides with the tooth centerline. In all, there are ten such X-Y local coordinate systems to account for five gear tooth pairs under investigation in each gear. Transformation from one tooth coordinate in a given gear to another tooth is readily possible because of the fixed geometric relation between the teeth. These local tooth coordinate systems are used to define the discrete tooth profile locations and appropriate deflections of the teeth.

The coordinates of the second system are labeled W and Z. These systems are local to each gear and rotate with the gear. Each W-Z coordinate system is parallel to its respective X-Y system. There are ten W-Z coordinate systems also. The Z-axis coincides with the tooth centerlines.

The third system is global and fixed at the center of the internal gear. This system is identified as the U-V system. The arrangement of the three coordinate systems is shown in Figure 14. The transformations between the coordinate systems for each gear pair are:

$$W1(I) = X1(I)$$

$$W2(I) = -X2(I)$$

$$Z1(I) = RRO1 + Y1(I)$$

$$Z2(I) = RRO2 - Y2(I)$$
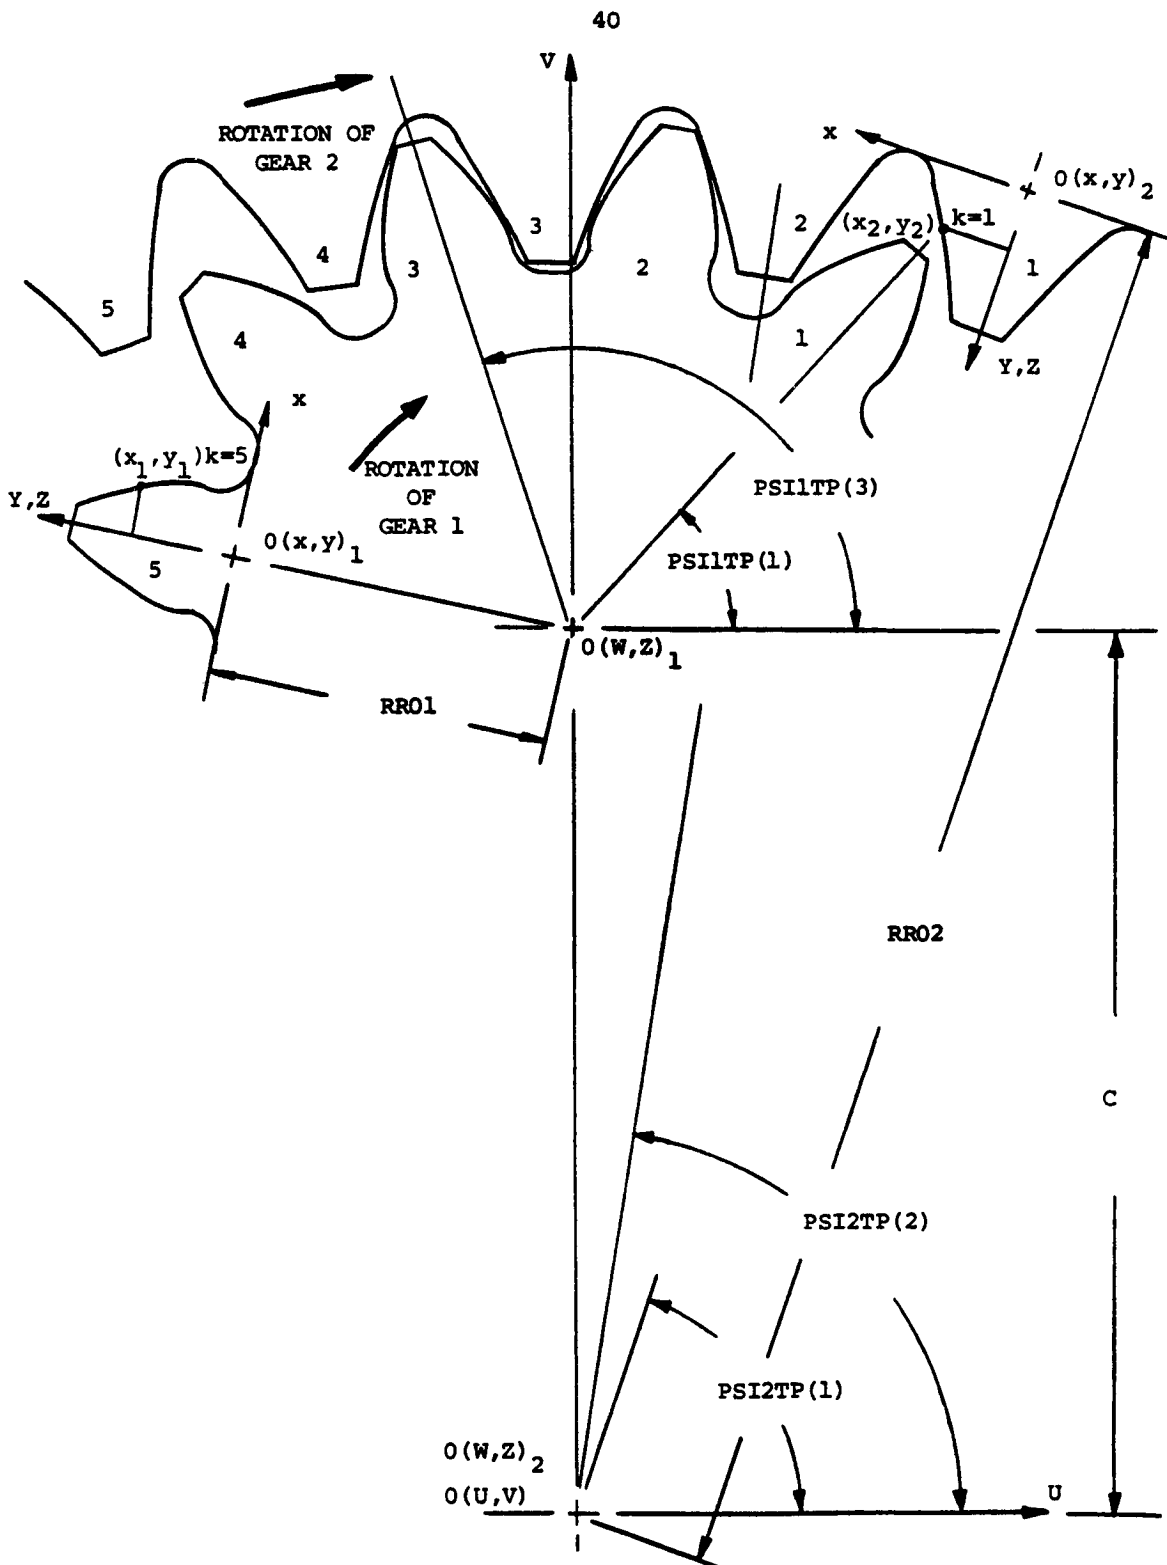

Figure 14 - Internal-External Gear Tooth
Coordinate System

$$U1(I) = W1(I) \times SIN[PSI1TP(I)] + Z1(I) \times COS[PSI1TP(I)]$$

$$V1(I) = -W1(I) \times COS[PSI1TP(I)] + Z1(I) \times SIN[PSI1TP(I)]$$

$$+ C$$

$$U2(I) = -\{Z2(I) \times SIN[PSI2TP(I) - 0.5\pi] - W2(I) \times$$

$$COS[PSI2TP(I) - 0.5\pi]\}$$

$$V2(I) = Z2(I) \times COS[PSI2TP(I) - 0.5\pi] + W2(I) \times$$

$$SIN[PSI2TP(I) - 0.5\pi] \qquad \qquad ...(7)$$

where

$I$ = gear pair 1 through 5

1 = external gear

2 = internal gear

### 3.4.3 External and Internal Gear Tooth Profiles

Development of the involute profile of a tooth follows well known geometric relations which are shown in Appendix A for convenient reference. Also shown in Appendix A are construction of the involute profile, and the respective external and internal local and global coordinates of the computer program.

In actual practice, deviations from the theoretical involute profile are introduced because of manufacturing tolerances, errors and by intent. A fourth potential source of modification is due to damage during operation. The intentional modifications are introduced to overcome the detrimental effects of profile deviations and toler- ances in the remaining system. As a rule, gears are fabricated with backlash on their teeth. Additional modifications are made to the tip to improve engagement between mating teeth, and to the root to avoid interference. Damage during operation exhibits itself as local burnishing, pits or spalling. The condition of a tooth profile can be

determined by means of a gear checker. This machine follows the tooth surface as the gear is rolled of its base circle. A moving pen and chart instrument then draws the profile as a function of the roll angle. A true involute produces a straight line and any deviation from this line is indicative of the degree of modifications and/or faults.

Thus, it is customary in gear analysis to define the profile modifications and errors by means of a profile chart. Figure 15 illustrates the relationship of the profile and involute chart for the external spur gear tooth. As indicated before, the profile modification of the tip deviates from the straight line of the true involute. A similar chart holds for the internal spur gear tooth. Figure 16 depicts samples of possible tooth profile modifications which can be used alone or in combination to simulate a large number of practical cases. Various profile modifications for the external and internal tooth are shown in Figures 17 and 18 respectively.

Analytically, the profile modifications can be expressed by means of a product consisting of the maximum amplitude of the modification and an appropriate shape function. This shape function uses the roll angle as the independent variable which can be structured so that the straight-line, parabolic, sinusoidal and pit like modifications of Figure 16 are faithfully represented. In this manner, the surface faults of a particular profile are combined with the true involute profile, as developed in Appendix A, to simulate the actual tooth shape. The X-Y coordinates of such a tooth profile from the tip to the beginning of the fillet are defined by the following general expression:
Figure 15 - Involute Chart - Profile Relationship

<u>External Tooth</u> (subscript 1 omitted)

$$X = R \ SIN\beta \ \pm \ \frac{STTM}{COS\theta} \ [\frac{RA \ - \ RAM}{RATM}] \ \pm \ \frac{PATM}{COS\theta} \ [1 \ - \ (\frac{RAT \ - \ RA}{RATM})^{\frac{1}{2}}]$$

$$\pm \ \frac{PER}{COS\theta} \ SIN \ [\pi(RAM \ - \ RA) \ \frac{CYC}{RATIP} \ + \ PAP] \ - \ DEEP$$

$$\pm \ \frac{STBM}{COS\theta} \ [\frac{RA \ - \ RAN}{RABM}] \ \pm \ \frac{PABM}{COS\theta} \ [1 \ - \ (\frac{RA \ - \ RABI}{RABM})^{\frac{1}{2}}]$$

$$Y = R \ COS\beta \ - \ RRO \qquad\qquad ...(8)$$

<u>Internal Tooth</u> (subscript 2 omitted)

$$X = -\{R \ SIN\beta \ \pm \ \frac{STTM}{COS\theta} \ [\frac{RA \ - \ RAM}{RATM}] \ \pm \ \frac{PATM}{COS\theta} \ [1 \ - \ (\frac{RAT \ - \ RA}{RATM})^{\frac{1}{2}}]$$

$$\pm \ \frac{PER}{COS\theta} \ SIN \ [\pi(RAM \ - \ RA) \ \frac{CYC}{RATIP} \ + \ PAP] \ - \ DEEP$$

$$\pm \ \frac{STBM}{COS\theta} \ [\frac{RAN \ - \ RA}{RABM}] \ \pm \ \frac{PABM}{COS\theta} \ [1 \ - \ (\frac{RABI \ - \ RA}{RABM})^{\frac{1}{2}}] \quad ...(9)$$

where

STTM = magnitude of straight line modification at tip

RA   = roll angle

RAM  = roll angle at end of modification at tip

RATM = length of tip modification in degrees of roll

PATM = magnitude of parabolic modification at tip

PER  = maximum profile error

CYC  = number of sinusoidal error cycles

RATIP= roll angle from end of modification to roll

      angle at the pitch point

PAP  = angle from start of sinusoidal error to start

      of involute

DEEP = depth of pit

STBM = magnitude of straight line modification at bottom

PABM = magnitude of parabolic modification at bottom

RABM = length of root modification in degrees of roll

RABI = roll angle at the bottom of involute

RAN = roll angle at end of modification at bottom

and the remaining parameters are defined in Appendix A. In the computer program, the tooth profile is represented by a finite number of points. The spacing between points is selected so that the segment between two points can be represented by a straight line. Depending on the size of the tooth, either one or two hundred points are used.

Thus by specifying the appropriate parameters any profile configuration of Figures 17 and 18 can be represented by equations (8) and (9) in digital form. The development of the fillet coordinates is shown in Appendix A.

### 3.4.4 Contact Points Between Gear Tooth Pairs

The location of the contacting gear teeth and the number of contacting gear tooth pairs cannot be determined directly by analytical means because of the possible presence of tooth modifications and the deformation of the loaded teeth. However, it is possible to determine the line of action, and initial and final points of contact of teeth with true involute profiles. Figure 19 shows the arrangement for an external-internal gear pair. The theoretical initial and final points of contact as shown in Figure 19 are used in this investigation as the starting points for a two step iterative search of the actual contact points as the gears rotate through a complete meshing cycle. The search for this actual contact considers first the unloaded (rigid body) motion of the gears and then repeats this search again while the gears rotate under load:
Figure 19 - Initial and Final Points of Contact, and Line
of Action of an Involute External-Internal
Gear Pair

## Step One - Rigid Body Motion

1. Transfer the local X-Y coordinates of the digitized tooth profiles to the rotating W-Z and global U-V coordinates. This transfer fixes the tooth (assumed to be the third of five) unto the respective gear and establishes the geometric arrangement between the two gears.

2. Determine the theoretical initial and final points of contact from the standard gear relations of Appendix A and the geometric arrangement of the two gears as shown in Figure 19.

3. The theoretical initial and final position of the center of the tooth are determined. The angular arc between the two angles is divided into forty-nine equal intervals. Since the true and actual positions of contact for modified involute profiles may differ, it is necessary to search for these positions. This search is accomplished by rotating each gear several intervals counter clockwise and then the proximity of each profile point of gear 1 and 2 is compared. When the proximity of any profile points of gear 1 and 2 fall within the specified acceptance criterion of |.0025| mm then actual contact is considered to be made. This search is performed at the initial and final point of contact. The angular arc is again determined and divided into forty-nine intervals. This new interval is used as the angle with which the gears will be rotated in forty-nine increments resulting in one complete mesh cycle. When the proximity of any

profile point is not acceptable, then the two gears are
rotated clockwise a fraction of an interval and a new
comparison is made until contact is found. For unloaded
teeth with true involute profiles, the contact occurs
near the theoretical point of contact. For modified
profiles, this search may continue beyond the original
theoretical point of contact. In Figure 20, the distance
$U_{11} - U_2(L)$ represents the closest distance between the
tip of the internal gear tooth and end of the involute
profile of the external gear tooth. The point $U_{11}$ is
determined from the surrounding profile points and by
using the relation between similar right triangles:

$$U_{11} = \frac{V_2(L) - V_1(J)}{V_1(J+1) - V_1(J)} [U_1(J+1) - U_1(J)] + U_1(J)$$

$$...(10)$$

The final contact position is determined in a similar
fashion except here the tip of the external gear tooth
and the end of the involute profile of the internal gear
tooth are in contact.

4. The initial and final tooth center position of tooth
number one is determined by subtracting two circular
pitches from the angular position of the third gear
tooth center. Incrementing in integral values of a
circular pitch results in initial and final positions
of teeth two through five. At this point the unloaded
initial and final positions of all five teeth of the
internal and external gear are established, and tooth
Figure 20 – Search for Initial Mesh Arc Contact

pair number three is contacting at the beginning of its mesh cycle.

5. A complete contact search for all five tooth pairs is made at fifty positions from initial through final contact of tooth no. 3. Actual contact at every mesh point for all five teeth and the contact position for tooth number three and any other teeth is recorded. At this point single or multiple tooth contact for all fifty mesh positions is determined. In case of multiple tooth contact the load will be shared between the contacting teeth. Each tooth carries a fraction of the total load proportional to its own tooth stiffness and the combined stiffness of all the contacting teeth. For the $i^{th}$ contacting tooth the shared load $Q(k)_i$ is

$$Q(k)_i = \frac{KP(k)_i}{KG_i}(Q_t) \qquad \qquad ...(11)$$

where $KP(k)_i$, $KG_i$ and $Q_t$ are the stiffness of the $i^{th}$ tooth, total mesh stiffness and total load at that mesh position respectively. Details of the methods for tooth deflection and stiffness calculations are discussed in Section 3.4.6. From these methods and knowledge of the shared load on each tooth it is now possible to determine the deflection of each tooth profile point. This completes the first search for contact assuming rigid body motion of the two gears.

Search for Contact of the Loaded Gears

1. The gear tooth deflections can be considered as another

form of tooth modification causing premature engagement

and delayed disengagement. Points A' and B' of Figure

21 demonstrate this action. Thus, by adding the tooth

deflection, the whole procedure of the first search

routine must be repeated. At the end of the procedure

the actual contact positions, mesh stiffness and static

loading for fifty positions of the total meshing arc

are determined. Also calculated are the deflections

of each profile point for all five tooth pairs at each

of fifty mesh angles.

### 3.4.5  Line of Action, Contact Ratio and Interference Conditions

The line of action of an unloaded involute tooth pair is tangent

to the base circle of gears 1 and 2, and its inclination is represented

by the theoretical pressure angle, $\phi$ (see Figure 19). Under load the

mating teeth deflect and the instantaneous line of action is no longer

tangent to both circles. The line of action will change with changes

in load, speed and position. Thus, we are concerned with the theoretical

and instantaneous lines of action (see Figure 21). Other parameters

that can be thought of as changing at any instant are pressure angles,

base radii, pitch radii, transmission ratios, etc. The net effect of

the change in line of action is to reduce the transmission ratio, TR,

or the ability to transmit the torque.

As mentioned before, the circumferential deflection of the teeth

causes premature engagement and delayed disengagement. This condition

is beneficial to the action of the gears since it increases the arc of

contact between the mating teeth. In Figure 21 the angular arcs A-B

and A'-B' represent the theoretical and instantaneous contact arcs.

PPD' = Instantaneous Pitch Radius
A = Theoretical Contact Point
A' = Actual Instantaneous Contact Point
B = Theoretical Final Contact Point
B' = Actual Final Contact Point
TLA = Theoretical Line of Action
ILA = Instantaneous Line of Action
$\delta_1$ = Deflection of Tooth at A, Gear 1
$\delta_2$ = Deflection of Tooth at A, Gear 2
RCP1 = $0_1$ - A'
RCP2 = $0_2$ - A'
RCCP1= $C_1$ - A'
RCCP2= $C_2$ - A'

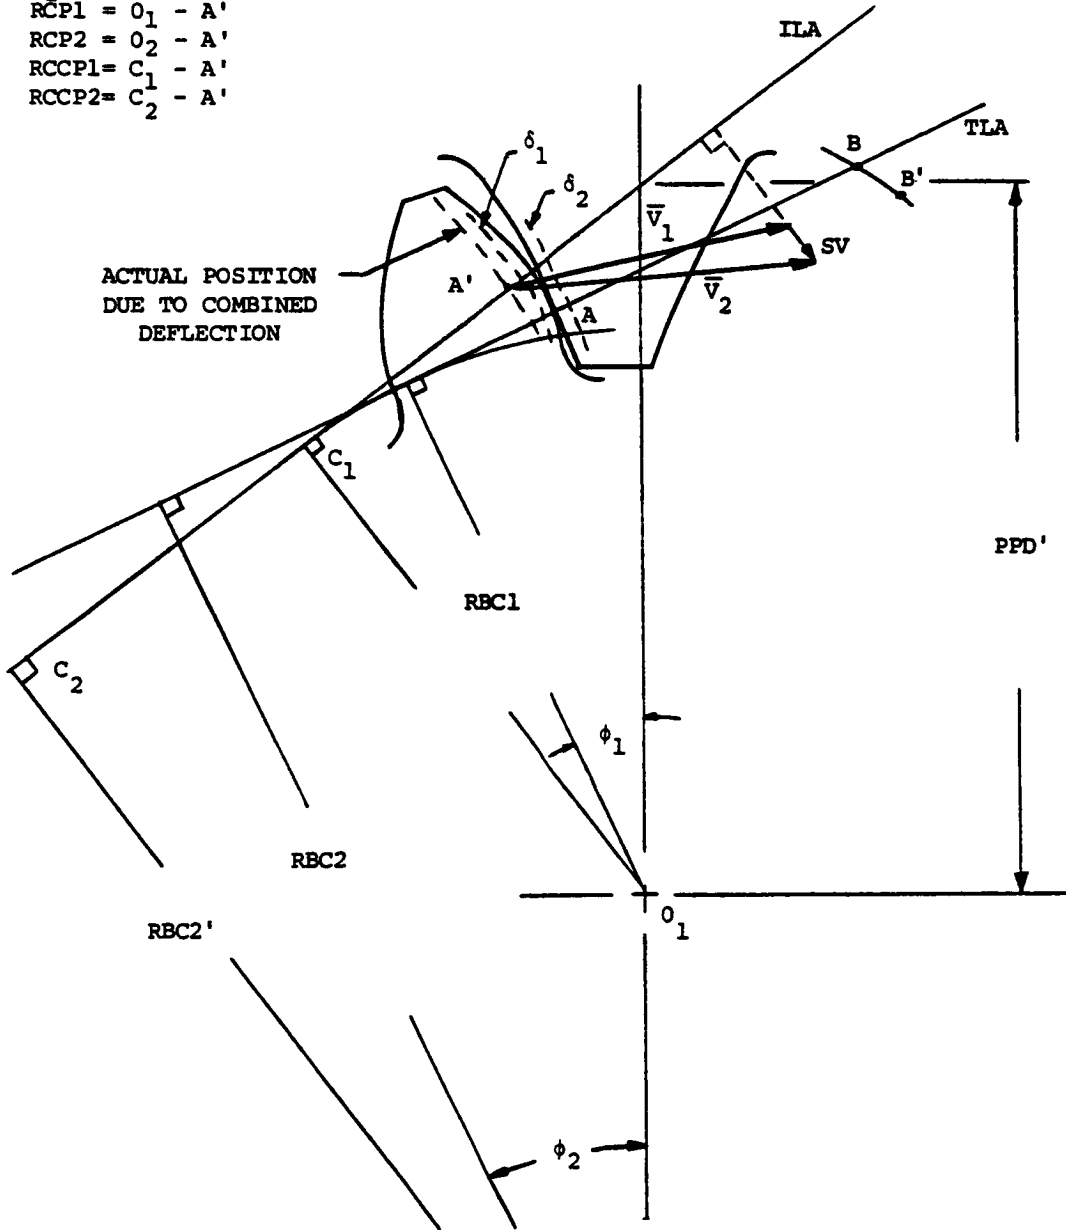

Figure 21 - Instantaneous Contact Point for Tooth Pair

Thus the loaded contact ratio, CR, for an error-less gear pair can be approximated as

$$CR = \frac{A' - B'}{p'} \qquad \qquad \dots (12)$$

where

p' = circular pitch under load

The deflection of the gear tooth under load enters into another consideration, namely, the possibility of interference. Formulae for avoiding the various interference conditions of external-internal involute gears have been derived from unloaded gears in terms of limit radii or angles. For the loaded condition the deflection of the teeth may increase the potential for interference. Thus, it is necessary to conduct two interference calculations using the ideal and instantaneous gear geometries.

Of course, any deviation from the involute action will increase the amount of sliding action between the teeth.

### 3.4.6 Deflections and Stiffness of the Teeth and Their Supporting Structure

When the teeth of a pinion and gear come into contact, transmission of load causes deflections in the gearing system as indicated in Figure 12. For the external-internal gear combination the overall deformation may be sufficiently large to influence the mesh characteristics and, thus, affect the static and dynamic behavior of the gear system. The actual deflection may be considered to consist of the summation of several deflection components starting with the Hertzian deformation at the contact point and extending into the foundation of the system. For the dynamic analysis it is necessary to consider inertial and damping effects as well which can best be treated by

subdividing the gearing system into smaller parts of masses, dampers and springs. In the context of this system subdivision, the deflections pertaining to the contacting gear teeth are radial and circumferential. The radial component is due to the radial deflection of the support bearings and shafts and the internal gear ring. The radial deflection of the pinion is negligible due to its rigid construction. Expressions for the radial deflection of bearings and shafts are readily available from standard textbooks.[26][27] A listing of deflection equations of bearings suitable for the ISG drives is given in Appendix B. The radial deflection of the ring gear is not as readily available because of its single point loading and complex geometry (see Figure 3). In general, experimental means or three-dimensional finite element analysis must be resorted to for an accurate assessment of the deflection. However, these measures may not be needed for the ISG drive because it is usually designed to minimize radial deflection. In Figure 4, the support bearing for the ring has been placed directly over the load preventing radial deformation of the ring. In Figure 3, the ring thickness over the internal gear teeth is heavy causing nearly rigid body loading of the outer cylindrical section. For this configuration a worst case condition can be assumed to occur as outlined in Appendix B-2. The worst case solution of Appendix B-2 is then used to evaluate the performance of the gears. Because of the rigid design, the radial deflections are held to the same order of magnitude as the circumferential deflection. Nevertheless, the radial deflection causes radial movement of the gears with a resulting reduction in contact length of the gears.

For a given design, selection of the appropriate bearing deflection equation from Appendix B-1 and bracketing of the ring deflection

leads to a combined radial deflection as follows

$$\delta_R = \delta_{REB} + \delta_{RIB} + \delta_{RES} + \delta_{RR} \qquad \dots(13)$$

where

$\delta_{REB}$ = deflection of external gear bearing

$\delta_{RIB}$ = deflection of internal gear bearing

$\delta_{RES}$ = deflection of external gear shaft

$\delta_{RR}$ = deflection of ring

The deflection along the gear circumference is due to Hertzian deformation, bending, shear, compression and rotation of the teeth at their root, and due to torsion of the pinion and gear ring.

The combined external-internal gear tooth pair deflections can be expressed in the following form:

$$\delta(k)_i = \delta_E(k)_i + \delta_I(k)_i + \delta_H(k)_i \qquad \dots(14)$$

where

$\delta_E(k)_i$ = deflection of the $k^{th}$ tooth of the external gear at mesh arc position i

$\delta_I(k)_i$ = deflection of the $k^{th}$ tooth of the internal gear at mesh arc position i

$\delta_H(k)_i$ = localized Hertzian deformation at the point of contact

For the contacting pairs, the gear tooth deflections $\delta_E(k)_i$ and $\delta_I(k)_i$ incorporate a number of constituent deflections. For the external gear:

$$\delta_E(k)_i = \delta_{ME}(k)_i + \delta_{SE}(k)_i + \delta_{NE}(k)_i + \delta_{BE}(k)_i + \delta_{RE}(k)_i$$

$$\dots(15)$$

In equation (15),

$\delta_{ME}$ = gear tooth deflection due to bending moment

$\delta_{SE}$ = gear tooth deflection due to shear force

$\delta_{NE}$ = gear tooth deflection due to normal force

$\delta_{BE}$ = gear tooth deflection due to deformation of
the surrounding hub area (rocking action)

$\delta_{RE}$ = gear tooth deflection due to torsion of the
rim or hub (circumferential deformation of hub)

For the internal gear, the deflection for the $k^{th}$ tooth pair at mesh arc position i is

$$\delta_I(k)_i = \delta_{MI}(k)_i + \delta_{SI}(k)_i + \delta_{NI}(k)_i + \delta_{BI}(k)_i + \delta_{RI}(k)_i$$

$$\dots (16)$$

where

$\delta_{MI}$ = gear tooth deflection due to bending moment

$\delta_{SI}$ = gear tooth deflection due to shear force

$\delta_{NI}$ = gear tooth deflection due to normal force

$\delta_{BI}$ = gear tooth deflection due to deformation of
the surrounding ring area (rocking action)

$\delta_{RI}$ = gear tooth deflection due to torsion of the
supporting ring (circumferential deformation
of the ring)

Expressions for the constituent deflections of the external gear have been derived by strength of material techniques [13]

In this investigation, the same methods have been applied to the internal gear. A detailed account of all the circumferential deflections in the ISG drive is shown in Appendix B-3

The circumferential deformations of the hub and ring affect the deflections on all teeth whether they are loaded or not. Thus, if the rigid body contact search of Section 3.4.4 does not find contact between

two teeth, it is possible that the two unloaded teeth would be declared in contact in the second contact search as a result of the attendant circumferential deformation. In this case, the final load sharing and deflections will be recalculated on the basis of this additional contacting tooth pair.

Both the radial and circumferential deflections affect the mesh stiffness and contact ratio characteristics. The radial deflection primarily affects the contact ratio and to a smaller degree the stiffness value. The circumferential deflection has a much more significant influence on the mesh stiffness. These effects are shown in Figures 26 & 29.

Thus, for any mesh arc position i, the calculated $k^{th}$ gear tooth pair stiffness $KP(k)_i$, mesh stiffness $KG_i$, and load sharing incorporate the effects due to manufactured profile errors, profile modifications, and radial and circumferential deflections by means of the iterated numerical solutions of equations (13) through (18).

The individual gear tooth pair stiffness can be expressed as

$$KP(k)_i = \frac{Q(k)_i}{\delta(k)_i} \qquad \ldots (17)$$

If the effective errors prevent contact, $KP(k)_i = 0$.

The sum of gear tooth pair stiffnesses for all pairs in contact at position i represents the variable mesh stiffness KGP

$$KGP_i = \sum_1^K KP(k)_i \qquad \ldots (18)$$

The load carried by each of the pairs moving through the mesh arc in the static mode can be determined as

$$Q(k)_i = \frac{KP(k)_i}{KGP_i} (P) \qquad \ldots (19)$$

where P is the total normal static load carried by the gears at any mesh position in the static mode

$$P = \sum_{1}^{K} Q(k)_i \qquad \ldots (20)$$

The static analysis thus described determines the variable mesh stiffness (KGP), transmission ratios (TR), and the contact position vectors (RCP1, RCP2, RCCP1, as shown in Figure 21) for subsequent dynamic calculations.

## 3.5 DYNAMIC ANALYSIS

The gear train shown in Figure 22 was modelled for the dynamic solution. This gear train is found in practical applications like turbine driven pumps, motor driven tank turrets or wind turbines as in Figure 4. The model consists of input and output devices, the external-internal gear transmission and interconnecting shafts and bearings. The analysis considers constant input and fluctuating output torque, damping in shafts, gears and bearings, backlash, noninvolute action caused by deflections and tooth modifications, and loss of contact between gear teeth. The coordinate system used in the static analysis is used also in the dynamic analysis. The instantaneous parameters which were determined for the fifty mesh arc positions in the static analysis will be combined with the equations of motion for the dynamical solution of the system.

For the model of Figure 22, the differential equations of motion can be given in the following form:

$$J_D \ddot{\theta}_D + C_{BD} \dot{\theta}_D + C_{B1} \dot{\theta}_D + C_{DS}(\dot{\theta}_D - \dot{\theta}_2)$$

$$+ K_{DS}(\theta_D - \theta_1) = T_D \qquad \qquad \ldots(21)$$

$$J_{G1} \ddot{\theta}_1 + C_{B2} \dot{\theta}_1 + C_{DS}(\dot{\theta}_1 - \dot{\theta}_D) + K_{DS}(\theta_1 - \theta_D)$$

$$+ [CGP_i (RBC1 \dot{\theta}_1 - RBC2' \dot{\theta}_2) + KGP_i (RBC1 \theta_1$$

$$- RBC2' \theta_2)] RBC1 = 0 \qquad \qquad \ldots(22)$$

$$J_{G2} \ddot{\theta}_2 + C_{B3} \dot{\theta}_2 + C_{B4} \dot{\theta}_2 + C_{LS}(\dot{\theta}_2 - \dot{\theta}_L)$$

$$+ K_{LS}(\theta_2 - \theta_1) + [CGP_i (RBC2' \dot{\theta}_2 - RBC1 \dot{\theta}_1)$$

$$+ KGP_i (RBC2' \theta_2 - RBC1 \theta_1)] RBC2' = 0 \qquad \ldots(23)$$

$$J_L \ddot{\theta}_L + C_{BS} \dot{\theta}_L + C_{BL} \dot{\theta}_L + C_{LS}(\dot{\theta}_L - \dot{\theta}_2) + K_{LS}(\theta_L - \theta_2)$$

$$= - T_D \times TR' = - T_L(TR') \qquad \ldots(24)$$

Importantly, the equations of motion are based on the instantaneous rather than the theoretical line of action. In equation (24), the load torque is written as a function of the instantaneous transmission ratio TR'. The bracketed terms in equations (22) and (23) represent the dynamic gear mesh force which is dependent on the dynamic displacements of the engaged gears, gear mesh stiffness and damping in the mesh.

The mesh stiffness, $KGP_i$ in equations (22) and (23), represents the combined effects of gear tooth profile errors and modifications, radial and circumferential deflections of the gear teeth, sharing of the load between teeth, height of engagement, and the angular position in the gear mesh cycle. Representative mesh stiffness cycles are shown in Figures 26 and 27. For a constant input torque, the variable mesh stiffness and the changes in transmission ratio due to noninvolute action represent major sources of dynamic excitation. The output torque, $T_L$, is a function of the input torque, the instantaneous transmission ratio and losses in the system.

During operation of the system in Figure 22, the dynamic excitation sources can create situations during which momentary disengagement of the mating gear teeth can occur. The information whether separation takes place can be obtained by reviewing the equations of motion.

The term $(RBC1 \, \theta_1 - RBC2' \, \theta_2)$ represents the relative dynamic displacement of gear 1 and 2. Considering that gear 1 is the driving gear, the following situations can occur:

64

Figure 22 - Internal-External Gear Train Used in the Dynamic Analysis

When    $RBC1\ \theta_1 > RBC2'\ \theta_2$

we have    normal operation of the gear system and the dynamic mesh

force is defined by

$$(QDT)_i = CGP_i(RBC1\ \theta_1 - RBC2'\ \theta_2)$$

$$+ KGP_i(RBC1\ \theta_1 - RBC2'\ \theta_2) \qquad \ldots(25)$$

If    $RBC2'\ \theta_2 \geq RBC1'\ \theta_1$ and $RBC2'\ \theta_2 - RBC1\ \theta_1 < BGM$

then the gears will separate and contact between the gears will be

lost.  For this case,

$$(QDT)_i = 0 \qquad \ldots(26)$$

If    $RBC2'\ \theta_2 > RBC1\ \theta_1$ and $(RBC2'\ \theta_2 - RBC1\ \theta_1) > BGM$

$$(QDT)_i = CG_i(RBC1\ \theta_1 - RBC2'\ \theta_2)$$

$$+ KGP_i[(RBC1\ \theta_1 - RBC2'\ \theta_2) - BGM] \qquad \ldots(27)$$

in this case, gear 2 will hit gear 1 on the backside.

Also when $KGP_i = 0;$  $(QDT)_i = 0$

An example of zero stiffness can be obtained from a pit extending

across the tooth profile.

The equations of motion (21) through (24) contain damping terms

for all components in the system.  For this investigation, the damping

in the bearing nearest the driving or driven element has been combined

with the respective damping of those elements.  Damping in the shafts

is due to material damping which, by experiment,[29] has been found to

be between 0.005 and .007.  Expressed as a critical damping ratio, a

representative value of .005 has been assigned for the shafts.  For the

shafts, the effective damping is then

$$C_{DS} = 2\xi_S \sqrt{\frac{K_{DS}}{\frac{J_D + J_{G1}}{J_D \times J_{G1}}}} \qquad \ldots(28)$$

$$C_{DS} = 2\xi_S \sqrt{\frac{K_{LS}}{\frac{J_L + J_{G2}}{J_L \times J_{G2}}}} \qquad \ldots(29)$$

where

$\xi_S$ = critical damping ratio

= .005

and the shaft masses are lumped into the masses $J_D$, $J_{G1}$, $J_{G2}$ and $J_L$.

Also, the effective damping of the gear mesh is:

$$CGP_i = 2\xi_G \sqrt{KGP_i \frac{1}{\frac{(RBC1)^2}{J_{G1}} + \frac{(RBC2)^2}{J_{G2}}}} \qquad \ldots(30)$$

where

$\xi_G$ = critical damping ratio of gear mesh

System response measurements of geared systems[6][9][8] indicated

that $\xi_G$ ranges between 0.03 and 0.10.  In equation (30) the average

gear mesh stiffness is used and the equivalent masses of gears 1 and

2 are concentrated at the base circles to reflect their effect along

the line of action.

The equations of motion (21) through (24) are numerically

integrated using a fourth order Runge-Kutta scheme.[28]  This method

is described in a number of references and will not be repeated here.

Before the integration can be performed, initial values, integration

time increment and integration duration must be determined. For a given design condition the initial displacements $\theta_D(0)$, $\theta_L(0)$, $\theta_2(0)$ and $\theta_L(0)$ are determined by applying the input and output torques to the system. For convenience, the first gear is used as the null point. The subsequent driver movement is considered plus and the driven movement as negative. The initial velocities $\dot{\theta}_D(0)$, $\dot{\theta}_1(0)$, $\dot{\theta}_2(0)$ and $\dot{\theta}_L(0)$ have been assigned the anticipated steady state velocities.

The integration time step must be selected short enough to avoid inaccuracies and instability in the integration process and yet long enough to minimize computer time. A measure of the optimum time step can be obtained by determining the undamped torsional natural frequencies of the system. The undamped equations of motion rewritten in matrix form appear below

$$[J]\{\ddot{\theta}\} + [K]\{\theta\} = 0 \qquad \qquad \ldots(31)$$

where the inertia matrix is

$$\begin{bmatrix} J_D & 0 & 0 & 0 \\ 0 & J_{G1} & 0 & 0 \\ 0 & 0 & J_{G2} & 0 \\ 0 & 0 & 0 & J_L \end{bmatrix} \qquad \ldots(32)$$

and the stiffness matrix is

$$\begin{bmatrix} K_{DS} & -K_{DS} & 0 & 0 \\ -K_{DS} & K_{DS} - KGP_{AVE} \times RBC1^2 & -KGP_{AVG} \times RBC1 \times RBC2 & 0 \\ 0 & -KGP_{AVG} \times RBC1 \times RBC2 & K_{DS} + KGP_{AVG} \times RBC2^2 & -K_{LS} \\ 0 & 0 & -K_{LS} & K_{LS} \end{bmatrix}$$

$$\ldots(33)$$

In equation (33) the weighted average of gear mesh stiffness, $KGP_{AVE}$, is introduced to simplify the solution for eigenvalues. $KGP_{AVE}$ is determined by summing up the discrete stiffness values, $KGP_i$, over one cycle and dividing by the number of discrete mesh positions in the cycle.

The undamped equations of motion are solved for the eigenvalues and eigenvectors by a Jacobi iteration technique. For the integration time step stable solutions have been obtained consistently by using one tenth of the shortest system natural period or less than two percent of the mesh stiffness period. The duration of the integration time step is predicated on the time needed for the start-up transients to decay. Review of the output data revealed essentially steady state behavior for integration time lengths equal to five times the longest system natural period.

As a first step, the dynamic force in the mesh as defined by equations (25) through (27) is calculated in the dynamic analysis subroutine FAST. Next, FAST interacts with the static subroutine SLOWM to determine the sharing of the dynamic load, the variation of the load through the mesh cycle, the sliding velocity, the maximum Hertz pressure and the velocity-Hertz pressure product along the tooth profiles.

The sliding velocity vector relationship at a given mesh position can be seen from Figure 21. In vector notation

$$SV(k)_i = \bar{V}_1 - \bar{V}_2 = RCP1'(k)\,\dot{\theta}_1 - RCP2'(k)\,\dot{\theta}_2 \qquad \ldots(34)$$

where

$RCP1'(k)_i$ and $RCP2'(k)_i$ are the instantaneous radii to the contact point of tooth k at mesh position i. In scalar form equation

(34) can be expressed as

$$SV(k)_i = \sqrt{(V_1)^2 + (V_2)^2 - 2V_1V_2 \cos (\alpha_{A1} - \alpha_{A2})} \quad ...(35)$$

For the same position the dynamic load QD(k) was established as

$$QD(k)_i = \frac{KP(k)_i}{KG_i} QDT_i \qquad ...(36)$$

and two dynamic load factors as

$$(DF1)_i = \frac{QDT_i}{Q_t} \qquad ...(37)$$

$$(DF2)_i = \frac{QD(k)_i}{Q(k)_i} \qquad ...(38)$$

where DF1 is defined as the ratio of total dynamic mesh force to the total static mesh load. DF2 is the dynamic load ratio for any given pair in engagement.

Two stress conditions are evaluated for the contacting teeth:

1. Hertzian Contact Stress using the equivalent cylinder approach for Hertzian deflection outlined in Section 3.4.6:

$$P_H(k)_i = \sqrt{\frac{QD(k)_i}{\pi FA} \left(\frac{1}{RCCP1'(k)} - \frac{1}{RCCP2'(k)}\right)} \qquad ...(39)$$

where

RCCP1'(k), RCCP2'(k) = equivalent instantaneous radii of curvature

F = minimum gear tooth face width

$$A = \frac{(1 - \mu_1^2)}{E_1} + \frac{(1 - \mu_2^2)}{E_2}$$

Using equations (35) and (39), the product $P_H(k)_i \times SV(k)_i$

is determined as an indication of the severity of the wear condition at the tooth profile surfaces.

2. Bending stress of the teeth using a modified Heywood formula suggested by Cornell:[15]

$$\sigma_B = \frac{QD(3)_j}{F} \cos\theta_j \; [1 + .26 \; (\frac{X_{js}}{RF_j})^{.7} \;] \; \frac{3Y'_{js}}{2X^2_{js}}$$

$$+ \sqrt{\frac{.36}{X_{js} \, Y_{js}}} \; (1 - \frac{X_j}{X_{js}} \, \mu \, \text{TAN} \, \theta'_j) - \frac{\text{TAN} \, \theta_j}{2 \, X_{js}} \qquad \ldots (40)$$

where

j = 1 or 2

For the modified Heywood formula, the position of the maximum stress in the fillet, $\gamma_{js}$ is found by iteration

$$\text{TAN} \, \gamma_{js(\ell+1)} = (1 + .16 \, A_{j\ell}^{.7}) \, A_{j\ell}/[B_{j\ell} \; (4 + .416 \, A_{j\ell}^{.7})$$

$$- (\tfrac{1}{3} + .016 \, A_{j\ell}^{.7}) \, A_{j\ell} \, \text{TAN} \, \theta_{j\ell}] \qquad \ldots (41)$$

where

$\ell$ = iteration number starting with 1

$$A_{j\ell} = \frac{2 \, X_{jo}}{RF_j} + 2(1 - \cos \gamma_{js\ell})$$

$$B_{j\ell} = \frac{Y_{jo}}{RF_j} + \text{SIN} \, \gamma_{js\ell}$$

and the remaining nomenclature is as in Figures 23 and 24.

Equation (40) predicts the maximum tensile fillet stress within about 5% to 10% of finite element methods.[15] It also predicts fairly well the location of the peak stress in the fillet. Because of its relative ease of use and the expected low stresses in the rigid

hub and ring, equation (40) is considered to be representative of the peak stresses of gear 1 and 2.

## 3.6  COMPUTER PROGRAM

The development of a digital computer program for the comprehensive analysis of the static and dynamic behavior of internal spur gear (ISG) drives was one of the tasks of this dissertation effort. The existing external spur gear program developed at CSU was used as the nominal starting point for the structure and nomenclature of the new ISG drive program. The ISG computer program package in its entirety, along with sample output print-out, is included in Appendix C. Highlights of the computer program, its structure, nomenclature and the input data required for the analysis of an external-internal spur gear drive are discussed in this section.

### 3.6.1  Program Structure

The ISG drive computer program package is written in Fortran IV Gl for use on the Cleveland State University IBM 370/158 digital computer. It has been prepared in three modules for operator convenience (see Figure 25). Module 1 represents the static analysis discussed in Section 3.4. In this module, the operator has the following options:

1.  INTERNAL STATIC permits the operator to make changes to the program and conduct a static analysis. This ability to change the program is desirable for future improvements. The program is compiled after every submittal and thus takes over 2 minutes of computer time on the CSU IBM 370/158 digital computer.

2.  The current INTERNAL STATIC can be compiled and it becomes now EXECUTE INTRSTAT. However, before the compiling is done, it is first necessary to delete the
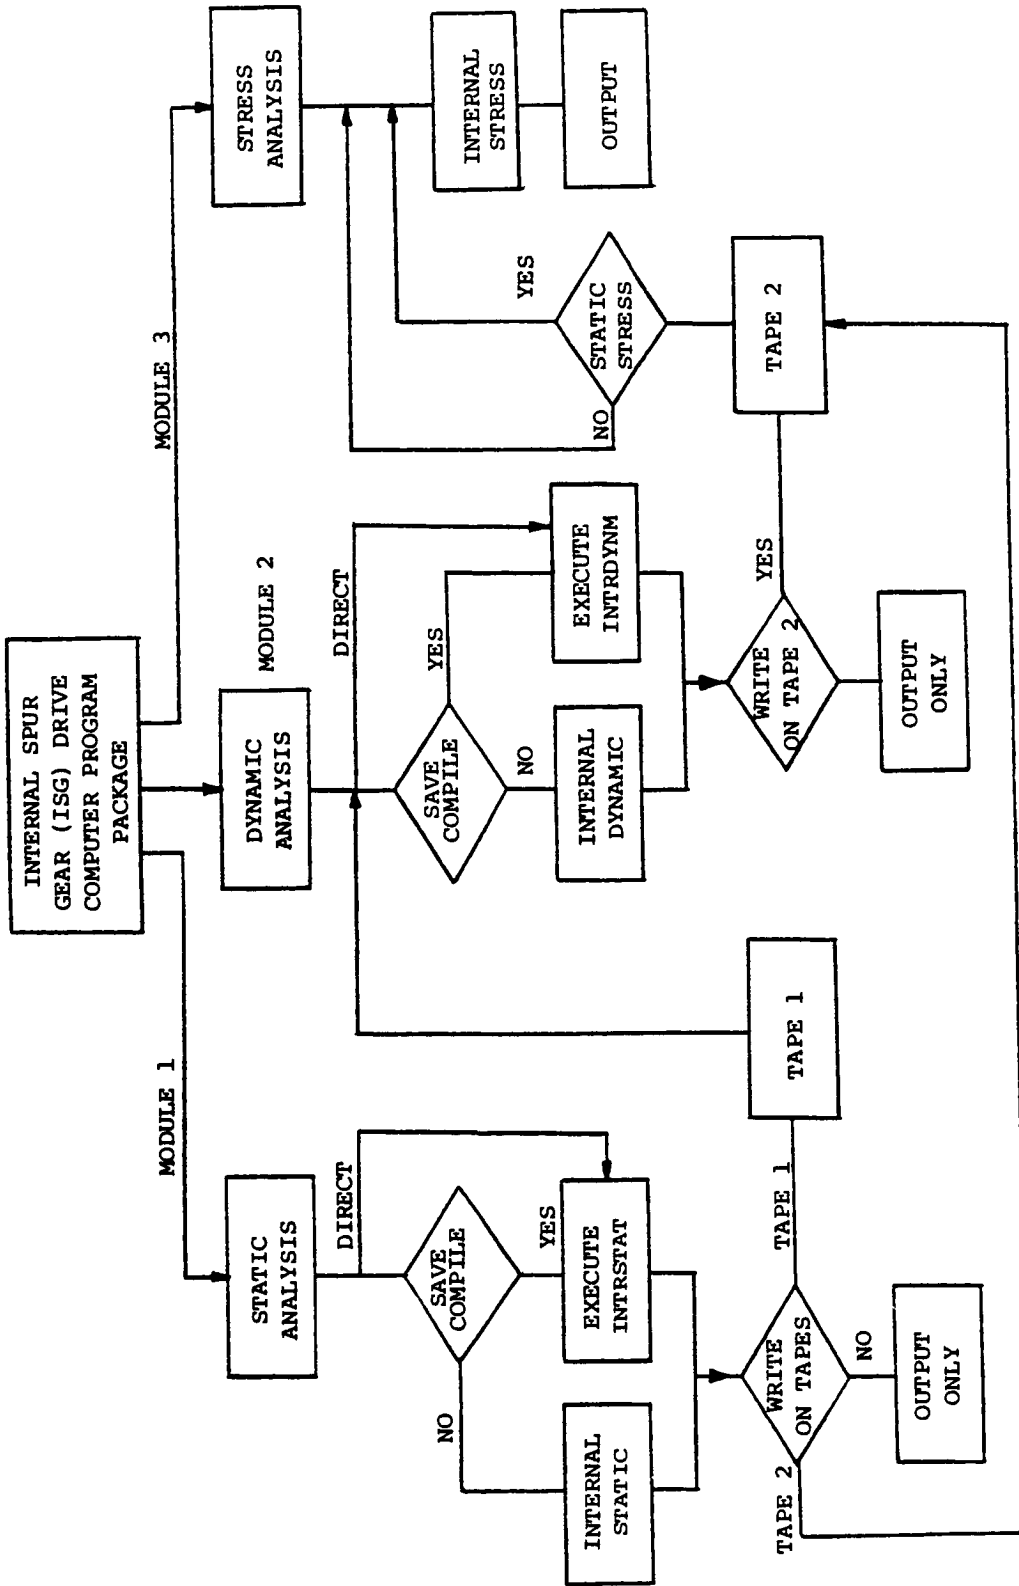

Figure 25 – Block Diagram of Computer Package for External-Internal Spur Gears

old EXECUTE INTRSTAT. Then the empty space on the file
is compacted, the old INTERNAL STATIC is deleted, the
new INTERNAL STATIC version is transferred to the de-
leted section and then compiled. Now the new EXECUTE
INTRSTAT is ready.

3. EXECUTE INTRSTAT permits no changes to the program, but
   the computer time is reduced to less than 2 minutes.
   Thus, parametric studies are made most efficiently di-
   rectly from the current EXECUTE INTRSTAT version.

Option 1 and 3 provide the additional feature to the operator of
being able to write output data on two tapes. Tape 8 and 9 are needed
for the dynamic and stress analysis respectively.

Module 2 represents the dynamic analysis as discussed in Section
3.5. In this module the operator has the same options as before but
the uncompiled and compiled versions are now called INTERNAL DYNAMIC
and EXECUTE INTRDYNM. Once again, EXECUTE INTRDYNM can be used di-
rectly for parametric studies. Both versions of the dynamic analysis,
in addition to input data, require the data from Tape 8, and can write
dynamic data on Tape 9 for use in the stress analysis.

Module 3 calculates the maximum tooth bending stress at the fillet
using the stress formulae discussed in Section 3.5. Tape 9 information
is needed for this analysis in terms of the 50 contact points, and
whether static or dynamic loading is used.

The three modules consist of an executive program and a number of
subroutines. Portions of the executive program are common to all
modules and some subroutine sections are shared by Module 1 and 3. The
input data is entered into the executive program by use of namelist

parameters, and Tapes 8 and 9. Again, some of the namelist parameters are common between the three modules. Thus, the resultant overall program package is larger than would be obtained with a combined program. However, the advantage of operator flexibility and quick computer turn-around made the "three module" approach far more convenient. Also, an initial step has been made towards preparing the analysis package for use in the CSU mini-computer HP 1000.

## 3.6.2 Description of the Executive Programs and Subroutines

The executive program of all modules is called MAIN. It contains the read statements for the namelist parameters and tapes, the call statements for the subroutines and the write statements for input data, diagnostics and output data. Each MAIN program has its own set of namelist parameters, subroutine call statements, and read and write statements suitable for the type of analysis of the given module.

## 3.6.2.1 Module 1

In addition to MAIN, Module 1 uses MAIN1 for additional executive control and write instructions. The MOD subroutine defines the digitized tooth profiles, checks for interference between mating teeth and determines the theoretical contact ratio. SLOWM first locates the geometric arrangement of the gears with respect to each other. Next it establishes the points of contact, number of contacting gear tooth pairs, sliding velocity vectors, length of dynamic cycle, and loaded contact ratio. Subroutine DEFLECT calculates the deflections except the Hertzian deformation due to a unit load. This unit load deflection is combined with the Hertzian deformation in SLOWM to determine the stiffness of the individual pairs, the variable mesh

stiffness, the static load and the deflection due to this loading.

### 3.6.2.2  Module 2

The FAST subroutine of this module analyzes the three degree of freedom, four mass, mathematical model of the geared torsional system depicted in Figure 22.  Calculations in FAST are based on a dynamic cycle which starts with the initiation of contact on a tooth entering the contact zone and ends with the initiation of contact with the tooth following it.  The length of this cycle is established in subroutine SLOWM by examining the stiffness function.  The position of tooth no. 3 when tooth no. 4 comes into contact·is defined as IEP.  Consequently, (IEP-1) is the endpoint of the dynamic cycle started when tooth no. 3 came into contact (Figure 27).  FAST calculates the dynamic force in the mesh as defined by equations (25) through (27).  The integration is performed in two small subroutines using the very efficient Runge-Kutta integration scheme by Franks.[28]  The RKUTTA subroutine contains the integration step size and keeps track of the iterations across the integration interval.  The actual integration is done in subroutine MORERK.  Subroutine VIBS uses a Jacobi iteration technique to determine eigenvalues of the gear train.  This information is returned to FAST for determination of the natural frequencies, eigenvectors, integration time step and duration.  FAST also calculates the instantaneous angular position and velocities, sliding velocities, Hertzian pressure, dynamic loads, dynamic load factors, and transmission ratio.  Subroutines STORE and XPLOT are used to store the data and then plot as many as four dependent variables against a single independent variable (see Appendix C for sample·output plots).

### 3.6.2.3  Module 3

Module 3 is set aside for calculating the maximum bending stress of the tooth fillet.  Portions of MAIN and MAIN1 have been modified for executive control and printing of pertinent information. Subroutine MOD has been modified to provide not only the tooth profile points but also a more refined breakdown of the fillet contour.  This additional refinement is needed for the iterative search routine of the maximum fillet stress location as indicated by equation (41).  The actual stress calculation is done in subroutine CORNEL.

CHAPTER IV

RESULTS, DISCUSSION AND SUMMARY

## 4.1 RESULTS AND DISCUSSION

### 4.1.1 Introduction

The internal spur gear (ISG) analysis methodology, which was developed for this report, was used to perform a series of comparative parametric studies in order to assess the ISG drive performance. Since there are no ISG drive performance data available, comparisons were made with known solutions of external spur gear drives. In particular, the results of the ESG study by Kasuba and Evans[19] can be used to compare the static and dynamic performance of internal versus external spur gear drives under identical load, speed and geometry conditions. From the study by Kasuba and Evans, this author selected one external gear set which was of practical interest to the internal gear design. The selected external spur gear (ESG) set consists of the following design parameters:

| | |
|---|---|
| Number of Teeth on 1st and 2nd Gear | 32 & 96 |
| Pressure Angle | 14.5° |
| Diametral Pitch | 8 |
| Face Width | 25.4 mm |

The analyses of the ESG set consider variations in tooth profiles, tooth support stiffness, critical damping ratios and shaft stiffness. For the ISG drive, static and dynamic computer analyses were conducted

under identical conditions. Next, ISG drives of practical interest
were investigated for the same output information to allow comparisons
between external and internal drives. Additional analyses were con-
ducted to investigate the effects of radial deflection of the bearings,
shafts, hub and gear rings on the ISG drive performance. Also, the
tooth bending stress program was used to determine the static and
dynamic stress for all fifty gear mesh positions.

4.1.2  Static Analysis

The dynamical model shown in Figure 22 was also used in the
static analysis (with all masses taken to be zero). The behavior of
the internal and external gear teeth were investigated for various
structure support conditions and load magnitudes. In the static analy-
sis the information of interest for the gear teeth consists of the
deflection, stiffness, load sharing, bending stress, unit sliding
velocities and Hertz pressure.

4.1.2.1  Comparison of ISG and ESG Set Performance

The results presented in Table 1 and Figure 26 show a com-
parison of the mesh stiffness characteristics between error-less
external and internal spur gear sets. The results indicate the in-
fluence of the tooth support stiffness on the overall gear mesh stiff-
ness for both ESG and ISG sets. By increasing the support torsional
stiffness (higher HSF, Appendix B-3.3), the loaded contact ratio
decreases, mesh stiffness increases, changes in instantaneous trans-
mission ratio decrease, and sensitivity to gear tooth errors increases.
The opposite occurs by decreasing the support stiffness. In the case
of the ISG set, the gear ring stiffness can be reduced effectively only

by decreasing the thickness of the rim (see Figures 3 and 4).

Table 2 demonstrates the significantly higher theoretical contact ratio of the ISG versus the ESG set. Also, the tabulated results in Table 1 indicate substantial changes in contact ratio with increasing loads and/or support flexibility. For different load magnitudes ranging from 88 to 700 N/m (500 to 4000 lbs./in.) the contact ratios change by 13% and 7% for the respective ISG and ESG sets. At the maximum load condition, the contact ratio of the ISG set is 3.09, i.e., three pairs are in continuous contact. This high contact ratio is obtained by the internal gear set, even with high gear tooth support stiffness (HSF = 1.0).

Profile errors and pitting affect the mesh stiffness characteristics of the ISG and ESG sets to varying degrees. For the case of only the pinion or gear having a narrow pit 0.5 mm wide (0.02 in.) at the pitch line, the torsionally stiff ISG gears absorbed the fault without a change in the mesh stiffness pattern whereas the ESG gears could not absorb this fault. Thus, causing significant interruptions of the mesh stiffness pattern. Only when the pit width was increased to 2.0 mm did the error affect the ISG mesh stiffness characteristics (Figure 27). The unabsorbed error caused non-contacting zones with resulting substantial changes in the mesh stiffness characteristics, i.e., the flexibilities in the mesh were able to bridge the non-contact zones. For the pit shown in Figure 27, the flexibility of the mesh was able to absorb a portion of the error by eliminating about 60% of the mesh stiffness interruption. The reason for this effective bridging of the non-contact zones can be found in the torsional ring flexibility and the inherent high contact ratio of the ISG set. In normal contact ratio gears as can be encountered with ESG sets, the mesh stiffness,

---- LOST CONTACT
ZONE

ANGLE OF ROTATION (PSI1TP), DEGREES

GEAR MESH STIFFNESS, KG (N/m) x $10^{-8}$

KG, would equal zero when these non-contacting zones due to errors occur. Sinusoidal errors of 0.013 mm (.0005 in.) on either the pinion or gear of the ISG drive caused non-contact zones and the resulting changes in mesh stiffness characteristics of Figure 28 due to its high torsional rigidity. In contrast, a torsionally flexible ESG drive was able to absorb the fault without affecting the mesh stiffness characteristics.[19]

The analysis procedure can also be used to investigate other surface fault-error combinations acting on both gears. For example, errors of Figure 16c caused mesh stiffness reductions over a longer span of the meshing cycle than were obtained when the identical error was on one gear only as in Figure 28. Thus, it must be concluded that each profile condition and mesh system flexibility will cause unique mesh stiffness patterns. The gear tooth contacts due to deflections do not coincide with the theoretical line of action. This results in noninvolute action producing variations in the transmission ratio, ΔTR. For the investigated cases in Tables 1 and 2, the trend in ΔTR for the ISG and ESG sets was the same. The magnitude of the ISG ΔTR was about 50% higher but not exceeding 2.7%. However, the transmission ratio of the ISG set is higher.

## 4.1.2.2  ISG Drives of Practical Interest

Review of the maximum stiffness, $KG_{max}$, in Table 1 reveals a 13% higher stiffness value for the torsionally stiff ISG drive which does not reduce significantly with changes in hub or ring radii changes. The reason for this small variation in stiffness can be attributed to the rather rigid internal gear ring. In order to reduce this circumferential stiffness of the ring, the rim thickness has to be reduced to 20% or less of the face width of the gear teeth. However, ISG drives of practical interest do not exhibit such small rim thicknesses in order

to minimize deflections in the radial direction (Figures 3 and 4). The inference is that ISG drives will be inherently stiffer than ESG drives and, because of their closely matched contours, will be less tolerant to sinusoidal imperfections or similar irregularities of the surface. This intolerance to surface irregularities can become limiting since grinding of the internal teeth is not practical.

### 4.1.2.3 Effects of Radial Deflection on Static Performance

Radial deflections due to bearings, shafts, pinion hub and gear ring cause radial movement of the gears in the rotating plane with a resultant reduction of contact length of the gears. This fact can readily be deduced from a plot of contact ratio versus radial deflections (Figure 29). The plot indicates a sharp reduction of contact ratio with small radial deflections. At .025 mm (.001 in.) radial deflection, the reduction of contact ratio levels off and reaches the theoretical contact ratio, $CR_T$ of 2.625 at a radial deflection of 0.05 mm (.002 in.). Additional radial deflection causes the contact ratio to drop below the $CR_T$. For the gear and loading combination of Figure 29 practical combined bearing, shaft, pinion hub and gear ring deflections can be held to 0.05 mm (.002 in.). Thus, it appears that the actual loaded contact ratio probably will not exceed the $CR_T$ because of the ever present radial deflection unless design and assembly practice offsets the radial deflection with an equal amount of reduction in center distance. It is interesting to note that the combined circumferential deflection of the two ISG drive gears of Figure 29 has a significantly greater and opposite effect on contact ratio than does the radial deflection.
Figure 29 - Effect of Radial Deflection of
ISG Drive on Contact Ratio

For the load condition of Figure 29, the two deflections offset each other at a radial deflection of .05 mm (.002 in.) and a corresponding maximum circumferential deflection of .015 mm (.0006 in.).

The contact search for radial deflections of 0.025 mm or less can be accomplished with the contact search method as discussed in Section 3.4.4. For larger radial deflections the contact search method was changed to include non-uniform rotation ("wiggling") for establishing of the limiting mesh points.

### 4.1.3  Dynamic Analysis

The gear train of Figure 22 was modeled for the dynamic analysis. The solution of the dynamic equations of motion (equations 21 through 24) leads to dynamic loads which depend on the magnitudes of the mass moments of inertia of all elements, shaft stiffness, transmitted loads, gear mesh stiffness characteristics, damping in the system, amount of backlash and speed.

### 4.1.3.1  Comparison of ISG and ESG Drive Dynamic Performance

For comparison purposes, identical geometry and operating conditions were applied to the ISG drive model of Figure 22 and the ESG drive model.[19] Figures 30 and 31 show the results of a series of analyses on error-less ISG and ESG gear trains using low and high stiffnesses for the shafts and teeth supports and varying amounts of damping. Review of the resulting curves indicates a smoother performance in terms of lower peak dynamic factors for the ISG drive.

Figure 32 demonstrates the dramatic effect of severe mesh stiffness interruptions due to sinusoidal errors on dynamic performance. For this type of error the two drives exhibit similarly violent

dynamic fluctuations. The performance of the ISG versus ESG drive due
to the effect of a surface pit is considerably smoother (Figure 33).
In this error condition, locating the pit on either the pinion or gear
of the ISG drive had little effect on performance.

There is a requirement for a minimum amount of damping to prevent
the Mathieu-Hill type instabilities.[9] For the considered ISG drive
of 32 and 96 gear teeth, there was no such instability encountered
within the operating range of 0 to 12,000 rpm with $\xi_G$ = .05 and $\xi_S$ = .005.
Because of the large support bearing of the ring gear (Figures 3 and 4)
the combined bearing and gear mesh damping, $\xi_G$, is probably near .15,
and thus Mathieu-Hill instabilities are unlikely to be encountered with
ISG drives.

The ISG analysis procedure has the capability for analyzing the
distribution of the dynamic loads, dynamic factors (Figures 30 through
33), load sharing, contact Hertz stress ($P_H$), contact stress-sliding
velocity product (PV) and maximum tooth bending stress for the entire
meshing zone. Figures 34 and 35 show the range of the maximum $P_H$ and
maximum PV values corresponding to the dynamic conditions illustrated
in Figures 30 and 33. In general, the higher contact ratio ISG drive
appeared to show lower values.

Figure 36 shows the maximum tensile tooth bending stress versus
all fifty gear mesh positions for the static and the 8000 rpm operating
condition of the ISG drive depicted in Figure 30, case d. As expected,
the pinion shows higher stress values both for the static and dynamic
condition. The peak stress values occur in the gear mesh position
range from 14 to 18 and 33 to 38. These gear mesh positions represent
the change over from three to two tooth contact. Figures 37 and 38 show
the stress pattern for the ESG drive.

### 4.1.3.2  ISG Drives of Practical Interest

For similar construction, ISG drives are torsionally stiffer than ESG drives because of the large outside diameter of the internal gear. Thus, the torsionally soft case of HSF = .65 and mass moment of inertia, $J_{G2}$ = 0.017 $m^2$-kg (Figures 30 through 33), can only be achieved with a severe reduction of the internal gear rim thickness (Figures 3 and 4). The dynamic load factors of ISG drives of practical interest with various mass moments of inertia, $J_{G2}$, and different gear mesh and shaft stiffnesses are shown in Figure 39. For the four cases investigated, the best performance, in terms of lowest gear dynamic load factors, was obtained for the ISG drive of high mass moment of inertia, high shaft stiffness and low torsional stiffness, HSF = .88. The ESG drive of equal shaft stiffness, HSF = 1.0 (Figure 30, Curve c) exhibited the highest dynamic load factors. The results of the analysis of practical ISG drives demonstrates the need for tuning of the various constituent elements in the model of Figure 22. The general trend indicates smoother performance from ISG drives of practical interest versus similar ESG drives.

### 4.1.3.3  Effect of Radial Deflection on Dynamic Performance

Figure 40 shows three cases of ISG drives subject to different radial deflections. Review of the results shows larger dynamic load factors with increase in radial deflection. The performance of the ISG drives exhibits considerable missing and "backhitting" of the gear teeth similar to the performance of gears with sinusoidal profile errors. Significant reduction of the dynamic load factors was evident with increase in gear mesh damping.

## 4.2  SUMMARY AND CONCLUSIONS

A new methodology has been developed for the static and dynamic load and stress analysis of the internal spur gear (ISG) drive. Prior to this report, there were no established methods for the above analyses. The currently published design techniques for ISG drives reflect the technology of the 1950's.

The analysis procedure is applicable to involute profiles and minor deviations from this profile as a result of modifications, imperfections and circumferential deflections. Because of the potential noninvolute profile and the effect of radial deflection on tooth position, an iterative procedure is used to calculate the statically indeterminate problem of multi-tooth contacts, circumferential deflection and contact ratio. The developed method can be used in gear combinations leading up to and exceeding the "very high contact ratio" (VHCR) of three. The static analysis can also be adapted for determining the gear mesh stiffness of a planet and ring gear assembly. For this adaptation it is necessary to supply the ring gear stiffness relying on strength of materials, finite element or experimental means. The maximum tooth bending stress of the external and internal gear is determined by "Cornell's method". This method is a modification of the empirical formula for stress of loaded projections based on photoelastic experiments by Heywood.

The new methodology was computerized with the computer package consisting of three modules which perform the static, dynamic and stress analyses respectively. The output from the three modules includes the static and dynamic loads, variations in transmission ratio, sliding velocities, maximum contact pressures and tooth bending stress

acting on the gear teeth at the fifty mesh positions. The results of the parametric computer studies yielded the following conclusions:

1. For equal geometries, the ISG drive achieves higher contact and transmission ratios than the ESG drive. For the investigated 32 and 96 tooth combination, the heavily loaded ISG drive reached the "very high contact ratio" of three. The unloaded or theoretical contact ratio is 2.625.

2. Because of the high contact ratio and the concave-convex tooth contours, the ISG drive is able to absorb pits across the surface better than ESG drives. However, the opposite effect is encountered when sinusoidal or similar surface irregularities are present.

3. ISG drives tend to be torsionally stiffer and heavier than ESG drives because of the large internal gear. Nevertheless, when both systems are sized optimally, then the ISG drive performance in terms of peak dynamic loading is better.

4. Radial deflections of shafts, bearings and gears reduce the contact ratio of ISG and presumably ESG drives. The effect on mesh stiffness is minor but the pattern is changed. The dynamic loading increases with radial deflection.

5. The dynamic factors of ISG drives can be reduced with increases in damping ratio. This effect is also evident in drives experiencing radial deflections.

6. The maximum product of Hertz stress and sliding velocity

is consistently lower than the ESG drive. The maximum Hertz stress performance is distorted because of the different peak dynamic loading of the various cases that were investigated. In general, the maximum Hertz stress appears lower also for the ISG drive. Peak bending stress of the pinions were the same whereas the gear of the ISG drive experienced an 18% lower stress value.

The derived new analysis procedure has established a method exclusively for the analysis and prediction of dynamic performance of the internal-external spur gear set. The list of advantages, as derived from this study, of the ISG drive over the ESG drive is quite impressive, and should lead to renewed interest in applying the ISG drives in advanced transmissions.

Recommendations for future work might include a finite element method for the ring gear deflections and an efficient contact search technique which would satisfy the intentionally built-in large radial deflections such as found in the planetary gear rings.

## A-2 DEVELOPMENT OF THE INVOLUTE PROFILE

The construction of the involute spur gear tooth follows exact geometric relations as indicated by the standard formulae in Section A-1. Thus, from knowledge of a few parameters all the other parameters can be determined. General design practice starts with an assumption of the number of teeth, diametral pitch, addendum, working depth, fillet radius and pressure angle at the pitch point. The radial distance, R, to any point along the involute line is now determined from the base radius and the pressure angle at that point (see Figure A-1). The involute can then be drawn by connecting finely spaced radial points with straight lines. In the computer program either one or two hundred points are used depending on the size of the tooth. Any position between two points is determined by linear interpolation. The external and internal tooth have the same involute profile. The distinction between the two arises from the fact that their tooth center is either on the concave or convex side of the involute profile. Figures A-2 and A-3 respectively show the construction of the internal and external involute tooth along with the fillet configuration and the position of the local and global tooth coordinate system.

APPENDIX B

DEFLECTIONS

The radial and circumferential deflections of the external-internal gear support bearings, gear ring and teeth as discussed in Section 3.4.6 are summarized in this Appendix.

B-1  Bearing Deflections

B-2  Radial Ring Gear Deflections

B-3  Circumferential Deformation of Gear Teeth

    B-3.1  Deflection of Point of Contact Due to Deformation

           of Teeth

    B-3.2  Deformation of the Teeth Due to Rotation of Their

           Foundation

    B-3.3  Deflection of the Teeth Due to Circumferential

           Deformation of the Rim and Gear Ring

    B-3.4  Hertzian Deformation at Contact Point

## B-1  BEARING DEFLECTIONS

Rolling element bearings are preferred for their use in ISG drives because of their load carrying capacity, durability and low maintenance. The deflection in rolling element bearings is mainly due to Hertzian contact deformation.  Because the maximum elastic contact deformation is dependent on the rolling element loads, it is necessary to analyze the load distribution occurring within the bearing prior to determination of the bearing deflection.

Harris[26] suggests an approximate solution for the maximum ball or roller load, $Q_{max}$ as:

$$Q_{max} = \frac{5 \; F_r}{Z \; \cos \alpha} \qquad \qquad \ldots (B1-1)$$

where

$F_r$ = radial load

$Z$  = number of balls or rollers

$\alpha$  = contact angle

The deflection of a ball or roller bearing are respectively:

$$\delta_r = 1.58 \times 10^{-5} \; \frac{Q_{max}^{2/3}}{D^{1/3} \; \cos \alpha} \qquad \qquad \ldots (B1-2)$$

$$\delta_r = 4.33 \times 10^{-6} \; \frac{Q_{max}^{3/4}}{\ell^{1/2} \; \cos \alpha} \qquad \qquad \ldots (B1-3)$$

where

$D$ = ball diameter

$\ell$ = length of roller

## B-2 RING DEFLECTION

The ring gear of Figure 3 is subject to a single load which is reacted by an inclined roller bearing. The ring gear consists of the internal teeth, intermediate tooth support ring, outer ring and cylindrical support. Under load the intermediate and outer ring act rigidly and thus transfer the load uniformly into the support cylinder. This represents nearly cantilever loading and its deflection represents a "best possible" solution. In the extreme, the cylinder can be looked at as reacting to the equal and opposite loading of a ring. This deflection represents the "worst possible" condition.

The applicable equations for either ring deflection are:

### Cantilever

$$\delta_r = \frac{F_r L^3}{3\ EI} \qquad \ldots (B2-1)$$

where

$$I = \frac{\pi}{64}\ (D^4 - d^4) \qquad \ldots (B2-2)$$

D = outside diameter of cylinder

d = inside diameter of cylinder

### Ring

$$\delta_r = .0745\ \frac{F_r R^3}{EI} \qquad \ldots (B2-3)$$

where

R = mean diameter of cylinder

I = moment of inertia of ring cross-section

$$= \frac{b\ h^3}{12}$$

h = ring thickness

b = ring gear width

## B-3  CIRCUMFERENTIAL DEFORMATION OF GEAR TEETH

### B-3.1  Deflection of Point of Contact Due to Deformation of Teeth

Weber[13] solved for the deflection at the point of application of an external gear tooth by equating the stress energy to the deforming work, $\frac{1}{2}P\delta$. In his formulation, the stress energy is composed of the partial energies due to the bending moment, the shearing force and the normal forces as seen in Figure B3-1.

$$\frac{1}{2}Q\delta = \frac{1}{2}\int_o^{Y_c}\frac{M^2}{EI}\,dy + \frac{1}{2}\int_o^{Y_c}\frac{V^2}{GFA}\,dy + \frac{1}{2}\int_o^{Y_c}\frac{N^2}{EA}\,dy$$

$$\ldots(B3-1)$$

In Figure B3-1 the applied force $Q$ is transferred to the center of the tooth resulting in an equivalent loading set

$$M = Q(Y_c - Y_n')\cos\theta \qquad \ldots(B3-2)$$

$$V = Q\cos\theta \qquad \ldots(B3-3)$$

$$N = Q\sin\theta \qquad \ldots(B3-4)$$

and for this cantilever loading

$$I = \frac{1}{12}\ell(2x)^3 \qquad \ldots(B3-5)$$

$$A = \ell\,2x \qquad \ldots(B3-6)$$

$$F = \frac{5}{6} \text{ for spur gear teeth} \qquad \ldots(B3-7)$$

if we replace, E by

$$G = \frac{E}{2(1+\mu)} \qquad \ldots(B3-8)$$

and  $\mu = 0.3$

then substitution and simplification leads to the expression for deflection at the point of contact

$$\delta = \frac{Q}{E}\cos\theta^2\left[12\int_o^{Y_c}\frac{(Y_c-Y)^2}{(2x)^3}\,dy + 3.12\left(1+\frac{TAN^2\theta}{3.12}\right)\int_o^{Y_c}\frac{dy}{2x}\right]$$

$$\ldots(B3-9)$$

In this equation x and y are the local coordinates of the involute or modified involute profile. By considering the digitized profile points of Figure B3-1, it is possible to solve for the deflection at the contact point by numeric integration. In this investigation the integration is carried out to the intersection of the fillet with the root radius, RRC1. Thus, a slight improvement over Weber's disregard of the fillet has been achieved.

Comparison of the more pronounced profile curvature of the external versus the internal gear tooth leads to the conclusion that Weber's solution equally applies to the internal tooth (see Figures B3-1 and B3-2). Equation B3-9 can be used for the deflection of the external or internal gear tooth by substituting the appropriate local coordinates for the respective tooth.
Figure B3-1 - External Gear Tooth Bending, Shear
and Normal Deflection Model
Figure B3-2 - Internal Gear Tooth Bending, Shear
and Normal Deflection Model

B-3.2 Deformation of the Teeth Due to Rotation of Their Foundation

Weber[13] investigated the effect of the elastic support of the teeth on the deflection at the contact point. For this investigation he assumed that a rigid tooth is acting on a semi-infinite support structure represented by the gear hub or ring, and that the loading is transferred to the support as indicated in Figures B3-3a through B3-3d. He then proceeded to find a stress function which satisfied all of the boundary conditions for the semi-infinite support. Again, equating the deforming work and stress energy:

$$\frac{1}{2} Q\delta = C_{11} M^2 + 2C_{12} MV + C_{22} V^2 + C_{33} N^2 \quad . \quad \dots (B3-10)$$

where $C_{11}$, $C_{12}$, $C_{22}$ and $C_{33}$ are factors whose determination is outlined as follows.

By potential functions we obtain the deflection in the Y-direction, where

$$V_{boundary} = \frac{2(1 - \mu^2)}{E} \frac{6M}{\ell b^2} \times \frac{2}{\pi b} \left[\frac{1}{2} \{x^2 - (\frac{b}{2})^2\} \ln \left|\frac{b + x}{b - x}\right| - \frac{xb}{2}\right]$$

$$\dots (B3-11)$$

and $\quad b = 2 x_{min} \quad \dots (B3-12)$

$x_{min}$ = x-dimension at fillet-to-root intersection

Now consider the work done by the load at the boundary due to M; the expression for the strain energy $C_{11} M^2$ is

$$C_{11} M^2 = -\frac{1}{2} \int_{-b/2}^{+b/2} \sigma y_{boundary} V_{boundary} \ell \, dx \quad \dots (B3-13)$$

where σy is the stress. Therefore,

$$\sigma y_{boundary} = \frac{2x}{b} \frac{6M}{\ell b^2} \quad \dots (B3-14)$$

By substituting $\sigma y_{boundary}$, $V_{boundary}$ in equation (B3-13) and integrating

$$C_{11} M^2 = - \frac{(1 - \mu^2)}{\pi E} \left(\frac{6M}{Lb^2}\right) \times \frac{4\ell}{b^2} \times \left(- \frac{b^4}{16}\right) \qquad \ldots (B3\text{-}15)$$

$$C_{11} = \frac{9}{\pi} \frac{(1 - \mu^2)}{E} \frac{1}{Lb^2} = \frac{9(1 - \mu^2)}{\pi E \ell b^2} \qquad \ldots (B3\text{-}16)$$

By similar procedure we get

$$C_{12} = \frac{(1 + \mu)(1 - 2\mu)}{2E\ell b} \qquad \ldots (B3\text{-}17)$$

$$C_{22} = \frac{2.4(1 - \mu^2)}{\pi E \ell} \qquad \ldots (B3\text{-}18)$$

and $\qquad C_{33} = C_{22}\left(1 + \frac{TAN^2 \theta}{3.1}\right) \qquad \ldots (B3\text{-}19)$

Substituting the expressions for $C_{11}$, $C_{12}$, $C_{22}$ and $C_{33}$ in equation (B3-10) and the load set $M = Y\, Y_c\, COS\, \theta$, $V = Q\, COS\, \theta$ and $N = Q\, SIN\, \theta$ we get:

The deflection of the point of contact due to rotation of the support structure

$$\delta = \frac{Q}{E} COS^2 \theta \left[\frac{5.2\, Y_c^2}{b^2} + \frac{Y_c}{b} + 1.4\left(1 + \frac{TAN^2 \theta}{3.1}\right)\right] \qquad \ldots (B3\text{-}20)$$
(a)

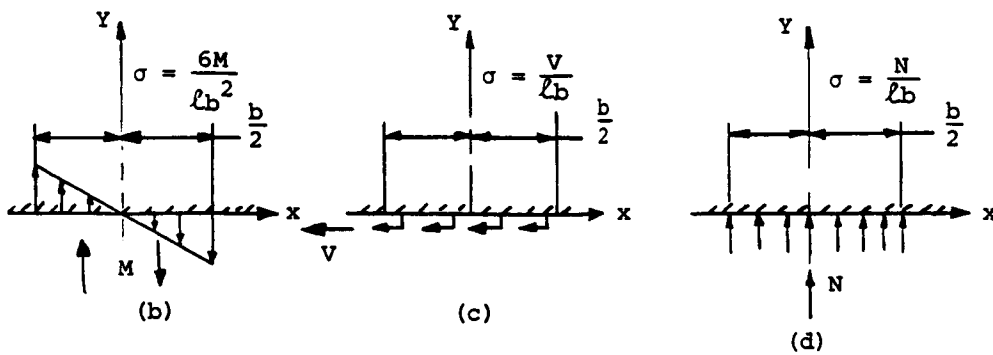

Figure B3-3 - Stress Distribution on Support Structure

### B-3.3  Deflection of the Teeth Due to Circumferential Deformation of the Rim and Gear Ring*

Assume the external gear is held rigidly as in Figure B3-4.  Under the effect of tangential force Q, the line HW is deformed and takes the position HW'.  Any differential element ABCD is deformed to A'B'C'D'.  The movement of A'B' relative to C'D' gives an angular rotation $d\theta$ about the center of the gear.

Total angular displacement of the point $W = \theta_t = \int d\theta$.  From Figure B3-4, $rd\theta = \gamma dr$; therefore

$$d\theta = \frac{\tau}{G} \frac{dr}{r} \qquad \qquad \ldots (B3-21)$$

and

$$\theta_t = \int_{r_i}^{r_o} \frac{\tau}{G} \frac{dr}{r} \qquad \qquad \ldots (B3-22)$$

For equilibrium, the total shearing force on any concentric surface is equal to the applied torque T; therefore

$$T = 2\pi r^2 F\tau \qquad \qquad \ldots (B3-23)$$

and

$$\theta_t = \frac{T}{2\pi LG} \int_{r_i}^{r_o} \frac{dr}{r^3} = \frac{Qr_i}{4\pi LG} \left( \frac{1}{r_i^2} - \frac{1}{r_o^2} \right) \qquad \qquad \ldots (B3-24)$$

The deflection, $\delta_E$, of the point of contact due to the circumferential deformation due to force Q

$$\delta_E = \frac{Q \cos \theta}{4\pi FG} r_i^2 \left( \frac{1}{r_{il}^2} - \frac{1}{r_{ol}^2} \right) \qquad \qquad \ldots (B3-25)$$

where

$F$ = hub face width

$r_i$ = radius to the contacting point

$r_{ol}$ = outside hub/rim radius

$r_{il}$ = effective radius of circumferential hub fixity

*These derivations are primarily based on [14].

For the internal gear ring deflection a similar rationale as for the external gear leads to the expression for deflection (see Figure B3-5).

$$\delta_I = \frac{Q \cos \theta}{4 \pi FG} r_2^2 \left(\frac{1}{r_{i2}^2} - \frac{1}{r_{o2}^2}\right) \qquad \ldots (B3-26)$$

where

$r_2$ = radius to contacting point on internal gear

$r_{i2}$ = root circle radius of gear ring

$r_{o2}$ = effective radius of circumferential gear ring fixity

A torsionally rigid hub is obtained if the effective hub fixity radius coincides with the root circle, i.e., $\delta = 0$. The hub stiffness factor, HSF, is used to indicate a degree of influence of the hub/ring flexibility on the overall gear mesh stiffness.

$$HSF = \frac{KG_{max}}{KG_{s\ max}} \qquad \ldots (B3-27)$$

where

$KG_{s\ max}$ = maximum mesh stiffness with torsionally rigid hubs/rings; $\delta_E = \delta_I = 0$

$KG_{max}$ = maximum mesh stiffness with designated hubs or rings, $\delta_E$ and $\delta_I \neq 0$

A combination of a rigid external gear hub and rigid internal gear ring is identified as HSF = 1.

of External Gear Hub
Figure B3-5 - Circumferential Deformation
of Internal Gear Ring

## B-3.4  Hertzian Deformation at Contact Point

Weber[13] applied Hertz's solution between two loaded cylinders in contact to the deformation of spur gears. In his formulation he used the following rationale:

The force at the contact point is distributed to the center of the tooth and then transmitted to the gear body. The tooth is cantilever which has an equivalent loading at the center consisting of bending, compression and shear. The shear load is distributed over the cross-section in the form of a parabola. The Hertzian stress is due to the shear component and reaches to the center of the tooth where it is transmitted as a transverse stress. The Hertzian compression is calculated from the point of contact in the direction of the applied force to the center of the tooth.

The teeth are treated as cylinders of lengths equal to the face width and radii equal to the radii of curvature at the contact point. For involute teeth the radii are the distances from the contact point to the tangent point of the respective base circles. For noninvolute profiles instantaneous base circles must be used. Figure B3-6 depicts the previously discussed geometry considerations as applied to the ISG drive. Distances $h_1$ and $h_2$ are along the line of action from the contact point to the center of the teeth.

Using Hertz's formulation for contact between cylinders

$$b^2 = 8 \ Q \ r(1 - \mu^2)/\pi E \qquad \qquad \dots (B3\text{-}28)$$

For the external-internal gear combination

$$\frac{1}{r} = \frac{1}{r_2} - \frac{1}{r_1} \qquad \qquad \dots (B3\text{-}29)$$

and

$\quad Q$ = load per tooth face width

$\quad r_1$ = radius of curvature of external gear

$\quad r_2$ = radius of curvature of internal gear

also,

$$P_{max} = \frac{2Q}{\pi b}$$

Considering the contacting gear teeth as slightly curved semi-infinite planes the Hertzian deformation

$$\delta = \delta_E + \delta_I = \frac{Q}{E} \frac{4(1 - \mu^2)}{\pi} \times [\ell n \frac{\sqrt{h_1 h_2}}{2r(1 - \mu^2)P_{max}} - \frac{\mu}{1 - \mu}]$$

$$\dots (B3-30)$$

where

$\quad \delta_E$ and $\delta_I$ are the deflection due to the Hertzian

deformation of the external and internal tooth
Figure B3-6 - Tooth Model for Hertzian
Contact Deformation

APPENDIX C

COMPUTER PROGRAM PACKAGE

This section contains the computer listing of all three modules, typical output data and instructions for entering the data.

C-1  Listing and Sample Run of the Static Analysis Program "Internal Static"

C-2  Listing and Sample Run of the Dynamic Analysis Program "Internal Dynamic"

C-3  Listing and Sample Run of the Stress Analysis "Internal Stress"

C-4  Entering of Input Data

X-Y COORDINATES OF POINTS ALONG THE PROFILE OF THE GEAR TEETH

THE GEAR TEETH HAVE A STANDARD PROFILE WITH NO MODIFICATIONS

THE Y-AXIS CORRESPONDS TO THE LINE OF SYMMETRY OF THE TOOTH. THE ORIGIN OF THE X-Y COORDINATE SYSTEMS IS LOCATED AT THE ROOT OF THE TOOTH A DISTANCE OF RRO1 (OR RRO2 FOR GEAR 2) FROM THE GEAR CENTER. VALUES TABULATED BELOW REPRESENT POINTS ON THE R.H. PROFILE OF THE TOOTH. POINT 1 IS LOCATED AT THE ADDENDUM CIRCLE. POINT 100 IS LOCATED AT THE ROOT CIRCLE. THETA VALUES REPRESENT THE ANGLE BETWEEN THE NORMAL TO THE PROFILE AND THE X-AXIS; COUNTERCLOCKWISE THETA IS DEFINED AS POSITIVE.

THE INVOLUTE STARTS AT Y = 0.2728 IN.  AND ENDS AT Y = 0.0859 IN.  ON THE TOOTH PROFILE OF GEAR 1.
THE INVOLUTE STARTS AT Y = 0.2681 IN.  AND ENDS AT Y = 0.0165 IN.  ON THE TOOTH PROFILE OF GEAR 2.
THE PITCH CIRCLE INTERSECTS THE TOOTH PROFILE OF GEAR 1 AT Y = 0.1462 IN.
THE PITCH CIRCLE INTERSECTS THE TOOTH PROFILE OF GEAR 2 AT Y = 0.1434 IN.

RRO1 = 1.8514 IN.
RRO2 = 6.1426 IN.

X AND Y VALUES ARE IN IN., THETA VALUES ARE IN DEGREES.

```

TABLES 2, 3 AND 4 LIST INFORMATION RESULTING FROM A STATIC ANALYSIS OF THE GEAR PAIR (NEGLECTING INERTIA
FORCES). THE DATA PRESENTED IN THESE TABLES WERE OBTAINED BY ROTATING THE DRIVING GEAR THRU ONE CYCLE
OF TOOTH ENGAGEMENT. IN EACH OF THESE TABLES POSITION 1 CORRESPONDS TO THE STARTING POINT OF CONTACT WHILE
POSITION 50 CORRESPONDS TO THE END POINT OF CONTACT.

## TABLE 2

PSI1 IS THE ANGLE OF ROTATION OF THE DRIVING GEAR IN DEGREES.
PSI2 IS THE ANGLE OF ROTATION OF THE DRIVEN GEAR IN DEGREES.
NCP IS THE NUMBER OF SEPARATE TOOTH PAIRS IN CONTACT AT A PARTICULAR POSITION.
PS IS THE TOOTH PAIR STIFFNESS IN LBF/IN AT A PARTICULAR POSITION.
KG IS THE COMBINED GEAR TOOTH SPRING CONSTANT (STIFFNESS) IN LBF/IN AT A PARTICULAR POSITION.
CG IS THE GEAR DAMPENING COEFFICIENT IN (LB-SEC)/IN.

NOTE: BOTH PSI1 AND PSI2 ARE MEASURED BETWEEN THE CENTER LINE.

TABLE 3

LOAD IS THE FORCE IN LBF, ACTING BETWEEN THE CONTACTING TOOTH PAIR IN A DIRECTION NORMAL TO THE PROFILE.
(THE TOTAL NOMINAL TRANSMITTED FORCE CARRIED BY ALL CONTACTING TOOTH PAIRS IS 1000.05 LBF.)
YC1 IS THE LOCATION OF THE CONTACT POINT ALONG THE TOOTH PROFILE OF GEAR 1; IN.
YC2 IS THE LOCATION OF THE CONTACT POINT ALONG THE TOOTH PROFILE OF GEAR 2; IN.
(YC1 AND YC2 ARE MEASURED RELATIVE TO THE X-Y COORDINATE SYSTEMS DEFINED IN TABLE 1)
SV IS THE SLIDING VELOCITY AT THE CONTACT POINT; FT/MIN.
HZP IS THE MAXIMUM HERTZ CONTACT PRESSURE AT THE CONTACT POINT; PSI.
PV IS THE HERTZ PRESSURE-SLIDING VELOCITY PRODUCT; LBF/(IN-SEC).

DYNAMIC ANALYSIS

THE SYSTEM USED IN THE DYNAMIC ANALYSIS IS PICTURED BELOW.

JL

KLS,CLS

JG2

KG,CG >>>----->

*JG1

JDS,CDS

JD

THE INTERACTION BETWEEN THE GEAR PAIR IS MODELED BY USING A LINEAR SPRING, KG (CALLED THE GEAR PAIR SPRING) IN PARALLEL WITH A LINEAR DASHPOT, CG (CALLED THE GEAR PAIR DASHPOT). KG AND CG ARE PERIODIC FUNCTIONS WITH A PERIOD EQUAL TO THE RECIPROCAL OF THE TOOTH MESHING FREQUENCY.

THE DAMPING FACTOR (ZETAS) OF THE SHAFT = 0.005

THE DAMPING FACTOR (ZETAG) OF THE GEAR PAIR = 0.050

THE SYMBOLS USED IN THE ABOVE FIGURE HAVE THE FOLLOWING DEFINITIONS:

JD IS THE MASS MOMENT OF INERTIA OF THE PRIME MOVER (DRIVER)

JG1 IS THE MASS MOMENT OF INERTIA OF THE DRIVING GEAR (GEAR 1)

JG2 IS THE MASS MOMENT OF INERTIA OF THE DRIVEN GEAR (GEAR 2)

JL IS THE MASS MOMENT OF INERTIA OF THE LOAD

KDS IS THE TORSIONAL SPRING STIFFNESS OF THE DRIVING SHAFT

KG IS THE LINEAR SPRING STIFFNESS OF THE GEAR PAIR

KLS IS THE TORSIONAL SPRING STIFFNESS OF THE LOAD SHAFT

CDS IS THE TORSIONAL DAMPENING COEFFICIENT OF THE DRIVING SHAFT

CG IS THE LINEAR DAMPENING COEFFICIENT OF THE LOAD SHAFT.

THE SYSTEM PARAMETERS HAVE THE FOLLOWING SPECIFICATIONS:

$$JD = 0.9376 \ (\text{IN-LBF-}(\text{SEC}^{**}2))/\text{RADIAN}$$

$$JG1 = 0.0188 \ (\text{IN-LBF-}(\text{SEC}^{**}2))/\text{RADIAN}$$

$$JG2 = 2.3000 \ (\text{IN-LBF-}(\text{SEC}^{**}2))/\text{RADIAN}$$

$$JL = 0.9376 \ (\text{IN-LBF-}(\text{SEC}^{**}2))/\text{RADIAN}$$

$$KDS = 902413.0 \ (\text{IN-LBF})/\text{RADIAN}$$

$$KLS = 902413.0 \ (\text{IN-LBF})/\text{RADIAN}$$

$$CDS = 1.290 \ (\text{IN-LBF-SEC})/\text{RADIAN}$$

$$CLS = 7.753 \ (\text{IN-LBF-SEC})/\text{RADIAN}$$

KG AND CG ARE TABULATED IN TABLE 2 OF THE STATIC ANALYSIS SECTION.
CDS AND CLS WERE CALCULATED USING THE VALUE ZETAS QUOTED ABOVE.
CG WAS CALCULATED USING THE VALUE ZETAG QUOTED ABOVE.
TABLE 5

SYSTEM VIBRATION DATA
*************************

THE INFORMATION LISTED BELOW REPRESENTS THE SYSTEM NATURAL FREQUENCIES AND THE CORRESPONDING EIGANVECTORS. THIS
INFORMATION IS OBTAINED FROM THE "VIBS" SUBROUTINE WHICH SOLVES THE GENERAL EIGANPROBLEM USING A JACOBI ITERATION
TECHNIQUE. NOTE THAT THE FIRST MODE IS A RIGID BODY MODE AND NOTE THE EFFECT OF THE GEAR RATIO ON THE EIGANVECTORS.
IN COMPUTING THIS VIBRATION DATA AN AVERAGE VALUE FOR THE GEAR STIFFNESS EQUAL TO 3318517.0 LBF/IN WAS USED.

NATURAL FREQUENCIES

EIGANVECTORS

| | (CYCLES/SEC) | JD | JG1 | JG2 | JL |
|---|---|---|---|---|---|
| 1ST MODE | 0.0 | 1.0000 | 1.0000 | 0.3333 | 0.3333 |
| 2ND MODE | 155.6 | 1.0000 | 0.0073 | -0.0216 | -2.9475 |
| 3RD MODE | 332.9 | 1.0000 | -3.5448 | -1.2837 | 0.3621 |
| 4TH MODE | 4374.5 | 1.0000 | -783.9355 | 18.0099 | -0.0230 |

TABLE 6

NUMERICAL INTEGRATION OF THE DIFFERENTIAL EQUATIONS OF MOTION
********************************************************************

THE DIFFERENTIAL EQUATIONS OF MOTION OF THE SYSTEM WERE INTEGRATED NUMERICALLY USING A 4TH ORDER
RUNGE-KUTTA INTEGRATION SCHEME. THE INITIAL CONDITIONS IMPLEMENTED FOR THE INTEGRATION ARE:

A. INITIAL ANGULAR VELOCITIES

THE INITIAL VELOCITY OF JD   IS   8000.00   RPM
THE INITIAL VELOCITY OF JG1  IS   8000.00   RPM
THE INITIAL VELOCITY OF JG2  IS   2666.67   RPM
THE INITIAL VELOCITY OF JL   IS   2666.67   RPM
B. INITIAL ANGULAR DISPLACEMENTS

THE INITIAL DISPLACEMENTS ARE DUE TO A TORQUE PRELOAD OF     1936.30   IN-LBS ON THE
INPUT SHAFT AND     5808.90   IN-LBS ON THE OUTPUT SHAFT.    THIS TORQUE PRELOAD IS
EQUAL TO THE NOMINAL STATIC TORQUE CARRIED BY THE SYSTEM.    THIS RESULTS IN THE FOLLOWING
INITIAL ANGLES OF TWIST OR WIND-UP:

THE INITIAL DISPLACEMENT OF JD   IS   0.00215   RADIANS
THE INITIAL DISPLACEMENT OF JG1  IS   0.0       RADIANS
THE INITIAL DISPLACEMENT OF JG2  IS  -0.00005   RADIANS
THE INITIAL DISPLACEMENT OF JL   IS  -0.00649   RADIANS

THE NUMERICAL INTEGRATION WAS CARRIED OUT FOR A LENGTH OF TIME EQUIVALENT TO   140 CYCLES
THE TIME REQUIRED FOR THE START-UP TRANSIENT TO DECAY (THIS TIME IS ASSUMED TO BE EQUALNG
TO 5 TIMES THE LONGEST SYSTEM NATURAL PERIOD) TO THE TIME REQUIRED FOR ONE ADDITIONAL
TOOTH PASSAGE CYCLE.    THE DATA TABULATED IN TABLES 7 AND 8 BELOW COMES FROM THIS LAST

TOOTH PASSAGE CYCLE, THE ASSUMPTION BEING THAT THIS REPRESENTS A STEADY-STATE SITUATION.
THE INTEGRATION TIME STEP USED IS 0.0000229 SECONDS. THIS REPRESENTS EITHER ONE TENTH
OF THE SHORTEST SYSTEM NATURAL PERIOD OR A CERTAIN PERCENTAGE OF THE PERIOD OF THE
STIFFNESS FUNCTION, WHICHEVER IS SMALLEST.

RT1,RT2 = 1.0000  0.8000

```
***********************************
*                                 *
*     XT PLOT OF THE RESULTS OF    *
*     THE NUMERICAL INTEGRATION    *
*                                 *
***********************************
```

THE DATA DEPICTED IN THE FOLLOWING X VERSUS T PLOTS ARE OBTAINED BY NUMERICALLY
INTEGRATING THE DIFFERENTIAL EQUATIONS OF MOTION. IN THESE PLOTS:

TIME IS THE INTEGRATION TIME; SECONDS
KG  IS THE GEAR STIFFNESS; LBF/IN
DF  IS THE DYNAMIC FORCE; LBF

THE DYNAMIC FORCE PLOT DISPLAYS A NORMALIZED DYNAMIC FORCE,
I.E. THE DYNAMIC FORCE DIVIDED BY THE NOMINAL TRANSMITTED FORCE.

THIS PLOT REPRESENTS ONLY THAT TIME PERIOD IN THE NUMERICAL INTEGRATION SEQUENCE
COVERING THE LAST PASSAGE OF A TOOTH PAIR THRU THE CONTACT ZONE. IT IS ASSUMED
THAT THE SYSTEM IS OPERATING IN A STEADY STATE CONDITION DURING THIS PERIOD.

INPUT SPEED IS    8000.00  RPM          BACKLASH IS    0.010000 IN.

```
                                        NORMALIZED DYNAMIC FORCE
                                  0.0    0.57    1.14    1.71    2.28        DF

THE INFORMATION IN THIS TABLE COMES FROM AN ANALYSIS OF THE NUMERICAL INTEGRATION
SEQUENCE COVERING THE LAST PASSAGE OF A TOOTH PAIR THROUGH THE CONTACT ZONE.
POSITION 1 CORRESPONDS TO THE STARTING POINT OF CONTACT WHILE POSITION 100
CORRESPONDS TO THE END POINT OF CONTACT. THE FOLLOWING SYMBOLS ARE UTILIZED IN
THIS TABLE:

PSI1 IS THE ANGLE OF ROTATION OF THE DRIVING GEAR; DEGREES.
PSI2 IS THE ANGLE OF ROTATION OF THE DRIVEN GEAR; DEGREES.
NCP IS THE NUMBER OF SEPARATE TOOTH PAIRS IN CONTACT AT A PARTICULAR POSITION
DF IS THE TOTAL DYNAMIC FORCE BEING TRANSMITTED ALONG THE LINE OF ACTION; LBF
YC1 IS THE LOCATION OF THE CONTACT POINT ALONG THE TOOTH PROFILE OF GEAR 1; IN.
YC2 IS THE LOCATION OF THE CONTACT POINT ALONG THE TOOTH PROFILE OF GEAR 2; IN.
SV IS THE SLIDING VELOCITY AT THE CONATCT POINT; FT/MIN.
HZP IS THE MAXIMUM HERTZ CONTACT PRESSURE AT THE CONTACT POINT; PSI.
PV IS THE HERTZ PRESSURE-SLIDING VELOCITY PRODUCT; LBF/(IN-SEC).

BOTH PSI1 AND PSI2 ARE MEASURED BETWEEN THE CENTER LINE OF THE CONTACTING TOOTH AND THE LINE OF
CENTERS. AN ANGLE OF APPROACH IS TAKEN AS NEGATIVE WHILE AN ANGLE OF DEPARTURE IS TAKEN AS POSITIVE.
YC1 AND YC2 ARE MEASURED RELATIVE TO THE XY-COORDINATE SYSTEMS DEFINED IN TABLE 1.

| POSITION | PSI1 | PSI2 | NCP | DF | YC1 | YC2 | SV | HZP | PV |
|---|---|---|---|---|---|---|---|---|---|
| 1 | -21.491 | -5.292 | 3 | 1774.07 | 0.088 | 0.268 | 0.17439E+04 | 0.12512E+06 | 0.43639E+08 |

TABLE 8

THE INFORMATION IN THIS TABLE COMES FROM AN ANALYSIS OF THE NUMERICAL INTEGRATION SEQUENCE COVERING THE LAST PASSAGE OF A TOOTH PAIR THROUGH THE CONTACT ZONE. POSITION 1 CORRESPONDS TO THE STARTING POINT OF CONTACT WHILE POSITION 100 CORRESPONDS TO THE END POINT OF CONTACT. THE FOLLOWING SYMBOLS ARE UTILIZED IN

THIS TABLE:

LOAD IS THE FORCE IN LBF  ACTING BETWEEN THE CONTACTING TOOTH PAIR.
      (THE LOAD IS DIRECTED NORMAL TO THE TOOTH PROFILE.)
   TD1 IS THE TOOTH DEFLECTION ON GEAR 1;   IN.
   TD2 IS THE TOOTH DEFLECTION ON GEAR 2;   IN.
   HD  IS THE HERTZIAN DEFLECTION OF THE CONTACT POINT;  IN.
   CD  IS THE COMBINED DEFLECTION OF THE CONTACT POINT;  IN.
      (ALL DEFLECTIONS ARE MEASURED ALONG THE LINE OF ACTION)

| POSITION | LOAD | TD1 | TD2 | HD | CD |
|---|---|---|---|---|---|
| 1 | 490.34 | 0.0002432 | 0.0002606 | 0.0000773 | 0.0005811 |

TABLE 9

THE INFORMATION IN THIS TABLE COMES FROM AN ANALYSIS OF THE NUMERICAL INTEGRATION SEQUENCE COVERING THE LAST PASSAGE OF A TOOTH PAIR THROUGH THE CONTACT ZONE. POSITION 1 CORRESPONDS TO THE STARTING POINT OF CONTACT WHILE POSITION 100 CORRESPONDS TO THE END POINT OF CONTACT. THE FOLLOWING SYMBOLS ARE UTILIZED IN THIS TABLE:

SF IS THE NOMINAL TRANSMITTED FORCE ALONG THE LINE OF ACTION; LBF
DF IS THE TOTAL DYNAMIC FORCE BEING TRANSMITTED ALONG THE LINE OF ACTION; LBF
DF1 IS THE DYNAMIC LOAD FACTOR FOR THE GEAR PAIR, ADJACENT SHAFTS, AND BEARINGS
SL IS THE FORCE IN LBF ACTING BETWEEN THE CONTACTING TOOTH PAIR FROM THE STATIC ANALYSIS
DL IS THE FORCE IN LBF ACTING BETWEEN THE CONTACTING TOOTH PAIR FROM THE DYNAMIC ANALYSIS
DF2 IS THE DYNAMIC FACTOR FOR AN INDIVIDUAL GEAR TOOTH PAIR TRAVERSING THE MESH ARC

| POSITION | SF | DF | DF1 | SL | DL | DF2 |
|---|---|---|---|---|---|---|
| 1 | 1000.00 | 1774.07 | 1.77 | 276.41 | 490.34 | 1.77 |
| 2 | 1000.00 | 1787.17 | 1.79 | 277.93 | 493.96 | 1.78 |

## C-4  ENTERING OF INPUT DATA

The three modules of the ISG drive computer package require input data which are obtainable from the namelist arrays or the two data files. Numerical data may be entered without format statements, and fields are generated as required. The variables required for the namelist arrays along with their respective headings are:

/HEDING/

| | | |
|---|---|---|
| TITLE 1 | any suitable title or information |
| TITLE 2 | can be entered on three lines from |
| TITLE 3 | Title 1 through Title 3 |
| TAPE | – Alphanumeric code to indicate whether certain information is to be filed on tape. Tape 8 is used for the dynamic analysis (Module 2) and Tape 9 is for the stress analysis (Module 3). |
| | 'YES' – write on tape |
| | 'NO'  – do not write on tape |

/CONTRL/

| | |
|---|---|
| INPUT | – alphanumeric code used to designate type of input data |
| | 'ENGL' – English (lbf, in., sec.) |
| | 'SI'  – metric (newtons, mm, sec.) |
| OUTPUT | – alphanumeric code used to designate output; codes used are same as for input |
| MODF | – alphanumeric code used to designate whether or not profile modifications are input |
| | 'NO'  – no modifications |
| | 'YES' – modifications listed under /PRFDEF/ |

/PHYPAR/  (two data points required per variable)

    E        - Young's modulus

    PR      - Poisson's ratio

    GAMA    - specific weight

    JG      - polar moment of inertia; optional, program
              will generate if no value entered

/GENPAR/

    DP      - diametral pitch (English input only)

    M       - gear module (metric module only)

    DELTP   - backlash

    TIN     - input torque

    RPMIN   - input RPM

    ZETAS   - damping coefficient of shaft

    ZETAG   - damping coefficient between gear teeth

    PHID    - pressure angle (degrees)

  * JD     - mass moment of inertia of driver

  * JL     - mass moment of inertia of load

  * KDS   - torsional spring stiffness of driving shaft

  * KLS   - torsional spring stiffness of load shaft

  * LDS   - length of drive shaft

  * LLS   - length of load shaft

/GEOPAR/  (two data points required per variable)

    TG      - number of gear teeth

    AD      - addendum

    WD      - working depth

    GRRF    - fillet radius of basic rack

   * RI    - hub radius

FW        - face width

UCUT      - undercut

RT        - rim thickness

RADEL     - radial deflection

COR12     - modifier for tooth center angle

COR34     - modifier for tooth center angle

/PARAME/

NLIM      - angular sweep parameter - Gear 1

MLIM      - angular sweep parameter - Gear 2

DELT      - increment

JJJJ      - adjustable do loop parameter - Gear 1

LLLL      - adjustable do loop parameter - Gear 2

DPSLI1    - angular correction due to radial deflection -

          Gear 1

DPSLI2    - angular correction due to radial deflection -

          Gear 2

DPEL1     - modifier for tooth center angle - Gear 1

DPEL2     - modifier for tooth center angle - Gear 2

* optional, program will generate if no value entered

In addition to evaluating purely involute gear teeth, the gear tooth profile can be modified to simulate tip relief or undercutting. Also, sinusoidal errors can be introduced, as well as pits, to simulate involute errors due to manufacturing and surface damage, respectively. These modifications are introduced in the /PRFDEF/ namelist. If MODF = NO, /PRFDEF/ is not included in the data card set.

/PRFDEF/   (two data points required per variable)

    PATM    - parabolic tip modification

    STTM    - straight line tip modification

    RATM    - roll angle of tip modification

    PABM    - parabolic bottom modification

    STBM    - straight line bottom modification

    RABM    - roll angle of bottom modification

    PER     - amplitude of sinusoidal error

    PAP     - phase angle of sinusoidal error

    CYC     - number of cycles of sinusoidal errors

    IPIT    - profile coordinate points over which pit

             occurs

    DEEP   - depth of pit

Use of the namelist arrays offers a simple, unformatted means of inputting data and is very convenient for looping more than one data set. After the initial data set, subsequent data sets need just two input revisions. If a later namelist array contains no revisions, only a card with the array heading and ending need be submitted. Unlisted variables default to the previous values. Examples of input data card sets illustrate the following namelist data card format.

1. Column one is blank.

2. '&' is used to signify new namelist array.

3. '&' is followed by the namelist name.

4. A blank separates the namelist name and the first variable name. Subsequent variables are separated by commas.

5.  There are two methods for defining the two element variables. The elements are defined in the order they are to be entered in the variable and separated by commas, i.e., TG=32, 96 defines TG(1) = 32 and TG(2)=96. If both elements are equal, they may be entered by listing the number of identical values, the multiplication symbol, and then the value itself, i.e., AD=2*0.125, defines AD(1)=0.125 and AD(2)=0.125.

6.  The last listed array value is followed by a blank and then the symbol from column 2 is repeated. The word END immediately follows the symbol and signifies the end of that array.

Because of the modular approach it is necessary to store certain information from one module for use in another module. Tape 8 stores the pertinent data from the static analysis which is needed for the dynamic analysis. Tape 9 stores the pertinent data from the dynamic analysis for use in the stress analysis. This tape contains some of the previously transferred static analysis data on Tape 8. The stress analysis then has logic to initiate a static or dynamic stress analysis.

The modules have the capability for accepting either SI or English gear input data and have options to print the results in either SI or English units. Input and output do not necessarily have to be of the same regime, i.e., SI output can be obtained from English input and vice-versa. Data submitted under the 'ENGL' code should be in pounds-force, inches and seconds. The data submitted under the 'SI' code should be in newtons, millimeters and seconds. The only exception to this is the density value under the 'SI' code should be in $kg/m^3$.

## GLOSSARY OF TERMS

| Text | Computer Program | Description |
|------|------------------|-------------|
| a | AD | addendum |
| A | | area |
| b | | ring gear width<br>maximum thickness of tooth |
| B | BGM | backlash |
| c | CR<br>C<br>$C_B$<br>CYC | loaded contact ratio<br>center distance of gears<br>damping coefficient<br>number of sinusoidal error cycles |
| d | DED | dedendum |
| DF1, DF2 | DF1, DF2 | dynamic load factors |
| D<br>DEEP | DEEP | ball diameter<br>depth of pit |
| E | E | Young's modulus |
| F | FW | face width<br>geometry factor |
| $F_r$ | | radial load of bearings |
| $F_t$ | | tangential load of gears |
| G | | modulus of torsion |
| h<br>HSF | HSF | ring gear thickness<br>hub/ring torsional stiffness factor |
| $h_t$ | HT | whole depth |
| I | | moment of inertia |
| ISG | | internal gear drive |
| J | | polar mass moment of inertia |
| [J] | [MM] | inertia matrix |
| KG | | gear mesh stiffness |
| KP | | gear pair stiffness |

| Text | Computer Program | Description |
|------|------------------|-------------|
| [K] | [SM] | stiffness matrix |
| L | | length of roller |
| L.A. | | line of action |
| $m_G$ | MG | gear ratio |
| $m_P$ | CR | contact ratio |
| M | | bending moment<br>module |
| N | | normal load |
| | TG | number of teeth |
| | OMG | constant angular velocity |
| p | CP | circular pitch |
| $p_b$ | BP | base pitch |
| P | | applied load at contacting point |
| | PABM | magnitude of parabolic modification<br>  at bottom |
| | PAP | angle from start of sinusoidal error<br>  to start of involute |
| | PATM | magnitude of parabolic modification<br>  at tip |
| | PE | profile error |
| | PER | maximum profile error |
| | PH | Hertzian pressure |
| | PM | profile modification |
| | PPD' | instantaneous pitch radius |
| | PSITP | static angular position |
| r | RPC | radius at pitch circle |
| $r_A$ | RAC | radius at addendum circle |
| $r_b$ | RBC | base radius circle |
| | RABI | RA at the bottom of involute |
| | RABM | length of root modification in<br>  degrees of roll |
| | RABOT | RA at bottom of involute |
| | RAM | roll angle at end of modification<br>  at tip |
| | RAN | RA at end of modification at bottom |
| | RAPP | RA at pitch point |
| | RAT | RA at tip |
| | RATIP | RA from end of modification to RA<br>  at the pitch point |
| | RATM | length of tip modification in degrees<br>  of roll |

| Text | Computer Program | Description |
|------|------------------|-------------|
| RCCP | RCC | instantaneous radius of curvature |
| $r_F$ | RF | fillet radius |
| $r_L$ | RLM | limit radius |
| $r_T$ | RT | edge radius of generating tool |
| $Q$ | $Q(k)_i$ | static gear pair load |
| $Q_t$ | QT | total mesh static load |
| QD | $QD(k)_i$ | dynamic gear pair load |
| $QD_t$ | QDT(I) | total mesh dynamic load |
| $Q_{max}$ | | maximum radial bearing load |
| | STBM | magnitude of straight line modification at bottom |
| | STTM | magnitude of straight line modification at tip |
| SV | | sliding velocity |
| T | | torque |
| $T_{IN}$ | TD | input torque |
| $T_{LA}$ | | theoretical line of action |
| TR, TR' | TDIN | theoretical and instantaneous transmission ratio |
| $T_{OUT}$ | TOUT | output torque |
| $U_1$, $U_2$ | | interval of contact |
| U | | abscissa in global coordinate system |
| V | | shear velocity ordinate in global coordinate system |
| W | | abscissa in rotating coordinate system of gears |
| X | | abscissa in local tooth coordinate system |

| Text | Computer Program | Description |
|---|---|---|
| Y | | ordinate in local tooth coordinate system |
| z | | ordinate in rotating coordinate system of gears<br>number of balls or rollers-bearings |

## GREEK SYMBOLS

| Text | Computer Program | Description |
|---|---|---|
| $\alpha$ | | contact angle - bearings |
| $\beta$ | | angle between point of contact and center of tooth |
| $\gamma$ | | angle between pitch point and center of tooth |
| $\gamma_s$ | | maximum fillet stress angle |
| $\delta$ | TDEFL | deflection |
| $\varepsilon$ | RA | roll angle |
| $\theta$ | | involute polar angle |
| $\theta$ | PSP | dynamic displacement |
| $\dot{\theta}$ | PSPD | dynamic velocity |
| $\ddot{\theta}$ | PSPDD | dynamic acceleration |
| $\mu$ | PR | Poisson's ratio |
| $\xi_G$ | ZETAG | critical damping ratio - gear |
| $\xi_S$ | ZETAS | critical damping ratio - shafts |
| $\pi$ | PI | 3.141592654 |
| $\sigma$ | | stress |
| $\tau$ | | torsional stress |
| $\phi$ | | pressure angle at any point |
| $\phi_n$ | | normal pressure angle |

16. Abstract

This research work has developed a comprehensive method for analyzing the static and dynamic loading and stresses of internal spur gear (ISG) drives. Prior to this study, there were no established methods for dynamic analysis of ISG drives. The currently published design techniques for ISG drives reflect the technology of the 1950's. Consequently, this comprehensive methodology represents a definite advancement of the ISG drive design techniques. The analysis can be applied to involute and noninvolute spur gearing as well as to the high contact ratio gear systems. In addition, the developed method sets the groundwork for studies of planetary gear dynamics. The developed methods are combined in a digital computer program so that the static and dynamic behavior of an ISG drive can be investigated in an uninterrupted sequence. In addition to the geometry and nominal load relations, the computer program takes into account the following:

1. Variable gear mesh stiffness due to changes in single and multiple tooth contacts.
2. Deformations of the internal gear rings.
3. Actual tooth geometry including any errors and defects.
4. Elastic and inertial effects of the entire rotating system.
5. Effect of load on contact ratio, mesh stiffness and premature or delayed engagement.

The variable mesh stiffness is combined with the drive train stiffness, inertia and damping to solve by numerical methods the nonlinear differential equations of motion for the dynamic loading of the gear teeth. Utilizing the computer program, parametric studies were made to determine the contributions of errors, damping and component stiffness on the dynamic behavior of ISG drives. The results of the analyses indicated an impressive list of advantages of the ISG drive over the external spur gear (ESG) drive. The principal reason for these advantages can be attributed to the high contact ratio of the ISG drive. The new methodology has finally provided an analysis procedure exclusively for the ISG drive. It reflects the latest state-of-the-art understanding of involute and noninvolute spur gear performance and is capable of analyzing the "very high contact ratio" (VHCR) gearing encountered with ISG drives.
