## ADHESION TESTING OF AIRCRAFT TIRES

Stephen N. Bobo U.S. Department of Transportation Transportation System Center

In December 1979 the FAA issued a new Technical Standard Order TSO-C62c to all users and manufacturers of aircraft tires. It was designed to upgrade the testing required to meet minimum airworthiness standards.

These changes to the testing requirements for new tires necessitated similar improved standards for retreads used in the national air carrier fleet.

Accordingly, an advisory circular (ref. 1) was prepared for comment which upgraded the testing standards for retreads to reflect the changes made in testing new tires under TSO-C62c. The advisory circular recommending the new dynamometer testing requirements called for testing every retread level of every tire size in an effort to accumulate sufficient tests and data to provide confidence that the retreading process including casing selection contained procedures which would provide for the continued airworthiness of the tires in service.

However, the number of tires to be tested to accumulate confidence would have presented an unacceptable and unrealistic cost to retreaders and their customers and an alternative approach was necessary.

For many years tire manufacturers and retreaders have been using laboratory adhesion tests as means for determining the effectiveness of the vulcanizing process in adhering the various tire components to one another. Adhesion testing appeared to offer a less burdensome alternative to replace some of the dynamometer tests recommended in the AC. Accordingly, test results and data were requested from retreaders who had used adhesion testing.

All of the American retreaders of aircraft tires submitted data, as did Goodyear, which obtained additional data from European adhesion tests. For some tires the Navy has required adhesion tests as a part of their purchasing procedure and this data was also made available. Such data was collected from various sources for over 700 tires, both commercial and military.

In meetings with industry, the FAA was presented with the industry consensus regarding the use of ply and tread adhesion tests to qualify tire retreading process specifications. The FAA has accepted this means of testing as one which can be used in the qualification of a tire retreading process specification.

The adhesion testing procedure used by most retreaders was a modification of the Hascar-Reiger method (ref. 2) in which a 1" strip of rubber is slit and introduced into a tensilometer. Variations of this method are described in references 1 and 3 to 6.

Figure 1 gives an example of the output from an adhesion test. The data is subject to wide variations in interpretation because of the stress-tear-relaxation characteristic of the rubber sample. Several methods of reporting the data have been adopted, including averaging all maximum values, averaging all minimum values and taking the mean of the maximum and minimum average values. The reporting sources usually list the method of recording and this is so noted in the data. Several other variations in method account for variations in test results, the three most important of which relate to sample preparation. Some laboratories attempt to cut the sample to the exact dimension, others correct for errors in size by normalizing the cut dimension to 25.4 mm (1 in.) width. Some laboratories cut the sample approximately 3.2 mm (1/8 in.) oversize and using a razor blade slit the intended path of travel of the tear line around the edge of the sample.

Several individuals have reported high values of adhesion when excess sample rubber thickness is not cut away, however laboratories as a rule do nothing to alter the thickness of the sample.

The location of the tear region varies depending upon the agency requesting the testing, and when it is known this information has been included in the data. Most organizations have reported buffline adhesion data, although some have reported maximum rather than average results.

Some organizations have reported adhesion data from the outside of the outer ply while some have reported between the second and third ply. Since there was no statistically detectable difference between these reported values they were lumped in the data.

The data was tabulated and placed in a data base called BANK (ref. 7). The fields are described in a listing. Most of the data on buffline adhesion is taken from TAV although TMX contains some buffline data. These two fields were separated because of uncertainty about the method of reading the primary recorder traces.

PAV gives values of outer ply adhesion. Some readings of maximum and minimum adhesion averages were available and these were recorded as PMX and PMN. Tire size is structured so that mathematical transformations such as linear regression or rank order correlation can be performed on the size variable.

Other information, such as R level, durometer tensile, and elongation measurements, is included where a sufficient amount of data was obtained.

The BANK program provides an interesting first level statistic printout of the data in each field (Figures 2 through 13). These include mean, standard deviation, and maximum and minimum values, as well as a data histogram.

In order to use simplified procedures for establishing minimum adhesion thresholds and realistic test sample sizes it is important to confirm the character of the distribution of the data. This may be accomplished by analysis of the data in terms of the probability that it fits on a normal distribution curve (Figure 14).

Figure 15 is a scatter plot of the probability that any given sample will lie below a given value, against ordinal value. To the extent that this plot is a straight line the distribution is normal. If the plot deviates greatly from a straight line the data does not have normal distribution. It may be seen that the plot in Figure 15 is a relatively straight line. A surer test is to use the log of probability and the log of the order value (Figure 16). This is useful to test the values lying in the skirts of the distribution curve. Since there is always a small number of data points in the region of the lower adhesion values, the use of the log plot highlights any abnormality of these values. Our analysis of these data have allowed us to conclude that the data is fairly normally distributed and can therefore be used to establish criteria for minimum threshold levels based on normal distribution. These criteria have been determined using an algorithm giving the probability that any number R of adhesion values will fall below the n lowest values.

For the FAA we selected a test sample size of 20 tires and used the three lowest readings as the threshold criteria. Using the algorithm, we determined that, using values of 30, 33, and 36 for buffline adhesion and 20, 23, and 26 for ply adhesion, the probability that a retreader having good tires would fail the test was about fifteen percent. The probability of failing a retest was about 2%. One the other hand the probability of detection of a sample of tires having a mean less than the threshold values increases very rapidly to 98% at a value of 1 standard deviation away from the threshold mean (Figure 17).

Tread and ply adhesion values are a very good measure of tire production uniformity and can therefore be used as a monitor of quality during production in statistical QC devices such as control charts. The threshold values given represent tires taken from a fleet in which a very small number of tire related incidents have occurred. They can therefore be considered as representing a safe population of tires.
