Abstract The conservation laws of elasticity for nonhomogeneous materials developed under this grant are used to study the crack behavior in adhesively bonded lap shear joints. These laws and the fundamental relationships in fracture mechanics of interface cracks, the problem is reduced to a pair of linear algebraic equations, and stress intensity solutions can be determined directly by information extracted from the far field. The numerical results obtained show that: (1) in the lap-shear joint with a given adherend, the opening-mode stress intensity factor, ( $K_I$ ) is always larger than that of the shearing-mode ( $K_{II}$ ); (2) $K_I$ is not sensitive to adherent thickness but $K_{II}$ increases rapidly with increasing thickness; and (3) $K_I$ and $K_{II}$ increase simultaneously as the interfacial crack length increases.

## FOREWORD

This report describes a portion of the results obtained on NASA Grant NSG 3044. This work was done under subcontract to the University of Illinois, Urbana, with Prof. S.S. Wang as the Principal Investigator. The prime grantee was the Massachusetts Institute of Technology, with Prof. F.J. McGarry as the Principal Investigator and Dr. J.F. Mandell as a major participant. The NASA - LeRC Project Manager was Dr. C.C. Chamis.

Efforts in this project are primarily directed towards the development of finite element analyses for the study of flaw growth and fracture of fiber composites. This report presents a method of analysis for adhesive or interlaminar cracks which propagate in the interface, rather than cohesively in the adhesive or interlayer. The latter case was treated in an interim report NASA CR-135248.

## ABSTRACT

A study on the elastic behavior of interface cracks in adhesively bonded lap shear joints is presented. The problem is investigated by using a recently developed method of analysis based on conservation laws in elasticity for nonhomogeneous solids and fundamental relationships in fracture mechanics of dissimilar materials. The formulation leads to a pair of linear algebraic equations in mixed-mode stress intensity factors. Singular crack-tip stress intensity solutions are determined directly by information extracted from the far field. Stress intensity factors and associated energy release rates are obtained for various cases of interest. Fundamental nature of the interfacial flaw behavior in lap-shear adhesive joints is examined in detail.

## 1. INTRODUCTION

While adhesively bonded joints have been employed in many secondary structural components, the effective use of adhesive joining technology in primary load-bearing structural members is still in its infancy. Applications of adhesive joints will not reach their full potential until certain critical problems are solved. The major factors responsible for this situation are the complex failure modes and mechanics presented in the joints. Because of many geometric, material and fabrication variables involved, the fracture problem of adhesive joints is extremely complicated. Current knowledge of the joint failure behavior is yet very limited. Analyses and design criteria for flaw resistance of adhesively bonded joints are seriously deficient.

Interfacial cracking, also called debonding, is one of the most frequently encountered modes of failure. It frequently occurs at geometric boundaries such as edges and re-entry corners due to inherent stress concentrations, or results from faulty joining in fabrication such as incomplete wetting between adherend and adhesive. Debonding is also found in adhesive joints subjected to combined high temperature and moisture absorption. Progressive reduction of stiffness, exposure of the interior of the composite to environmental attack, and final disintegration of the structure are frequently observed to occur by the presence and growth of interfacial cracks. The lap-shear joint shown in Fig. 1 is considered in this study, because it is one of the most widely used joint configuration in structural applications. Understanding the fundamental nature of interfacial cracks is of utmost importance in the reliability and safety design of the adhesive joints for primary load-bearing structures. In this paper

analytical study on the interfacial crack behavior in the adhesively bonded lap-shear joints is presented.

The interface crack problem was apparently first studied by Williams [1]. Elasticity theories for cracks of this nature were attempted by many investigators, and solutions characteristically involve oscillatory stress singularity [2-7]. A major concern for the oscillation of near-field stresses is that they lead to physical absurdity of crack surface interpenetration or overlapping, as pointed out by England [2] and Malyshev, et al. [8]. This implies that the solutions for the interface crack problem are physically inadmissible. The unsatisfactory aspects of the oscillatory stress singularity were discussed by several researchers, for example, Refs. [2,8-10]. An alternate model of a closed crack tip with frictionless contact was first proposed by Comninou [9] to correct these effects. The stress singularity of the model is different from that of the oscillatory one with a finite normal tensile traction ahead of the crack tip. The crack tip in a nominal tensile field has an extremely small contact area in comparison to the size of the crack. Recently, Achenbach, et al. [10] and Keer, et al. [11] proposed another models which include the crack face closure, relative slip conditions at the interface, and different definitions of stress intensity factors. In view of the complexities aforementioned, the interfacial crack problem in adhesively bonded joints is obviously rather difficult. The complex structural geometry, the presence of the multiphase material system, and the unknown multiaxial stress state acting on the crack introduce additional complications. The very local nature of the interface crack singularity as shown in [7,12] is noted to introduce the thickness of the thin adhesive layer as a characteristic dimension in the problem. Any simplifications, which fail to consider the

crucial role of the thin adhesive layer, would lead to a severe drawback in studying the full nature of the adhesive joint fracture. The importance and complexities of interface debonding in adhesive joints have long been recognized [13-15]. However, research progress on this kind of real-life defect has been relatively slow.

In this paper, a study on the interfacial crack behavior in adhesively bonded lap-shear joints is presented. By using the recently developed conservation laws of elasticity for nonhomogeneous solids [16-20] and fundamental relationships in fracture mechanics of interface cracks, the problem is reduced to a pair of linear algebraic equations, and stress intensity solutions can be determined directly by information extracted from the far field. This feature makes the current approach particularly suitable and attractive. Solutions are obtained for adhesively bonded lap-shear joints with various material systems and geometric configurations of the crack and the joint. The method of analysis is of practical use in the design and analysis of adhesive joint fracture. The fundamental nature and unique features of the interface flaw behavior in adhesively bonded joints are revealed.

## 2. FORMULATION

The Eshelby-Rice conservation law for a homogeneous solid in a plane elasticity problem [16-19] has recently been extended to a solid composed of two dissimilar materials [20] with the following form:

$$J_1(S) = \int_S (W n_i - \sigma_{jk} n_k u_{j,i}) ds - \int_{\ell} ([W] \delta_{i2} - \sigma_{j2} [u_{j,i}]) ds = 0, \quad (1)$$

where  $W$  is the strain energy density;  $\sigma_{jk}$ , the stress tensor;  $u_j$ , the displacement vector;  $n_i$ , the outward unit normal of an arbitrary closed contour  $S$  which encloses a portion of the continuum, and  $\ell$  is a portion of the interface bounded by  $S$  as shown in Fig. 2. The bracket  $[ ]$  in Eq. 1 denotes the jump of a function across the interface  $x_2 = 0$ , i.e.,

$$[W] = W(x_1, 0^+) - W(x_1, 0^-), \quad (2)$$

$$[u_{j,i}] = u_{j,i}(x_1, 0^+) - u_{j,i}(x_1, 0^-). \quad (3)$$

Continuity conditions of displacements and interlaminar stresses across  $x_2 = 0$  require

$$[u_j] = 0 \quad \text{and} \quad [\sigma_{j2}] = 0. \quad (4a,b)$$

The  $J_1$  component of the conservation integral in Eq. 1 can be simplified to

$$J_1(S) = \int_S (W n_i - \sigma_{jk} n_k u_{j,i}) ds = 0, \quad (5)$$

which is the same as the analogous result for a single phase material.

For a solid containing an interface crack between two dissimilar materials as shown in Fig. 3,  $J_1$  in Eq. 5 along a path  $\Gamma$  has the standard J-integral form in homogeneous fracture mechanics, i.e.,

$$J \equiv J_1(\Gamma) = \int_{\Gamma} (W dx_2 - T_1 \frac{\partial u_1}{\partial x_1} ds), \quad (6)$$

where  $\Gamma$  is an arbitrary path surrounding the crack tip, provided that the crack surfaces are free from traction and the interface is a straight line. Similar independent integrals (similar to Rice's J-integral of course with appropriate modifications) for elastic media with spatially varying moduli were noted by Atkinson [21] through an energy-momentum tensor formalism.] The J is shown to relate to the energy release rate G of an interface crack in a usual manner, i.e.,

$$J = G = G_I + G_{II}, \quad (7)$$

where  $G_I$  and  $G_{II}$  are the energy release rates associated with the mode I and mode II stress intensity factors. The interface crack-tip stress intensity factors,  $K_I$  and  $K_{II}$ , are defined in a complex form as

$$K_I - i K_{II} = 2\sqrt{2\pi} e^{\beta\pi} \lim_{z \rightarrow 0} z^{\frac{1}{2} + i\beta} \phi_1(z), \quad (8)$$

where  $\phi_1(z)$  is a complex potential in the well-known Kolosov-Muskhelishvili formulation [3,22], and  $\beta$  is a bimaterial constant given in Ref. [3].

It is noted that  $K_I$  and  $K_{II}$  defined in Eq. 8 for an interfacial crack in dissimilar media are different from those for a crack in a homogeneous medium. Thus, the  $K_I$  and  $K_{II}$  may not possess the usual significance and physical interpretation as in the cohesive (or homogeneous) fracture. While the overall stress intensity factor [3,23] may be used to express the maximum magnitude of stresses and to correlate crack extension, accurate description of the oscillatory singular stress field in the neighborhood of the crack tip requires detailed knowledge of individual stress intensity factors. Because of the complexity of the problem, numerical procedures are necessary

obtaining accurate solutions for interface crack problems. For example, and Mar [24] used a hybrid-stress finite element method to achieve this. and Stern [23] employed a contour integral method based on Betti's reciprocal work theorem and, recently, Smelser [25] used crack-flank displacement data provided by numerical solutions to yield the interface crack-stress intensities. Each of these numerical approaches requires its own computational scheme to handle the problem and has given satisfactory results. In this section, an alternate and convenient method of analysis is proposed for determining the interfacial  $K_I$  and  $K_{II}$  in bonded joints.

Using the stress field established by Rice et al. [3], one can readily see that the J-integral in Eq. 7 is related to the stress intensity factors of an interfacial crack by

$$J = \sum_{i=1}^2 \frac{1 - \nu_i}{4\mu_i} (K_I^2 + K_{II}^2) \quad (9)$$

for a plane strain case. The coefficients in Eq. 9 are replaced by  $1/[4\mu_i(1 - \nu_i)]$  for a plane stress condition. The J-integral *alone* does not provide adequate information for determining individual values of  $K_I$  and  $K_{II}$  for an arbitrary, mixed-mode interfacial crack. Further development of Eq. 9 based on the introduction of known auxiliary solutions for the crack problem can overcome this difficulty.

Consider two independent equilibrium states with associated field variables denoted by superscripts 1 and 2 for the elastically deformed bimaterial system. Superposition of the two equilibrium states leads to another equilibrium state, 0. The J-integral for the superimposed state can be shown to have the

$$J^{(0)} = J^{(1)} + J^{(2)} + M^{(1,2)}, \quad (10)$$

where  $M^{(1,2)+}$  is another conservation integral with the form

$$M^{(1,2)} = \int_{\Gamma} \left( W^{(1,2)} dx_2 - \left[ T_i^{(1)} \frac{\partial u_i^{(2)}}{\partial x_1} + T_i^{(2)} \frac{\partial u_i^{(1)}}{\partial x_1} \right] ds \right). \quad (11)$$

$W^{(1,2)}$  in Eq. 11 is the mutual potential energy density of the bimaterial system, defined by

$$W^{(1,2)} = C_{ijkl} u_{i,j}^{(1)} u_{k,l}^{(2)} = C_{ijkl} u_{i,j}^{(2)} u_{k,l}^{(1)}. \quad (12)$$

Applying the J-K relationship in Eq. 9 for the superimposed state and combining it with Eq. 10, one can obtain

$$M^{(1,2)} = 2\alpha \left[ K_I^{(1)} K_I^{(2)} + K_{II}^{(1)} K_{II}^{(2)} \right] \quad (13)$$

where

$$\alpha = \sum_{i=1}^2 \frac{1}{4\mu_i} (1 - \nu_i). \quad (14)$$

M-integrals in Eqs. 11 and 13 deal with interaction terms only, and are used directly in solving the interface crack problem. The M-integral is closely related to the details of the stresses and deformation at the crack tip (i.e.,  $K_I$  and  $K_{II}$  in Eq. 13), but yet may be evaluated in the far field (i.e., the integral in Eq. 11), where such a calculation can be carried out with greater accuracy and convenience than near the crack tip. It is also noted that, while  $K_I$  and  $K_{II}$  characterize the controversial near-field oscillatory singular stresses, the energy release rate  $G$ , and, perhaps,  $G_I$  and  $G_{II}$ , are quantities well defined and can be evaluated conveniently mathematically and physically.

<sup>†</sup>The M-integral used here and elsewhere in this paper is defined by Eq. 11, and should not be confused with those in Refs. [17] and [18].

### 3. SOLUTION PROCEDURE

Equation 11 together with Eq. 13 provides sufficient information for determining the stress intensity solutions for a mixed-mode interface crack problem, when known auxiliary solutions are introduced. Denote the first auxiliary solution by a superscript 2a for a crack between two dissimilar materials subjected to mode-I loading only with

$$K_I^{(2a)} = 1 \quad \text{and} \quad K_{II}^{(2a)} = 0. \quad (15)$$

Equation 13 can be simplified to

$$M^{(1,2a)} = 2\alpha K_I^{(1)}, \quad (16)$$

where  $M^{(1,2a)}$  has the same form as Eq. 11 with the subscript 2 being replaced by 2a.  $T_i^{(1)}$  and  $u_i^{(1)}$  in Eq. 11 can be determined along a properly selected integration path  $\Gamma$  in the far field by any convenient method such as the commonly used finite element analysis. For a plane crack problem with the loading of Eq. 15,  $T_i^{(2a)}$  and  $u_i^{(2a)}$  are derivable by the Kolosov-Muskhelishvili formulation, and the auxiliary solution has the following form:

$$u_i^{(2a)} = \sqrt{\frac{r}{2\pi}} f_i^{(I)}(\ln r, \theta; \mu_1, \nu_1, \mu_2, \nu_2), \quad (17)$$

$$T_i^{(2a)} = \sigma_{ij}^{(2a)} n_j, \quad (18)$$

$$\sigma_{ij}^{(2a)} = \frac{1}{\sqrt{2\pi r}} g_{ij}^{(I)}(\ln r, \theta, \mu_1, \nu_1, \mu_2, \nu_2) + O(1). \quad (19)$$

Exact forms of the functions  $f_i^{(I)}$  and  $g_{ij}^{(I)}$  may be found in [3,4].

The second auxiliary solution, denoted by the superscript 2b, for the material solid under a pure-mode II loading such that

$$K_I^{(2b)} = 0 \quad \text{and} \quad K_{II}^{(2b)} = 1, \quad (20)$$

can be found by the same formulation. The conservation integral is, therefore, expressed by

$$M^{(1,2b)} = 2\alpha K_{II}^{(1)}, \quad (21)$$

where  $M^{(1,2b)}$  has a form similar to that of Eq. 11.

It is important to note that the auxiliary solutions,  $u_i^{(2a)}$ ,  $T_i^{(2a)}$  and  $u_i^{(2b)}$ ,  $T_i^{(2b)}$ , are independent of the particular boundary-value problem being posed. Therefore, they may be determined independently by any convenient analytical method once for all. In solving for  $K_I^{(1)}$  and  $K_{II}^{(1)}$ , the integrals,  $M^{(1,2a)}$  and  $M^{(1,2b)}$ , must be evaluated accurately and explicitly. For a given crack geometry, loading condition and bimaterial constant, this can be achieved by integrating Eqs. 16 and 21 along a properly selected contour in the far field so as to avoid crack-tip complications. In conjunction with the auxiliary solutions determined, a numerical method, using a conventional finite-element approach, is currently employed to calculate  $T_i^{(1)}$  and  $u_i^{(1)}$ . The M-integrals are then formally evaluated by using the second-order Gaussian quadrature along a contour  $\Gamma$  passing through Gaussian stations of each element (Fig. 4).

## 4. NUMERICAL RESULTS AND DISCUSSION

The solution procedure aforementioned is programmed for studying general two-dimensional interface crack problems. Evaluation of the conservation integrals is conducted in conjunction with a conventional finite element method by using eight-node isoparametric elements. Solutions are obtained for lap-shear joints with various adherends, adhesives, and geometric configurations. Accuracy and convergence of the results are affected by several unusual features of the problem and the method of analysis due to the singular nature of the crack and inherent approximation involved in the numerical evaluation of the conservation integrals. Assessments of solution accuracy are made by examining relevant problems for which unquestionably correct and exact solutions are available in the literature. Excellent agreement is obtained between current results and reference solutions. Details of the study are reported elsewhere [26]. Current results have an accuracy within approximately three percent deviation from reference solutions based on the optimum mesh and the integration contour presently selected. The primary objectives of this section are to determine stress intensity solutions, which characterize local stresses and deformation, and to examine effects of material and geometric variables on the crack-tip response. Of particular interest are the complex failure modes and energy release rates associated with the interface crack.

### 4.1 Interfacial crack and Joint Configuration

The lap-shear joint considered in Fig. 1 is composed of two high-stiffness and high-strength adherends bonded by a thin adhesive layer. The upper and lower adherends and the adhesive layer are assumed to have uniform

thicknesses of  $t_1$ ,  $t_3$  and  $t_2$ , respectively. The overlap region has a dimension  $L$ . A crack of length  $a$  is located along the interface of the upper adherend and the adhesive near the traction-free edge. Except for the interfacial crack, perfect bonding is assumed everywhere. The two adherends are made of materials with elastic constants  $E_1$ ,  $\nu_1$  and  $E_3$ ,  $\nu_3$ , and the thin adhesive layer has properties of  $E_2$  and  $\nu_2$ . The adhesive and adherends are assumed to be linear, elastic. Studies of related cases such as the center-of-bond cohesive crack and the eccentric crack problems were reported elsewhere [27-28].

#### 4.2 Effects of Adhesive Properties on Interfacial Crack-Tip Response

Geometric variables in the problem are given as the following:

$$\begin{aligned} \theta &= 45^\circ, \quad L = 0.5 \text{ in.}, \\ t_1 = t_3 &= 0.05 \text{ in.}, \quad t_2 = 0.005 \text{ in.}, \\ a &= 2.5 t_2 = 0.0125 \text{ in.} \end{aligned} \tag{22}$$

The upper and lower adherends are made of the same aluminum with elastic constants,  $E_1 = E_3 = 10 \times 10^6$  psi, and  $\nu_1 = \nu_3 = 0.33$ . Effects of different kinds of adhesive on the crack-tip response are examined by considering various values of  $E_2$ . For the purpose of generality, adhesives with a broad range of modulus values covering three decades on a logarithmic scale are studied. The cases with  $E_1/E_2 = 20 \sim 40$  are typical for aluminum/epoxy systems. Higher  $E_1/E_2$  values correspond to the joints with less rigid adhesives or subjected to a "hot and wet" environment.

Crack-tip stress intensity solutions and associated energy release rates are obtained as functions of the modulus ratio shown in Figs. 5 and 6. Failure modes in the joints are observed clearly. The interfacial crack

experiences a mixed-mode fracture even under uniaxial loading. Both  $K_I$  and  $K_{II}$  decrease rapidly as the adhesive modulus decreases, and the difference between  $K_I$  and  $K_{II}$  increases with  $E_1/E_2$ . The mode-I stress intensity factor is higher than that of the mode-II in the entire range studied, except for the cases of  $E_1/E_2 \approx 1$ . This suggests that the dominant mode of failure is opening-mode. In the case of  $E_1/E_2 = 1$ , the crack is cohesive, and the nature of the crack-tip singularity changes. The values of  $K_I$  and  $K_{II}$  in this case are found to be consistent with the results in [27]. The total energy release rate and the energy release rate of individual fracture mode are determined also. For given adherends, the reduction of  $E_2$  increases the coefficients of  $K_I$  and  $K_{II}$  in Eq. 9, which influence the  $G$  value significantly. The  $G_I$  is found to increase rapidly with  $E_1/E_2$ ;  $G_{II}$ , on the other hand, decreases as a less stiff adhesive is used. The rapid increase of  $G_I$  and  $G$  corresponds to a decrease of  $K_I$  and  $K_{II}$  in the interface crack problem—a unique phenomenon not observed in the homogeneous crack problem in general. In the case of very large  $E_1/E_2$ , the adhesive may become incompressible with Poisson's ratio approaching 0.5. The incompressibility of the soft adhesive is not considered in the present study.

#### 4.3 Effects of Dissimilar Adherends

Effects of dissimilar adherends on the interface crack behavior are studied for lap-shear joints with the same geometry and crack length used in the previous section. The adhesive layer and the lower adherend have the following elastic properties:  $E_2 = 0.5 \times 10^6$  psi,  $\nu_2 = 0.35$  and  $E_3 = 10 \times 10^6$  psi,  $\nu_3 = 0.33$ . The problem is solved by considering the joints with various  $E_1$ 's ranging from  $E_1/E_2 = 1$  to 1000. The results

are given in Figs. 7 and 8, in which  $K_I$ ,  $K_{II}$ ,  $G_I$ ,  $G_{II}$  and  $G$  are related to  $E_1/E_2$  in semi-logarithmic plots. Adherends with dissimilar properties are found to have significant effects on the crack-tip response. The opening-mode stress intensity factor increases appreciably but the shearing-mode stress intensity remains relatively constant as the stiffness of the upper adherend approaches that of the lower one, i.e.,  $E_1/E_2 \rightarrow 20$ . As  $E_1/E_2$  exceeds 20, an opposite trend of changes of  $K_I$  and  $K_{II}$  are observed;  $K_I$  remains relatively unchanged and  $K_{II}$  increases gradually. The ratio of  $K_I/K_{II}$  in the joint with dissimilar adherends is always smaller than, or at most equal to, that of a joint with the same upper and lower adherends. Effects of dissimilar adherends on energy release rates are shown in Fig. 8. The  $G_I$  is approximately one order of magnitude larger than  $G_{II}$  in the entire range of  $E_1/E_2 > 20$ . The total energy release rate increases rapidly initially, and then remains relatively constant with the change of  $E_1/E_2$ . As the stiffness of the upper adherend exceeds that of the lower one, crack resistance of the joint becomes less sensitive to the dissimilarity of the two adherends. But a higher fracture resistance is obtainable as the upper adherend becomes less stiff.

#### 4.4 Effects of Adhesive-Layer Thickness

Effects of the adhesive-layer thickness on fracture of the joint have long been recognized. Bascom, et al., for example, [13,14] showed experimentally that fracture energy release rates are related closely to the bond thickness. Extensive analytical studies on debonded composite laminates were conducted by Erdogan [5,6,29]. Several unique features of the geometric variable on the composite failure behavior were revealed. Wang, et al. [27] studied center-of-bond cohesive cracks and reported fundamental

characteristics of thickness effects on the adhesive joint fracture. In this portion of the study, lap-shear joints with a geometric configuration and crack length identical to the one used in previous sections are considered. The joints are made of identical aluminum adherends and epoxy adhesive with elastic constants:  $E_1 = E_3 = 10 \times 10^6$  psi,  $\nu_1 = \nu_3 = 0.33$ , and  $E_2 = 0.5 \times 10^6$  psi,  $\nu_2 = 0.35$ , respectively. The adhesive thicknesses, ranging from  $t_1/40$  to  $t_1/5$  (i.e., from 0.00125 in. to 0.01 in.), are considered.

Relationships among  $K_I$ ,  $K_{II}$ ,  $G_I$ ,  $G_{II}$ ,  $G$  and the normalized bond thickness,  $t_2/t_1$  (with  $t_1 = t_3 = 0.05$  in.) are shown in Figs. 9 and 10. The  $K_I$  is found to be insensitive to the change of the adhesive-layer thickness, but  $K_{II}$  increases rapidly with  $t_2$ . Quantitatively,  $K_I$  is always larger than  $K_{II}$  in all cases studied. This is particularly true for the joint with a thinner adhesive, in which  $K_I$  has a value about one order of magnitude higher than that of  $K_{II}$  in general. The  $K_I$  clearly dominates the fracture of the joint with a thinner bond, but the shearing mode failure becomes increasingly important as the adhesive thickness increases. Associated energy release rates are given in Fig. 10 for joints with various  $t_2/t_1$ 's. The decrease in the adhesive-layer thickness leads to an increase of fracture resistance in the joints (i.e., a reduction in the total energy release rate and the maximum cleavage stress). The change of fracture resistance with the bond thickness in a lap-shear joint is consistent with the results reported in Ref. [29]. However, variations of interfacial crack-tip stress intensity factors and associated energy release rates are different from the solutions obtained for center-of-bond cohesive crack problems, in which  $K$ 's and  $G$ 's are almost independent of the adhesive-layer thickness. This situation is expected as stress singularities are different in the two cases.

#### 4.5 Effects of Crack Length

Effects of the interface crack length are of significant interest because of the particular joint configuration and the loading condition applied. The geometry of the lap-shear joint studied in this section is identical to that in the previous cases. The two adherends are the same aluminum, and the adhesive is an epoxy resin with material constants reported previously. Solutions obtained for various crack lengths are reported in Figs. 11 and 12, in which  $K$  and  $G$  are related to  $a/L$ . Both  $K_I$  and  $K_{II}$  shown in Fig. 11 increase rapidly for shorter cracks (e.g.,  $a/L < 0.02$ ), and change almost linearly as  $a/L$  becomes longer. The opening-mode stress intensity factor is approximately four times higher than that of the shearing-mode in the entire range of  $a/L$  studied. Effects of the crack length on energy release rates are shown in Fig. 12. Well defined relationships are observable. In the case of a very short crack, i.e.,  $a \rightarrow 0$ , there exists a strong interaction between the crack tip and the edges of the joint. Basic nature of the short interfacial crack and its interaction with geometric boundaries are currently under investigation.

## 5. SUMMARY AND CONCLUSIONS

An investigation of the interfacial crack behavior in adhesively bonded lap-shear joints is presented. The method of analysis is formulated on the basis of conservation laws in elasticity of nonhomogeneous solids and fundamental relationships in fracture mechanics of interface cracks. The current approach provides a convenient and accurate means to examine the basic nature of interface cracks in adhesive joints. Fracture parameters such as stress intensity factors and associated energy release rates describing crack-tip deformation and stresses are determined. Complex failure modes in the joints are studied. Solutions are obtained for problems with various kinds of adhesive and adherends, joint configurations and interfacial crack lengths. Based on the results obtained, the following conclusions may be drawn:

1. Adhesive properties have significant effects on the interfacial crack tip response. In the lap-shear joint with a given adherend, the opening-mode stress intensity factor is always larger than that of the shearing-mode. The difference between  $K_I$  and  $K_{II}$  increases with  $E_1/E_2$ . While both  $K_I$  and  $K_{II}$  decrease with decreasing  $E_2$ , the total energy release rate and that associated with the opening-mode fracture increase rapidly - a phenomenon unique to the interface crack and not observed in homogeneous crack problems in general.

2. The change of two identical adherends to dissimilar ones influences appreciably the failure behavior of the joints.  $K_I$  increases rapidly but  $K_{II}$  remains relatively constant as the stiffness of the upper adherend approaches that of the lower one. An opposite trend in the changes of  $K_I$  and  $K_{II}$  is observed as  $E_1/E_2 > 20$ . As  $E_1/E_2$  exceeds 20, crack

distance of the joints becomes relatively insensitive to the dissimilarity of the two adherends. The joint has a higher fracture resistance as the upper adherend becomes less stiff than the lower one.

3. Effects of the adhesive layer thickness on interfacial fracture are different from those on a center-of-the-bond cohesive crack in lap-shear joints.  $K_I$  is shown to be insensitive to the change of the adhesive thickness, but  $K_{II}$  increases appreciably. The decrease of the adhesive thickness leads to an increase of fracture resistance in the joint due to reduction of crack extension driving force.

4. Increasing the interfacial crack length increases  $K_I$  and  $K_{II}$  simultaneously. However, stress intensity solutions increase more rapidly for shorter cracks than for longer ones. For the cases of  $a/L > 0.02$ , approximately linear relationships between  $K$ 's and  $a/L$  are observed. On a semi-logarithmic plot,  $G_I$ ,  $G_{II}$  and  $G$  vary with  $a/L$  almost linearly, suggesting that well defined relations among them may exist.

## 6. ACKNOWLEDGMENTS

The authors wish to express their deep gratitude to Professor H. T.orten, Department of Theoretical and Applied Mechanics, University of Illinois, for his fruitful discussion and encouragement during the course of this study. The computational work was carried out in the Digital Computer Laboratory of the University of Illinois and supported in part by the Research Board of the University and by NASA-Lewis Research Center through Grants NSG 3044.
