PREFACE

This document is part of a University of Central Florida contract report, "A Continuation of Base-Line Studies for Environmentally Monitoring Space Transportation Systems at John F. Kennedy Space Center."

The entire report consists of four volumes and an executive summary, all identified as KSC TR 51-2, NASA CR 163122:

Volume I: Terrestrial Community Analysis

Volume II: Chemical Studies of Rainfall and Soil Analysis

Volume III: Part I--Ichthyological Studies, Ichthylological Survey of Lagoonal Waters; Part II-Ichthyological Studies, Sailfin Molly Reproduction Study

Volume IV: Part 1--Threatened and Endangered Species of the Kennedy Space Center: Marine Turtle Studies, Part II--Threatened and Endangered Species of the Kennedy Space Center: Threatened and Endangered birds and Other Threatened and Endangered Forms

Executive Summary

THE CHEMISTRY OF RAINFALL AND SOILS AT JOHN F. KENNEDY SPACE CENTER

The general objectives of this contract were as follows:

(1) to characterize and quantify selected components of the environment,

(2) to select from among the components studied those which would be appropriate for the detection and assessment of possible perturbations induced by future NASA operations;

(3) to develop baseline data sufficient to define normal variation (i.e., changes not associated with NASA activities) in those selected environmental components; and

(4) to determine the kinds and amounts of measurements required to detect and document environmental perturbations that might be caused by future NASA activities.

The results of a study which was designed to monitor, characterize, and evaluate the chemical composition of precipitation (rain) which fell at the Kennedy Space Center, Florida (KSC) during the period July, 1977, to March, 1979, are the subject of the first section of this report. In the second section results obtained from a soil sampling and associated chemical analysis program will be described.

PRECIPITATION CHEMISTRY

Introduction

Sampling and chemical analysis of precipitation were used to determine acidity, conductivity, and individual ionic species concentrations. Sample acidity was determined based on dissociated acid concentration (free acidity), strong acid concentration, and titratable acidity. Concentrations of sodium, potassium, calcium, magnesium, ammonium ion, chloride, fluoride, nitrate, orthophosphate, and sulfate were also determined regularly. No attempt was made to evaluate the composition of atmospheric deposition which occurred by means other than rainfall. Throughout this text, the term precipitation means only wet deposition in the form of rainfall, collected by a procedure which excludes dry deposition.

Objectives of this study were:

1. Determine and characterize the acidity of rain whch fell on Merritt Island and KSC in a time period prior to the first Space Shuttle launch.

2. Determine concentrations of major contributors to the overall rainfall, including sodium, potassium, calcium, magnesium, ammonium, chloride, fluoride, nitrate, orthophosphate, sulfate, aluminum, and vanadium.

Once established, these prelaunch ambient data can be utilized in assessing long-term and short-term effects of Space Shuttle launches on the composition of precipitation. Such post-launch assessment of long-term effects can be attempted only if a post-launch precipitation monitoring program is operational. Post-launch assessment of significant episodic changes in precipitation composition depends on the ability to sample and chemically analyze a portion of the specific precipitation when it occurs.

No attempt was made to identify specific sources which contribute to the measured composition of rain at KSC. Experimental design emphasized determining existing composition and allowed only restricted conclusions which pertain to relationships among components in the rain to be drawn.

For several years, NASA has been evaluating potential environmental effects associated with launch of the Space Shuttle. One potential problem comes from solid rocket boosters (SRB) on the launch vehicle. The SRB propellant is approximately 70% ammonium perchlorate as oxidant, 16% powdered aluminum as fuel and stabilizer to control burning rate, 14% polybutadiene acrylic nitrile as binder, and minor constituents (NASA, 1978). The SRB exhaust products, by weight percent composition are HCl (21.2%), Al_2O_3 (30.1%), CO (24.1%), CO_2 (3.4%), H_2 (2.1%), N_2 (8.5%), H_2O (9.3%), and $FeCl_2$ (0.6%) (NASA, 1978). A diffusion model has been developed and is briefly summarized by Susko (1979). This model makes it possible to calculate downwind concentrations of exhaust products in the ground cloud. Each launch will generate and release approximately 10^5 kg HCl below 4 km altitude. Precipitation during or immediately after launch may lead to scavenging HCl and result in acid rain.

Predictions (Pellett, 1977) indicate that acid rain of pH less than 1.0 could occur in proximity to the launch site. Acid rain of pH less than 3.0 could occur at extended distances, depending on meteorology and exhaust cloud dynamics which occur during and after launch.

Precipitation collection at sites on or near KSC, latitude 80° 44' W, longitude 28° 38' N, began in July 1977. One site on the campus of UCF (University of Central Florida, latitude 81° 20' W, longitude 28° 33' N), was also utilized. One aspect of site selection was dictated by requirements to provide data from samples collected in proximity to a NASA ambient air quality monitoring network operated by the Booster Exhaust Study Test (BEST). In addition, several sites were selected in proximity to several locations used both as part of a soil chemistry program described in the second part of this volume, and as part of a terrestrial community analysis program (Stout, 1979).

Samples were obtained using collectors open to the atmosphere only during periods of precipitation. Rainfall was collected at 24-hour intervals Monday through Friday; exceptions which increased the intervals did sometimes occur. Samples were generally representative of precipitation which occurred during 24-hour periods ending on Tuesday though Friday, and 72-hour periods ending on Monday.

Several experiments were carried out to evaluate and account for the variability observed in precipitation data. Analytical, sampling, and spatial variability in precipitation data were measured. The quality of chemical analysis data was monitored routinely using the compositional anion/cation ratio, measured conductivity/predictive conductivity ratio, and predictive pH. Predictive conductivity was calculated by summing the ionic concentration and equivalent conductance product for each measured chemical species on a sample by sample basis. Predictive pH can be calculated from the sum of the anion, sum of the cation difference when contribution to the cation sum excludes hydrogen ion. Sample stability, storage conditions, and contamination problems were also studied.

Background

Acidity of precipitation has increased dramatically in some areas in the past 30 years. Precipitation with a pH less than 5.65 is considered to be acidic. The CO_2 - HCO_3^- equilibrium in precipitation is such that rainwater in equilibrium with the accepted standard atmospheric CO_2 concentration of 316 ppm will contain concentrations of H_2CO_3 and HCO_3^- which render it slightly acidic (Reuss, 1975). Precipitation, therefore, is not expected to have a neutral pH of 7.0 but is naturally somewhat acidic. The presence of HCO_3^- in precipitation can be extremely important because it acts as a buffer to prevent significant increases in pH (Reuss, 1975) to the extent that basic or alkaline precipitation is rare. The introduction of acidic materials or acid precursors into the atmosphere and the ultimate incorporation into precipitation must occur to an extent which will significantly decrease HCO_3^- concentrations (Reuss, 1975) before acid precipitation will occur.

Until the latter 1960's occurrences of acid precipitation in the U.S. were not documented extensively. During the past 10 years, several reports on the collection and chemical analysis of acid precipitation in the northeastern U.S. have appeared (Likens, 1976, Cogbill and Likens, 1974; Likens and Bormann, 1974; Likens, Bormann, and Johnson, 1972). Only two nationwide sampling and precipitation chemistry programs have been performed. Each covered relatively short time periods (Junge and Werby, 1958, Junge, 1963, and Lodge, 1968) during the late 1950's and late 1960's. During the past year, the National Atmospheric Deposition Program became operational (Gallaway and Cowling, 1978) with sites located mostly in the eastern U.S. and a few scattered sites in the middle and western U.S. Many of the original U.S. studies emphasized determining major chemical species present in the precipitation and assessing the influence that precipitation would have on nutrient cycling in ecosystem studies. As the acidity of precipitation has increased, greater attention has been given to evaluating regional, national, and global sources of pollution which may contribute to creating acid precipitation. More recently, expanded interest and effort has been utilized to study the problem. In the U.S., Federal and state government agencies, private industry, and universities have participated in studies to monitor the composition of precipitation in the U.S. (Galloway and Cowling, 1978; Liljestrand and Morgan, 1978; McColl and Bush, 1978; Valiela, et. al., 1978, Jacobson, et al., 1976; Richardson, 1976, Cooper and Lopez, 1976, Miller, 1975).

Several detailed studies have been performed to evaluate methods of analysis, sample collector design, and sample handling (Galloway and Likens, 1978, 1976; Lewis and Grant, 1978; Slanina, et al., 1978, Volchok and Graveson, 1976). Because precipitation samples typically contain chemical species at parts per million and lower concentrations, extreme care must be exercised in collection, sample storage, and analysis. Sample storage options have recently been evaluated (Galloway and Likens, 1978, Peden and Skowron, 1978; Galloway and Likens, 1976). Chemical analysis methods involve a variety of techniques. Choice of the appropriate techniques has varied for individual programs. Several studies to evaluate individual techniques have been performed (Mulik, 1978). Recent developments in analytical instrumentation now make possible the

relatively rapid and routine analysis of precipitation samples for major chemical species and for many species present at trace concentrations.

A recent report (Likens, 1976) presents views and summarizes results of acid precipitation studies in the U.S. and Scandinavia during the past 25 years. As consumption of fossil fuels has increased on a global scale, the acidity of precipitation has been observed to increase. The consequences of this increase have far-reaching implications. The gradual erosion of manmade objects constructed from cement and marble has been occurring at accelerated rates and may be due to increases in concentrations of acidic compounds in the atmosphere and in precipitation. Systematic and detailed studies to evaluate the interactions and influences that acid precipitation may have on soils, rivers, and lakes, and plant and animal life are in their infancy. It is believed that some of these natural systems already are undergoing stress and gradual change due to acid precipitation (Likens, 1976). Several years or decades of study may be required to even partially assess the impact of acid precipitation on the environment.

The effects of acid precipitation on aquatic and terrestrial ecosystems was the subject of a recent literature review (Cornell University, 1976) and an international symposium (Dochinger and Seliga, 1976). Hornbeck, et al. (1977) analyzed the longest continuous set of precipitation data obtained in the U.S. and evaluated seasonal patterns in acidity of precipitation and their implications for forest stream ecosystems. Data for the northeastern U.S. from 1965 to 1973 were utilized. Gorham (1976) presented an overview of acid precipitation and its influence on aquatic ecosystems. The papers include extensive bibliographical information.

Although acid precipitation is increasing in the U.S., several European countries have experienced even greater acid precipitation. Recent reports summarize results and describe the magnitude of efforts which are occurring in Scandinavia, the Netherlands, and England to study this rapidly growing global problem (Granat, 1978; Vermeulen, 1978; Martin and Barker, 1978). Acid rain has been studied in Canada (Summers and Whelpdale, 1976). The southern Ontario region is particularly susceptible to these occurrences (Dillon, et al., 1978). Many of these programs are designed to assess sources for pollutants and transport of pollutants across national boundaries which cause the problem while others continue the attempt to assess the impact of increased pollution on the environment.

Assessment of Precipitation Acidity

Recent studies which have emphasized assessing acidity of precipitation samples or acidic components in atmospheric aerosols and particles have varied. Data are typically generated by titration of the sample while monitoring titration progress through measurement of pH when adding hydroxide ions. The hydroxide ion either is generated coulometrically within the sample or added as a dilute standard solution of sodium hydroxide. In most cases, evaluation of the potentiometric titration data is accomplished by linearization of selected portions of the titration curves. The original theory which is used as the basis for this

approach was introduced by Gran (1952). Liberti, et al. (1972) determined the nonvolatile acidity of rain water by a coulometric procedure where the data were treated by the Gran theory. Both strong acidity and nonvolatile weak acidity were determined. Strong acidity is a measure of the total concentration of the free hydrogen ion, present due to totally dissociated acids such as HCl, HNO_3, and H_2SO_4. Weak acidity is a measure of the total concentration of undissociated acids which are present. Weak organic acids such as formic acid and acetic acid may be responsible. Galloway, Likens, and Edgerton (1976) identified several weak acids in precipitation which occurred at Ithaca, N.Y., and Hubbard Brook, N.H.

Askne and Brosset (1972) determined the strong acid component in precipitation by titrating samples with 0.001M NaOH and using the Gran plot treatment of data. Krupa, Coscio, and Wood (1976, 1976a) evaluated a coulometric titration procedure for detecting strong and weak acid components in rainwater and presented evidence for multiple hydrogen-ion donor systems in rain. Galloway and Likens (1979) considered the magnitude of error associated with measuring acidity and suggested a generalized procedure for analyzing pH and acidity in acid precipitation samples. Brosset (1978) evaluated water-soluble sulfur compounds in aerosols using a modified Gran plot technique. $(NH_4)_2SO_4$, $(NH_4)_3H(SO_4)_2$, and NH_4HSO_4 were identified in the five particle sulfate phases. Jacobson, et al. (1976), concluded that samples collected in Yonkers, New York, in 1974, titrated as though they contained a monoprotic acid with an equivalence point pH near 7.

Seymour, Clayton, and Fernando (1977) used an iterative calculation to segment and linearize potentiometric titration curves. Modified Gran plots were obtained which allow both acid dissociation constants and concentrations to be determined for acidic components in the sample. Applications for the determination of acidic components in atmospheric condensates and rainwater were shown. Seymour, et al. (1978) then used the modified Gran plot technique to evaluate variations in the acid content of rainwater in the course of a single precipitation and concluded that strong acids, NH_4^+ and dissolved CO_2 represented the major acid components. These latter developments and refinements of techniques allow a clearer elucidation of specific acidic species in precipitation although their utilization would seen to be limited to research projects rather than routine analysis.

Studies in the Southeastern U.S.

Studies to evaluate the composition of precipitation in the southeastern U.S. and Florida have been quite limited. The data of Junge (1963) and Junge and Werby (1958) include results obtained from samples collected near Palm Beach and Tampa, Florida. During the summer of 1973, the Florida Area Cumulus Experiment (FACE) was conducted in south Florida. The program measured the effects of cloud seeding on aerial rainfall. From this program emerged a two-year study (1974 to 1976) of precipitation composition (Wisniewski and Cotton, 1977). Haines (1976) reported acidity measurements from rain collected on the Georgia coast in 1975. More recently, a precipitation collection network of 26 sites

which extends from the Florida panhandle to the Keys has become operational (Brezonik and Edgerton, 1979). Most sites are sampled biweekly by collecting bulk precipitation.

Meteorology

Two recent publications have appeared which attempt to relate meteorological factors and acid precipitation. Both utilize interpretation of air-mass trajectories (NOAA, 1978) which are associated with precipitation which occurred in Ithaca, N.Y. (Miller, Galloway, and Likens, 1978) and metropolitan New York (Wolff, et al., 1978). Precipitation composition was related to air mass movement and location for several days prior to arrival at the sampling location. Seasonal differences were also noted.

Seasonal variations in precipitation composition have been observed in most studies which continued uninterruptedly for at least one complete year. Acidity is at a maximum during the summer. These maxima also correspond to increased levels for sulfate and nitrate in precipitation. The higher temperatures of summer can increase the rate of oxidation of SO_2 and nitrogen oxide to sulfuric acid and nitric acid respectively. The more stable summertime air mass results in increased residence time over the continental U.S. for potential acid precursors. These combined effects may account for the elevated acidity, sulfate, and nitrate levels present in precipitation during the summer months.

Existing KSC Air Quality

In a recent report, Thorpe (1978) summarized composition of the SRB ground cloud, ambient air quality, and monitoring programs in east central Florida and pollutant sources near KSC. Several sources may contribute to the composition of rainfall as measured in this study. Thorpe concludes that there are relatively few significant pollutant sources near KSC and ambient air quality is good. The major local sources of pollutants include two power plants operated by Florida Power and Light (FPL) and Orlando Utilities (OU). These plants are located approximately 22 km southwest of the Shuttle launch pad. Both plants burn natural gas and fuel oil. The FPL plant burns low sulfur fuel (1%) while th OU plant burns number 6 fuel oil with sulfur contents between 1% and 3%. The 1976 emission estimates for the FPL and OU plants were 12,000 tons SO_2 for each and 13,000 and 36,000 tons NO_2 respectively (Thorpe, 1978). Other sources of pollution which may be significant include asphalt and cement plants, some agricultural burning, and local automobile traffic. Combustion of fossil fuels in automobile engines can generate NO and NO_2 which can be oxidized to HNO_3^-. Using catalytic converters to reduce auto emissions may be increasing H_2SO_4 concentrations near ground level (Holden, 1975).

Typical Chemical Composition of Precipitation

The major chemical species observed to occur in precipitation are discussed below. Emphasis is placed on general sources of origin (Granat, 1972, Butcher, 1972) and the contribution that each has to the composition of precipitation in Florida.

Free Acidity. The measured acidity of precipitation based on pH is due primarily to the presence of strong acids such as HCl, HNO_3, and H_2SO_4. Sources of these strong acids are described in the following paragraphs when individual anions are considered.

Sodium. The predominant source is seawater. Sodium enters the atmosphere as sea spray. Anthropogenic source emissions may also introduce small amounts. In marine environments, incorporation of sea salt may have a slight neutralizing effect on precipitation. Sea water has a pH of about 8.5. Considerable sea salt exists in precipitation at KSC and at all coastal locations in Florida. Precipitation for all of inland peninsula Florida should be subjected to moderated levels of sea salt.

Potassium, Calcium, Magnesium. For coastal locations in Florida, sea spray provides a significant source for these species. Alternate sources include dust in the atmosphere resulting from soil erosion and anthropogenic emissions. The latter will contribute little compared to the other sources at KSC.

Ammonium. Ammonium ions in precipitation are produced by the reaction of NH_3 with hydrogen ion present in precipitation. The NH_3 can be generated by bacterial action on nitrogen compounds in the soil (Junge, 1963). The NH_4^+ functions as a weak acid pka = 9.2 in precipitation (Seymour, Clayton, and Fernando, 1977). Several ammonium compounds in the atmosphere have been identified as $(NH_4)_2SO_4$, $(NH_4)HSO_4$, $(NH_4)_3H(SO_4)_2$ (Brosset, 1978).

Chloride. The predominant source of chloride is seawater. Chloride enters the atmosphere as sea spray. Anthropogenic sources introduce small quantities mainly as HCl. This is not, however, a significant source of chloride at coastal locations in Florida. It has been proposed (Mohnen and Yue, 1977) that HCl in the atmosphere is produced by the reaction of H_2SO_4 and NaCl. The latter originates in the ocean. This process simply generates HCl in place of H_2SO_4 and does not change the total amount of strong acid present. Similarly, the amount of Cl^- is not affected by this process.

Sulfate. There are several potential sources of sulfur-containing compounds in the atmosphere. Anthropogenic emissions (predominantly sulfur dioxide), microbial processes in soils which produce sulfate hydrogen sulfide, and sea spray are all likely to contribute in the KSC area. Sulfur dioxide and hydrogen sulfide are oxidized to sulfate through a variety of postulated mechanisms. Sea spray is the predominant amount of "neutral" sulfate in coastal regions and is a significant source at KSC. The presence of SO_4 in precipitation at concentration levels in excess of those predicted to be present due to sea spray (Granat, 1972) are often associated with the acid rain phenomenon. Significant excess SO_4^{2-} is present in certain precipitation events at KSC.

Nitrate. Nitrogen oxides enter the atmosphere from a variety of sources. These include bacterial action and combustion. The internal combustion engine produces nitrogen oxides by oxidizing nitrogen in the

atmosphere. Both NO and NO_2 are oxidized and can result in increased concentrations of nitrate and nitric acid in precipitation.

Fluoride. Fluoride as HF can be present in the atmosphere. Combustion of fluorine-containing fuels and certain industrial waste gases are sources (Israel, 1974). Producing phosphate fertilizers by the reaction of H_2SO_4 with phosphate rock containing considerable amounts of $Ca_5(PO_4)_3(F^-, Cl^-, \text{or } OH^-)$ generates HF. The phosphate industry in west central Florida is a potential regional source for HF in the atmosphere and, therefore, in precipitation.

Precipitation Collectors

Samples were collected with Aerochem Model 201 automatic wet/dry precipitation collectors purchased by NASA. The collectors are an improved version of the A.E.C. collector designed by the Health and Safety Laboratory of the Atomic Energy Commission (Volchok and Graveson, 1976; Galloway and Likens, 1976). The collectors were manufactured by Webco Miami, Inc. The collectors were operated using 12V 7 ampere-hr. batteries from June 1977 to November 1977. Higher capacity 12V 30 ampere-hr. batteries were utilized for subsequent collections. The latter batteries gave reliable performance when replaced at two to four-week intervals with recharged batteries. Precipitation samples were collected in polyethylene buckets which have (approximately) a 15-liter capacity. Dimensions are 28.6 cm diameter and 23.4 cm depth; this yields a collection surface of 640 cm^2.

Precipitation Collection Sites

Fifteen locations at or near KSC were utilized. One additional collector was located on the UCF campus. The specific location for each collector was established using a variety of criteria. Operational sites were located near some of the reference stands identified for study in the terrestrial community analysis program and some were at sites designated in the NASA/BEST program. In most cases, collectors were located in remote areas so the potential influence of heavy highway traffic could be minimized. Collectors were positioned so that no objects projected above the collector unless they fell below an imaginary 45-degree angle measured above the horizon in all directions. A map showing the location of sites and indicating when collector operation was initiated at each site is shown in Figure 1. A general description of each site follows.

Site 01. The collector was 25 meters west of a large brackish lagoon and was located in a grass covered opening which was mowed periodically. The collector was circled by 15-meter high trees which were typically 20-30 meters removed from the collector. A moderately traveled dirt road is located within 25 meters of the site. The ocean is approximately 0.5 km to the east.

Site 02. The collector was located on the grassy roadside of a moderately traveled paved road. There are trees approximately 20 meters west of the site.

Site 03. The collector was located in a sandy field which had a sparse grass cover 20 meters from the taxiway at the Ti-Co Airport. The site is about four km north northwest of the Florida Power and Light and Orlando Utilities power plants.

Site 05. The collector was in a grassy, cleared area encircled by trees at distances of from 50 to 200 meters. The grass which extends outward as far as 50 yards is mowed periodically. Mosquito Lagoon, a large body of brackish water, is 500 meters east of the site. State Road 3 travels north-south past the site at a distance of 50 meters.

Figure 1. Location of Precipitation Collection Sites

Site 06. The site is near a paved, well-traveled road which provides a major entrance to the center. The collector sat in a grass-covered field that was mowed periodically. Bodies of water approach the site from east and west. Considerable industrial activity is present to the south and east of the site.

Site 07. The collector was located at Dunn Airport, Titusville, in a grassy area that was mowed regularly and was approximately 750 meters from the airstrip. There are a few trees approximately 30-100 meters away. The site is adjacent to the Titusville recreational facility (Tennis/Handball Courts). The collector was located approximately 20 meters from a parachute club drop zone.

Site 08. There is sparse vegetation and some grass that was mowed periodically. Trees partially shield the site from the Banana River, 300 meters east. There is some vehicular traffic on a paved access road to and from a nearby radar installation.

Site 10. The site is encircled by 10-meter trees at a distance from 10 to 30 meters away. The distance to the ocean is approximately one km. The Banana River is about 500 meters west. There is abundant vegetation; the surrounding grass was mowed periodically.

Site 11. The collector sat on a beach dune about 50 meters from the ocean. The dune contours are irregular and extend above the collector to the west. Scattered scrub vegetation is present on the dunes. Access to the site is by a lightly traveled paved road.

Site 12. The site is on a fire break with palmetto plants extending outward on all sides for a distance of 100 meters. The plants were below the horizontal plane of the collector top. Access is by a sparsely traveled dirt road.

Site 13. There is scrub vegetation and uncovered soil but no grass in the cleared area where the collector was located. Tree setback is 25 meters on the east side which partially shelters the site from ocean effects. State Road 3 is 100 meters west and the NASA Causeway is 500 meters south of the site. These paved roads are the major access to the KSC industrial area from the south, west, and north.

Site 14. This site is located in a sandy cleared area at the north end of the Shuttle runway. The average distance between the two-meter high bushes and the collector was three to five meters. The sparse grass near the collector was mowed periodically. Access is by a lightly traveled dirt road.

Site 16. The collector was located in a cleared grass covered area which was mowed periodically. The collector was adjacent to Camera Site UC1. Four-meter trees to the east shelter the site from ocean effects. Access is by a dirt road from State Road 3.

Site 18. This site is located on the campus of UCF. The collector was located in a sandy grass covered area which was mowed periodically. The UCF physical plant complex is located within 50 meters. The collector was located near isolated pine trees which approached the 45° horizon-vegetation top criteria established for site location. Access is by a paved road. University service vehicle traffic was moderate within 100 meters of the collector.

Site 19. The collector was located in a grassy field and encircled by trees at distances that ranged from 50 to 200 meters on all sides. A major body of brackish water is located 200 meters west of the site. Access is by a dirt road.

Precipitation Collection

The polyethylene buckets used to collect precipitation samples and all laboratory ware which contacted the precipitation samples was thoroughly cleaned with dilute Alkonox solution and 3M HNO_3. Each piece was then rinsed with deionized water until the conductivity of the final rinse water was less than 1.0 umho/cm.

Deionized water with a conductivity of less than 1.0 umho/cm was used during all procedures which involve cleaning operations. This water was obtained from a deionizing system which also included a carbon filter. All deionized water utilized for chemical analysis procedures was obtained from a Culligan SR deionizing system which delivered water with a conductivity of less than 0.07 umho/cm.

Collectors were typically checked between 8 a.m. and noon Monday through Friday. Sample pickups were made by UCF personnel on Monday, Wednesday, and Friday from July through September 1977, and intermittently thereafter. Beginning in October 1977, NASA/BEST personnel were responsible for daily pickups. A sample collection log was maintained for each day that precipitation collectors were checked. Several entries were made and included: 1) time of arrival at the site, 2) weather conditions during site visitation, 3) operation of collector, 4) visual inspection of the sample bucket, and amount of precipitation. If precipitation was present, the amount to the nearest 0.1 inch was estimated. Presence of dirt or insects in the sample was noted. A clean bucket was placed in the collector and the cover from the clean bucket placed tightly on the bucket which had been removed from the collector. In February 1979, several sites were equipped with standard Taylor 11-inch rain gauges. These gauges have an outer cylindrical funnel diameter of four inches and an inner measuring cylinder diameter which allows measurement of rainfall amount from a scale which yields a ten-fold increase in readability. These gauges measure rainfall to the nearest 0.01 cm.

Sample Identification and Classification

The sample identification was an 11-digit number and was assigned as follows:

Digit corresponding to entries on Precipitation Chemistry Data Sheet (see Figure 2).

1 and 2	Month (01...12)
3 and 4	Day (01...31)
5 and 6	Year (77...79)
7	Not used
8	Represents the frequency of precipitation collector servicing. (0...9) values reflect the number of days that lapse between servicing with 0 indicating daily servicing
9 and 10	Collector Site Number (01...)
11	Sample Type (0...9) This digit is defined as follows and classification was based on a subjective judgment:

0 Clean rainfall precipitation
5 Battery/collector failure left rainfall sample uncovered and somewhat contaminated, analysis performed
6 Rain sample contaiminated, analysis performed (less than five insects, etc.)
7 Rain sample contaminated, however, with no visual discoloration of sample; analysis performed
8 Rain sample too contaminated for analysis

To facilitate data reduction, clean samples were those which received a "0." Slightly dirty samples were those classified as "5", "6", or "7."

Procedures for Handling and Chemical Analysis of Precipitation Samples

The contents of the sample buckets were transferred into previously cleaned plastic graduated cylinders. Each sample volume was measured to the nearest ml and recorded. A portion of each sample was transferred to a previously cleaned 250 ml polypropylene or polyethylene bottle for storage until chemical analysis on the sample could be accomplished. Conductivity, pH, and titratable acidity were determined on a portion of each sample separate from that saved for additional analysis. Priority was given to the measuring of certain chemical parameters in the event that sample size was insufficient to allow measurements to be made for all chemical species. A flow diagram which summarizes the various chemical analyses performed is presented in Figure 3. Titratable acidity was determined only if sample volume exceeded 120 ml which represented about 0.2 cm of precipitation. If sample volume was less than 50 ml, determination of concentrations of individual ionic species was not attempted except in select samples where acidity was high and dilution of the sample would not jeopardize accuracy.

In general, sample volume and conductivity were measured shortly after samples arrived in the laboratory. Results were recorded directly onto a data sheet (Figure 2). Samples were refrigerated if chemical analysis was not performed within 24 hours. Measurement of pH, pHNV (pH after bubbling nitrogen gas through the sample), and titrations were typically performed within eight hours. Conductivity was measured to the nearest 0.1 umho/cm with a Yellow Springs Instrument Model 31 conductivity bridge. An electrode with a 1.00 cm^{-1} cell constant was used.

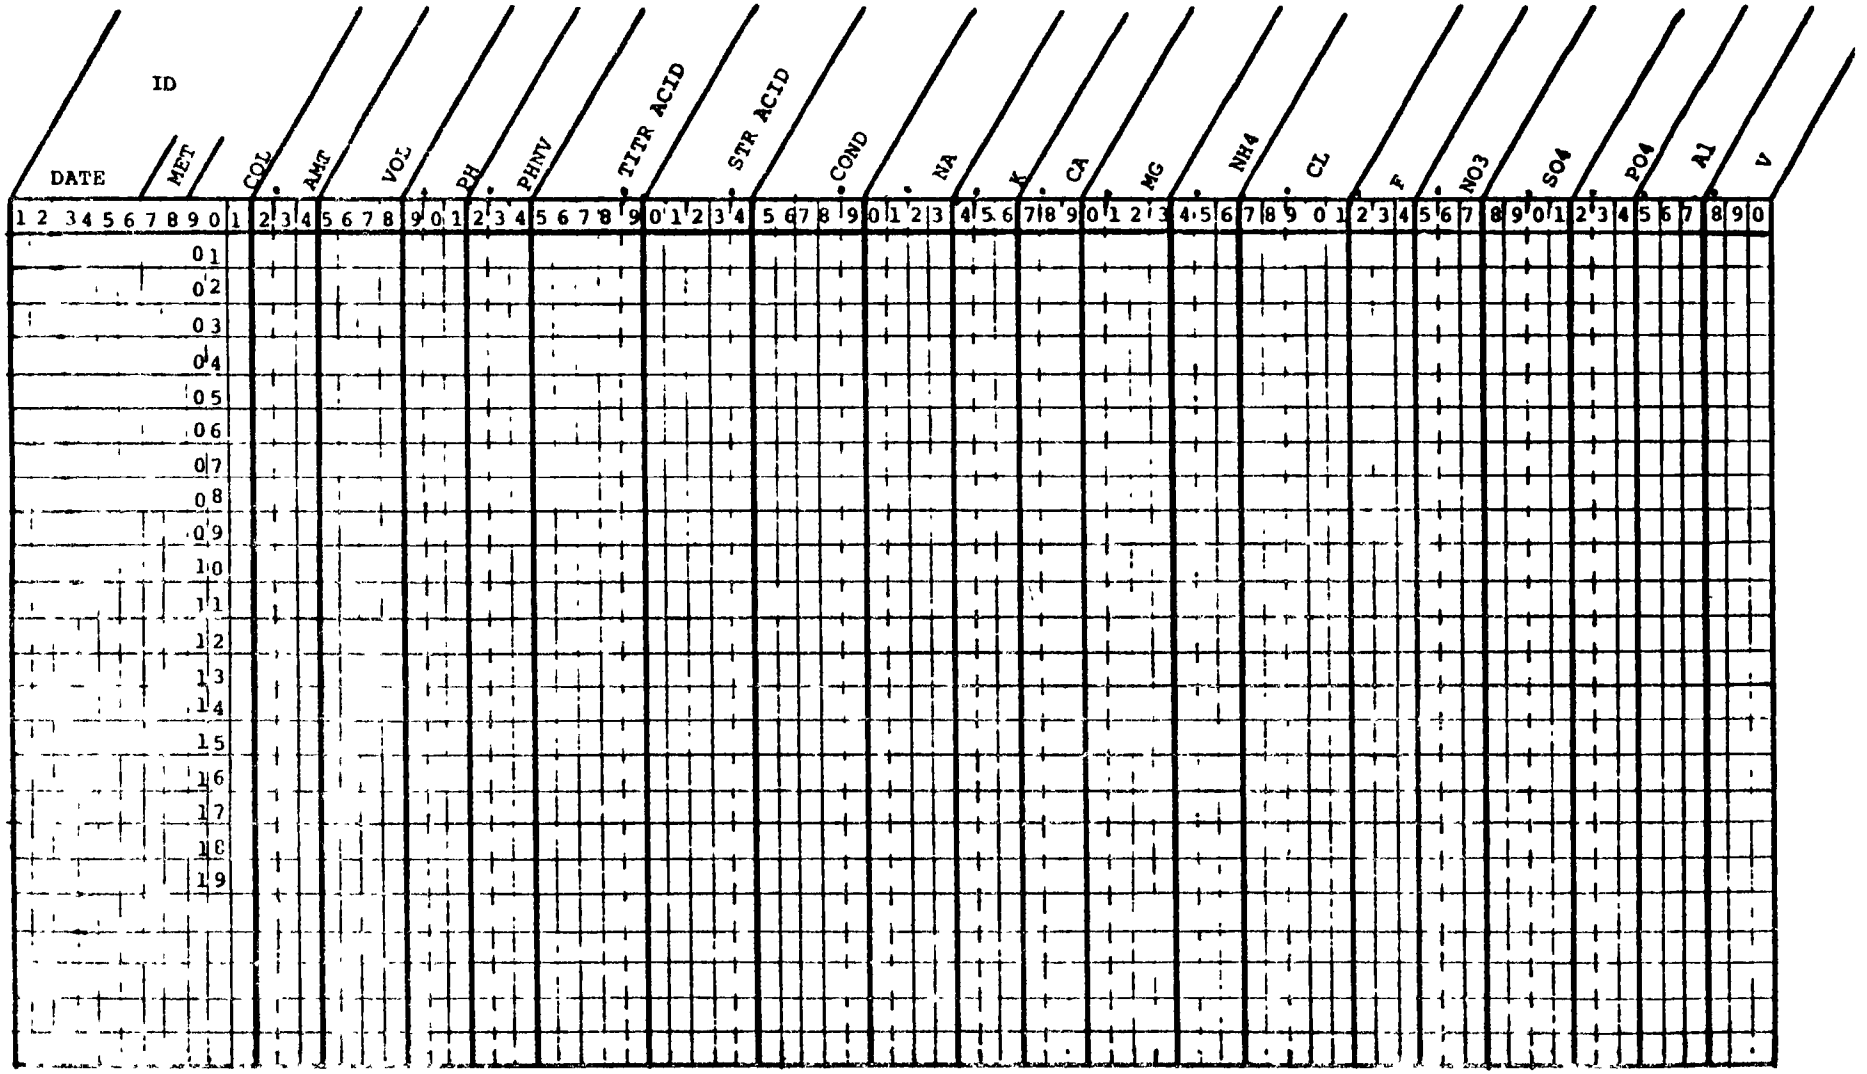

Figure 2. Precipitation Chemistry Data Sheet

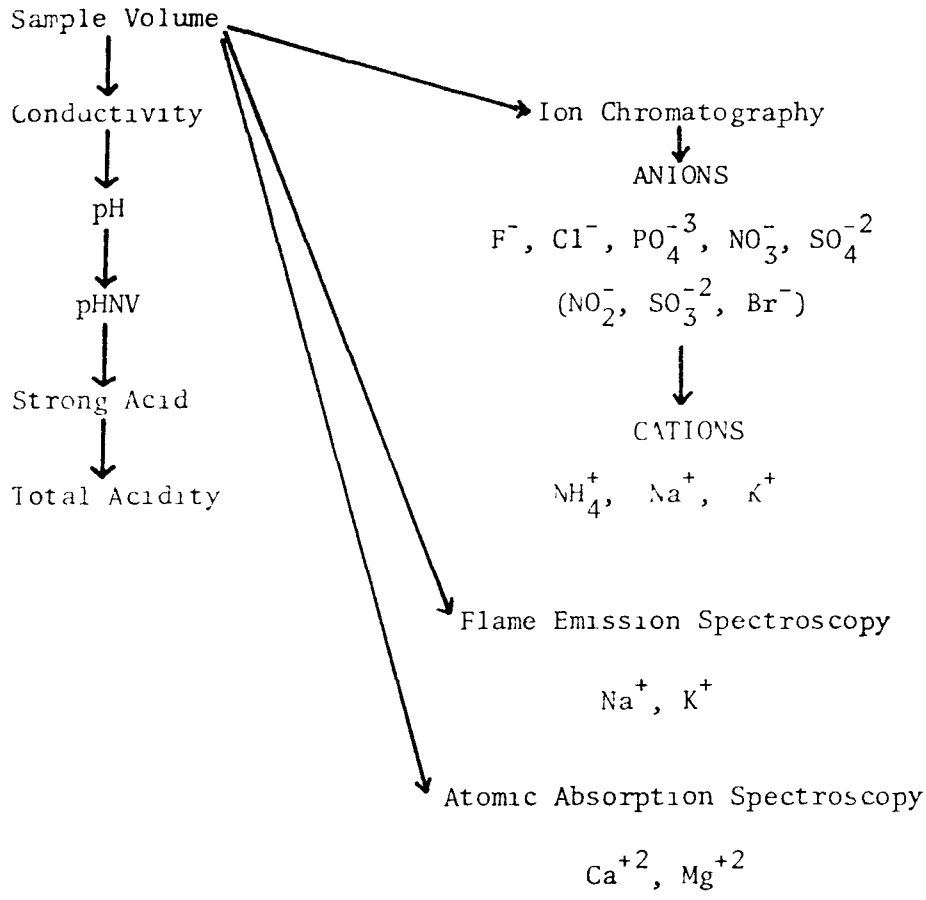

Figure 3. Flow Diagram Showing the Chemical Analysis Sequence for Precipitation Samples

Sample pH was measured at ambient room temperature using a suitable glass and reference electrode pair or suitable combination electrode. Samples were not stirred when the measurement was made. An Orion Model 901 or Corning Model 130 pH meter was used after standardization with buffers of pH 7.00 and 4.01. Nitrogen gas saturated with water vapor was bubbled through the sample for 20 minutes to remove volatile components prior to measuring pHNV. Nitrogen gas was passed over the sample during pHNV measurement. Typically, 15 to 30 minutes was required for the pH reading to stabilize.

If sample pH was less than 4.7 and sufficient sample was available, a potentiometric titration was performed. A 50.00 ml portion of the sample used to determine pHNV was titrated with standardized 0.02 N NaOH under a nitrogen atmosphere. The NaOH was added in volume increments of 5.0 to 50.0 ul. The size of volume increments was selected to allow approximately 10 additions of NaOH to be made before the measured pH increased above 5.0. Sufficient NaOH was then added to increase the pH to above 9.0; 10 additional volumes of NaOH were then added in 20 ul increments. Titration data were treated by the Gran plot technique (Gran, 1952; Rossotti and Rossotti, 1965) to determine the strong acid concentration and total titratable acidity. The strong acid concentration was determined from data collected below pH 5.0, using the following relationship:

$$\psi = (V_o + v)\ 10^{-ph}$$

where ψ is the Gran function, V_o is sample volume, v is volume of NaOH added, and pH is the measured pH upon addition of v. An end point volume (Vep) in microliters for NaOH was determined by extrapolation of the ψ vs. v plot to $\psi = 0$. A linear least squares fit to the data was performed. Results were calculated as follows:

$$\text{Strong acid (microequiv./l)} = \frac{(Vep)(N\ NaOH)(1000)}{V_o}$$

Total titratable acidity was determined from data collected above pH 9.0 using the following relationship:

$$\psi' = (V_o + v)\ 10^{ph}$$

where ψ' is the Gran function and other terms are as previously described. An end point volume for NaOH was determined using ψ' in place of ψ (as previously described) and titratable acidity was calculated as follows:

$$\text{Titratable acidity (microequiv. / l.)} = \frac{(Vep)(N\ NaOH)(1000)}{V_o}$$

where Vep is the ψ' function end point volume. A typical Gran plot is shown in Figure 4. Results were recorded on the Precipitation Chemistry Data Sheet, Figure 2.

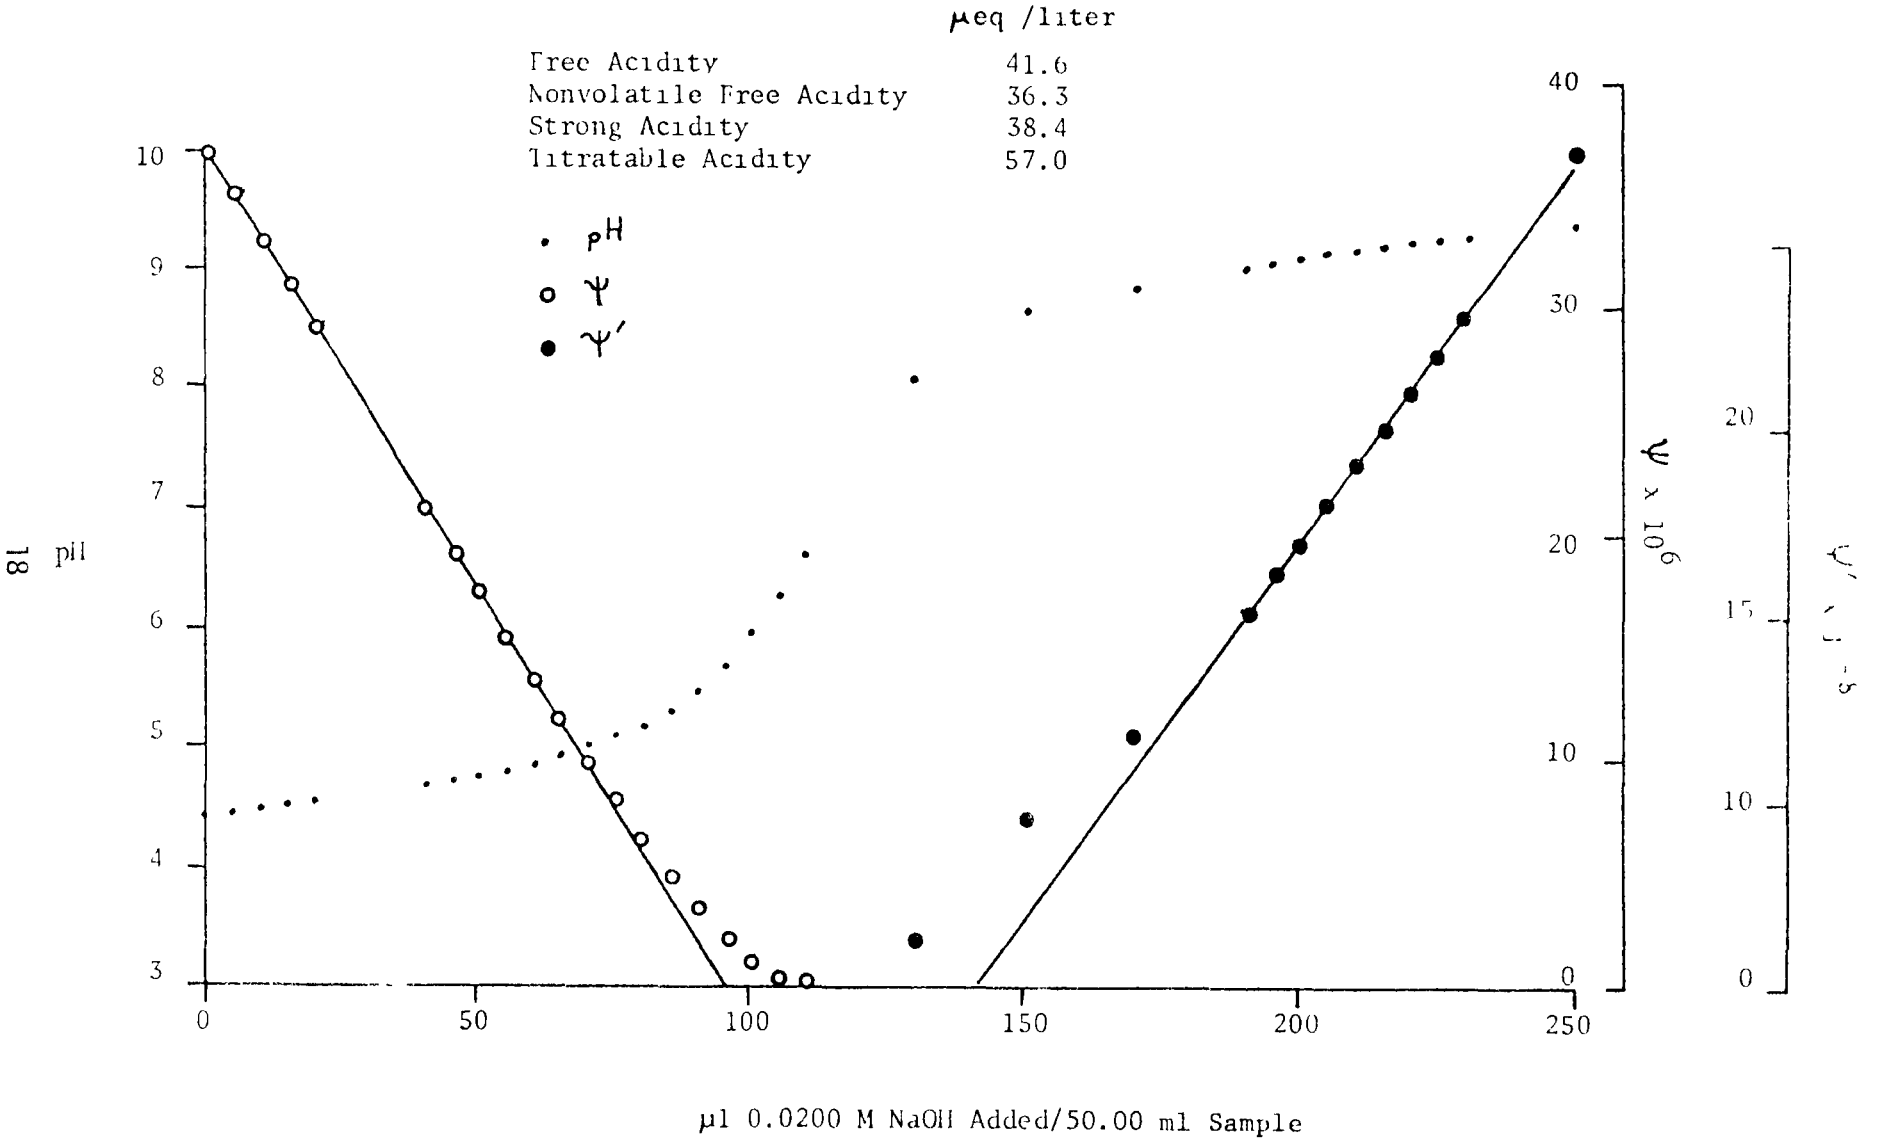

Figure 4. Potentiometric Titration Curve and Gran Plot Functions for a Precipitation Sample Collected February 3, 1978, at UCF Site 18

The concentrations for the major anions F^-, Cl^-, NO_3^-, SO_4^{-2} and PO_4^{-3} present in the precipitation samples and for the cations Na^+, K^+, and NH_4^- were determined by ion chromatography (IC). The ion chromatographic technique was introduced in 1975 and promises to revolutionize chemical analysis at low concentrations for common ionic species such as F^-, Cl^-, NO_3^-, and SO_4^{-2} (Mulik, 1978). The application of IC to the analysis of precipitation samples has been demonstrated (Mulik, 1978) and is of particular advantage for determining SO_4^{-2} where available methods are not sensitive enough.

A Dionex Model 14 Ion Chromatograph was used in these studies. The Model 14 is capable of dual-column operation, allowing both anions and cations to be determined. The IC was operated according to manufacturer's instructions (Dionex, 1976). Table 1 summarizes conditions used in routine operation of the IC for determining anions and cations.

Standard solutions for calibrating the IC were prepared fresh daily by diluting 1000 ppm stock solutions of each anion or cation. Chromatogram peaks were quantitated by measuring peak height, component identification was based on retention behavior. IC determinations were typically completed within one week of receipt of samples.

The anions are best determined from a single chromatogram obtained using an eluent composed of 0.003 M $NaHCO_3$ and 0.0024 M Na_2CO_3. The elution is normally completed in about 18 minutes at a pump pressure of 35 percent. The normal water peak is overcome by preparing each sample and standard to contain exactly the same concentration of $NaHCO_3$ and Na_2CO_3 as the eluent.

The monovalent cations are best determined on a single chromatogram by employing an eluent of 0.003 M HNO_3^- at a pump pressure of 35 percent, the elution is complete in 17.5 minutes.

Prior to injecting the sample, the sample loop was rinsed with approximately two ml of deionized water. A sample volume of approximately one ml was required for anions and a sample volume of approximately two ml was required for cations. Each syringe was previously rinsed with the respective sample or standard.

When increased sensitivity is required, the IC detector attenuation can be changed from 30 to 10 to 3 micromho, etc. A limiting factor is encountered, however, because base-line noise increases. This interference was more noticeable in anion chromatograms.

Initially, fluoride and chloride were separated and quantitated using an eluting solvent that contained 0.003 M $NaHCO_3$. A flow rate of about 150 ml/hr. was utilized. A dual pen recorder operated to give relative sensitivity factors of one and two-tenths allowed chromatogram quantitation with sufficient accuracy and precision over the 0.01 and 5.0 ppm concentration range when the 10 micomho IC detector range was used.

Table 1. Ion Chromatograph operational parameters

A. Column Description

Column	Anion Dimensions	Anion Ser. No.	Cation Dimensions	Cation Ser. No.
Precolumn (1)			6 x 250 mm	3316
Precolumn (2)	3 x 150 mm	2878	6 x 150 mm	2727
Analytical	3 x 500 mm	2868	6 x 250 mm	2402
Suppressor	6 x 250 mm	2372	9 x 250 mm	2523

(1) Located between eluent pump and injection valve
(2) Located between injection valve and analytical column

B. Operating Conditions

	Retention Time, Min.	Concentration Range ppm

(5) Injection volume 1.0 ml, eluent pump 35% which yields an eluent flow of about 150 ml/min; eluent is 0.003M HNO_3
(6) 30umho scale

Phosphate, nitrate, and sulfate were separated using an eluting solvent that contained 0.003 M $NaHCO_3$ - 0.024 M Na_2CO_3. Other conditions were identical to those identified for fluoride and chloride. Beginning in November 1978, samples were run exclusively with the 0.003 M $NaHCO_3$ - 0.024 M Na_2CO_3 eluent. All samples and standards were spiked with a quantity of 0.3 M $NaHCO_3$ - 2.4 M Na_2CO_3 to match the eluent concentration. Phosphate concentrations were consistently below detection limits (approximately 0.1 ppm) of the IC procedure used and do not present a significant contribution to composition.

Base-line noise was found to be minimal for cations. When low concentrations of NH_4^+ were found in the presence of high concentrations of Na^+, the resolution of NH_4^+ was greatly improved by a 1:5 dilution of the sample. The same observation applies to small concentrations of K^+ in the presence of large concentrations of NH_4^+.

Concentrations of the major cations Na^+, K^+, Ca^{+2}, and Mg^{+2} present in precipitation samples were determined by flame spectroscopy. This technique has been widely used for determining these species and is characterized by suitable accuracy and precision at expected cation concentration levels.

An Instrumentation Laboratory (IL) Model 751 Flame Spectrophotometer was used. Flame emission was utilized to determine Na^+ and K^+ while atomic absorption was utilized to determine Ca^{+2} and Mg^{+2} concentrations. This instrument is a dual-channel spectrophotometer which can be used to simultaneously determine two species.

Sodium and potassium were determined after sample and standard pretreatment to introduce 0.1% wt/wt cesium. Occasional dilution was required to decrease sample concentrations to within the concentration range of the calibration curves. The sodium calibration curve was established using five standard solutions which contained from 0.1 ppm to 2.5 ppm sodium. Solutions were prepared fresh daily by diluting a 1000 ppm stock solution. The potassium calibration curve was established using five standard solutions which contain from 0.05 to 0.5 ppm potassium. The IL 751 is microprocessor controlled and reduces data to allow direct concentration read-out based on the entered calibration curve; it operated according to manufacturer's specifications (IL, 1976). A "red" sensitive R955 photomultiplier tube was required to achieve sufficient sensitivity for potassium.

Calcium and magnesium were determined simultaneously by atomic absorption. Samples and standards were treated to contain 0.1% wt/wt lanthanum diluent. Calibration curves for calcium and magnesium covered the range 0.1 to 1.0 ppm and 0.005 to 0.6 ppm, respectively. Flame conditions were optimized for calcium which achieved maximum sensitivity for calcium and still allowed acceptable sensitivity for magnesium. Direct concentration read-out from both channels was made as previously described for sodium and potassium. Standard conditions (IL, 1976, 1977a) were used. Flame spectroscopy determinations were usually completed within ten days of sample receipt.

The concentration of Al and V in precipitation samples is quite low (Galloway, Likens, and Edgerton, 1976). Therefore, it is not possible to utilize conventional flame spectroscopy to determine the concentration for these metals. A flameless atomization source is required to generate enough high atoms to result in a significant absorption signal when atomic absorption is used. An IL 555 controlled temperature furnace (CTF) was the flameless atomization source for the IL 751; it was operated according to manufacturer's directions (IL, 1977b). Several problems were experienced. Difficulty was encountered when temperature program cycles had to be optimized. Extreme difficulty was experienced when sample drying conditions were set. Erratic behavior was observed. During the sample atomization cycle, high temperatures are required for successful atomization of Al and V. At these temperatures, the functional lifetime of temperature sensors and the graphite sample cuvettes was so short that accurate calibration was impossible. Because of these problems, no meaningful results were obtained for Al and V.

Evaluation of Sample Collection and Chemical Analysis Procedures

Several experiments were performed to evaluate the compositional integrity of precipitation samples. Factors were evaluated based on chemical analysis of samples obtained or treated in a variety of ways. A description of each study follows.

Collection of precipitation in clean containers is required if the sample composition is to be representative and not influenced by the sampling container. Plastic containers are preferred for collecting precipitation samples to be analyzed for major inorganic ions; glass is preferred for collecting samples if organic species are to be determined (Galloway and Likens, 1976). A series of experiments was performed to evaluate the effects of time on sample bucket cleanliness when the lid on the collector does not open to expose the bucket to the atmosphere. Although during normal operations of the KSC precipitation network, exchange of buckets would normally occur each work day, several occasions arose where selected sites could not be visited for security reasons for several days. It was beneficial to know whether buckets would become contaminated to some extent during these extended time intervals. During February 1978, and again during March 1978, four operational collectors were utilized at Site 14 and outside the chemistry laboratory adjacent to the Apollo Warehouse at KSC. Clean buckets were placed in collectors at staggered intervals so that at the end of a seven-day period, one bucket at each site had resided in a collector for one, two, five, and seven days. An identical set of buckets was maintained in the laboratory. At the end of the study period, all buckets were returned to the laboratory and thoroughly rinsed with 200 ml of deionized water. The rinse water was analyzed to determine contamination levels by measuring conductivity and determining major anions and cations.

The quality of generated chemical analysis data was monitored throughout the study period. While gross errors in procedures could be recognized in such parameters as anion/cation ratio, the general reliability of data obtained was evaluated separately. Precision associated with each procedure for measuring chemical concentrations can be and was

evaluated by repeating procedures with several separate portions of a given sample. The magnitude of errors associated only with measuring chemical composition is referred to as analytical variability. It can be evaluated with as few as two analyses for each species in separate portions of the same sample. This was done on a semi-routine basis. In selected situations, six to ten replicate determinations were performed.

Spike recovery studies can be used to assess the quality and reliability of the methods used to determine chemical composition of samples. A known quantity of each analyte of interest is added to a portion of the sample. This addition increases the concentration of each analyte in the sample. The spiked sample and a portion of the original sample are then analyzed using the accepted procedure. Results obtained for each analyte in the two samples are compared and the difference for each analyte is compared to a value determined from the known quantity of each added analyte. Systematic errors can be detected in the experimental procedures or errors introduced by the presence of other chemical species or physical properties associated with the sample matrix. Steps can then be taken to minimize these errors. Spike recovery studies were performed at periodic intervals.

The compositional stability of precipitation samples is questionable and several investigators have assessed various conditions intended to retard changes (Galloway and Likens, 1978; Peden and Skowron, 1978). We also evaluated different sample storage conditions to determine whether significant differences in stability would be observed. Separate portions of a single sample were analyzed and stored at either room temperature (4°C) or frozen. At periodic intervals, portions of each sample were removed and subjected to chemical analysis again.

A series of experiments was performed to establish the contribution that different sources of variability have on determining the measured composition of precipitation samples. These experiments involved collecting precipitation samples and an analysis to determine the chemical composition of each. Analytical variability, as previously described was evaluated.

Sampling variability, which represents the difference in rainfall composition between samples collected at the same time in adjacent, identical collectors, was evaluated using five or six collectors placed approximately five meters from each other. Data were collected for at least ten rainstorms to evaluate this variable. Collectors were located at Site 14 and were used to perform this study during November and December of 1977, and again during June and July of 1978.

Spatial variability represents the difference in rainfall composition over a widespread area. The evaluation of this parameter was based on rainfall composition data obtained from samples of the entire collector network or from a smaller set of collection sites as was required for comparison purposes.

Data Management

During the study period, approximately 1500 precipitation samples were collected; most were subjected to chemical analysis. The data obtained as a result of these activities were initially summarized on the Precipitation Chemistry Data Sheet (Figure 2). These data were stored on computer disk as 80-character card images. Data storage, retrieval, and archiving were accomplished using a Harris minicomputer with a 256K CPU memory and a Hewlett-Packard minicomputer. The latter system, which has a 32K CPU memory, tape drive, disk drive, paper tape punch, printer, and plotter, is located at KSC and was used most extensively. Original Fortran IV programming was used in all aspects of data management. Access was by interactive RS232 type terminals.

A "rain" program manipulated the raw data from the card image format. The rain program output included raw data tabulation and associated calculation outputs. Calculation of various parameters was intended to allow evaluation of data quality and to assess various components of precipitation.

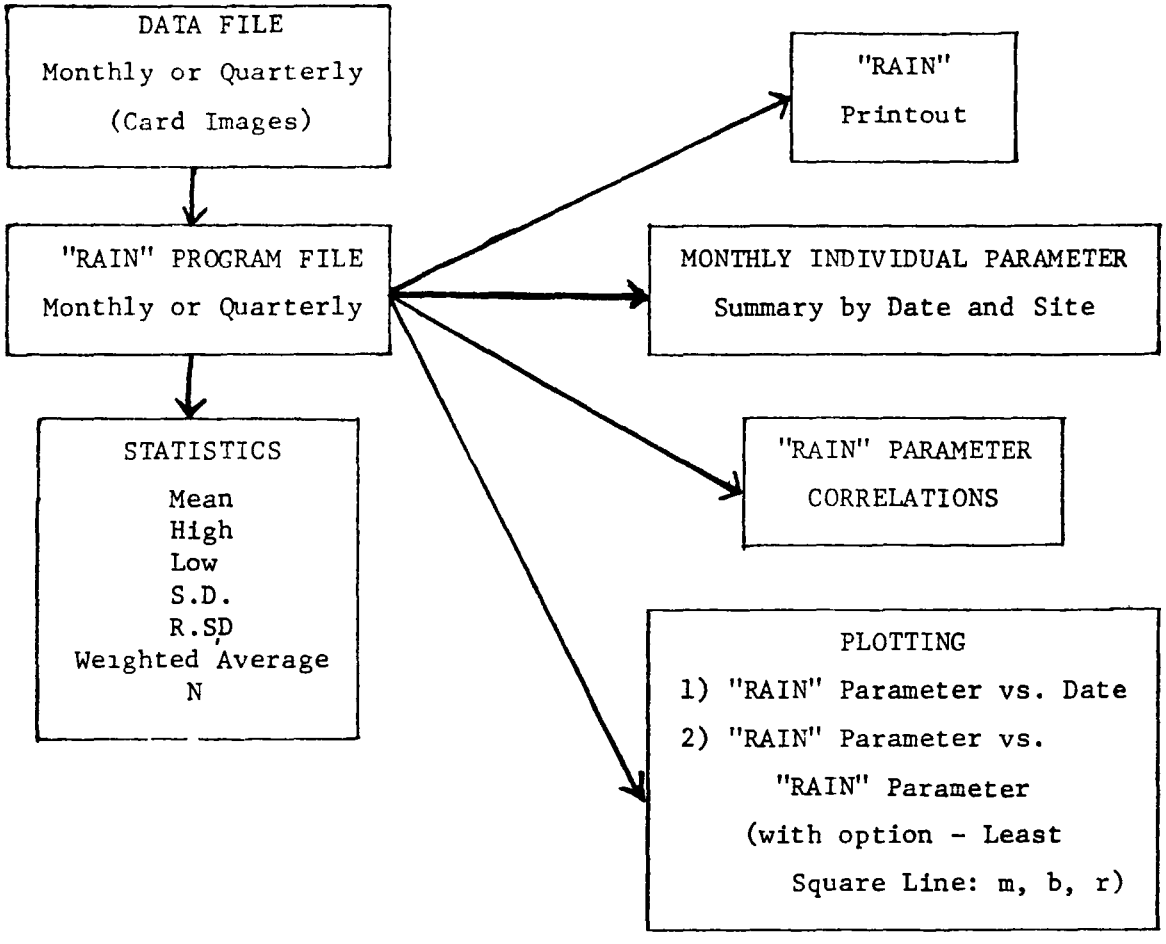
Disk files were created by month and by quarter from the rain program output. Other programs assessed results in individual rain program disk files. Figure 5 summarizes prominent features of the system.

The utilization of computer outputs varied. For example, anion/cation, Cl/Na, Na/Mg, acidity/predicted acidity, etc. were utilized to determine the reliability of the chemical analysis performed on each sample. In addition, Cl/Na, Na/Mg, and calculated sea salt were utilized to assess the contribution of sea salts to precipitation composition and more specifically to document Cl input from the ocean. Types of acidity in precipitation were documented through interpreting pH and titration measurements. A sample rain program printout is shown in Figure 6. A brief description for each parameter in the print-out follows.

"RAIN" PROGRAM LEGEND

RAW DATA

AMT	Depth of precipitation (cm) mesured by an independent measuring device, e.g. rain guage located in close proximity to the primary collector
VOL	Volume of precipitation (ml) in the primary collector
pH	Negative logarithm (base 10) of hydrogen ion activity in the precipitation sample. Measurement is made potentiometrically with a glass indicator electrode and suitable reference electrode. Accuracy is limited by the value of buffer solutions used for calibration, typically ±0.01 pH unit, measurements are made at 25°C
pHNV	The same as pH except volatile weak acids, e.g. carbonic acid (H_2CO_3), have been removed from the sample by bubbling nitrogen gas through the sample prior to measurement.



OPTIONS THAT ALLOW SORTING OF DATA BASED ON SAMPLE ID ARE PART OF EACH PROGRAM.

Figure 6. "Rain" Program Print-out

"RAIN" PROGRAM LEGEND (Continued)

RAW DATA

TITRACID — Titratable or total acidity in the precipitation sample excluding volatile weak acids which were removed prior to this determination. Determination is accomplished by potentiometric titration of the precipitation sample using standardized 0.02N sodium hydroxide. The potentiometric titration data beyond the equivalence point is treated by the Gran plot method to determine the equivalence point. Units are microequivalents per liter.

STRACID — Contribution due to strong acids, e.g. sulfuric, nitric, and hydrochloric, on the total acidity of the sample. The strong acid contribution is determined by Gran plot treatment of the titratable acidity potentiometric titration data obtained prior to the equivalence point. Units are microequivalents per liter.

COND. — Conductivity of the precipitation sample. The conductivity represents contributions from all ionic species in the sample including dissociated acids. Units are micromhos/cm.

NA...V — Measured concentration of each identified chemical species. Concentration units are micrograms per milliliter or parts per million (ppm).

DATA and RATIOS

NA...V — Data for each identified chemical species expressed as microequivalents per liter (UEQ/L)

CMPPT — Tabulates precipitation depth based on volume collected and 640 cm^2 collection area

PVOL — Volume of precipitation that should have been collected in the wet bucket of the wet/dry collector based on measured AMT

COLEF — Collector efficiency as defined by:

$$COLEF = (VOL/PVOL)\ 100$$

SAN — Sum of the anion concentrations present in the precipitation sample expressed as UEQ/L

SCA — Sum of the cation concentration present in the precipitation sample expressed as UEQ/L

A/C — Ratio of SAN/SCA

CL/NA — Concentration ratio for these two species; ratio of 1.165 (eq/eq) is expected if sea salt represents the only source of Na and Cl

NA/MG — Concentration ratio for these two species; ratio of 4.4 (eq/eq) is expected if sea salt represents the only source of Na and Mg

SS — Sea salt (SS) contribution to the precipitation composition:

if CL/Na >1.165, SS = NA (1.293)
if CL/Na <1.165, SS = CL (1.103)

NC — Neutralizing cation component including contributions of Na, K, Ca, Mg, NH_4, or nonacidic cations corrected for sea salt

COND — Defined previously

PCOND — Predictive conductivity, this value indicates what the conductivity of precipitation sample should be based on the

determined concentrations of ionic species and the equivalent conductance of each:

$$PCOND = \sum_{1}(C_1)\ (\Lambda_1)$$

where C_1 is the concentration (microequivalents/liter) and is the specific conductance (micromhos/cm) of the 1 th chemical species; contributions from H, Na, K, Ca, Mg, NH_4,Cl, NO_3, SO_4, PO_4 are included.

COND/PCOND — This ratio should equal one if all chemical species which are present have been determined accurately

PACID — Acidity (microequivalents/liter) of the sample predicted based on determination of cations and anions in the precipitation sample exclusive of hydrogen ion:

$$PACID = \sum_{1}(A_1)-\sum_{J}(C_J)$$

where A_1 represents the anion (Cl, NO_3, SO_4, PO_4) concentrations corrected for that of sea salt origin and C_J represents the cation (Na, K, Ca, Mg, NH_4) concentrations corrected for that of sea salt origin

PPH — Represents predicted pH based on PACID

H — Hydrogen ion concentrations or sample free acidity as calculated from the measured pH of the precipitation sample, units are microequivalents/liter

HNV — Hydrogen ion concentration as calculated from the measured pHNV of the precipitation sample; units are microequivalents/liter

TITRACID — Described previously

STRACID — Described previously

WACOMP — TITRACID minus HNV, an alternate way to express the weak acid component of precipitation after volatile acids have been removed; units are microequivalents/liter

WAFA — HNV minus STRACID and yields any dissociated nonvolatile weak acid present in the precipitation sample; units are microequivalents/liter

%HSA — Strong acid components' contribution to total acidity, determined by STRACID X (100)/TITRACID

%HWA — Undissociated weak acid contribution to total acidity, determined by (TITRACID - HNV) (100)/TITRACID

%WFA — Dissociated nonvolatile weak acid contribution to the total acidity, determined by (HNV - STRACID) (100)/TITRACID

AMTH — Amount of free acid deposited, units are microequivalents/640 cm^2

AMTSA — Amount of strong acid deposited, units are microequivalents/640 cm^2

AMTTA — Amount of total acid deposited, units are microequivalents/640 cm^2

PACID/H — Predicted acidity/free acid ratio

K-S...Na-S — Represents the identified species concentration in excess of that contributed by sea salt

XPACID — Predicted acidity calculated by SAN-SCA+H

XPPH — Predicted pH based on XPACID

Results

Precipitation Sample Collection

Approximately 1500 precipitation samples were collected from July 1977 to March 1979 as part of a routine sampling schedule. In addition, approximately 200 samples were collected during additional studies. Routine chemical analysis was performed on these samples. The number of collection sites increased gradually during the program. The first site began operation in late June 1977 on the U.C.F. campus. In July 1977, four sites were established at KSC; the number increased as shown in Figure 1.

The justification and rationale used to locate collectors at specific sites as shown in Figure 1 has already been discussed. Within the constraints utilized, it appears that the composition of precipitation at only a few sites was significantly affected by local environment.

Precipitation Collector Efficiency

The specific design of a rain collector influences the efficiency of sample collection. For comparison purposes, precipitation amount received by the wet/dry collector and Taylor standard rain gauges was evaluated. In general, the efficiency of the wet/dry collector was slightly less than 100 percent compared to the standard rain gauge when small amounts of precipitation were received. The efficiency was close to 100 percent when amounts of precipitation exceeded 1 cm. The sensor which detects precipitation falling on the wet/dry collector consists of a metal grid with approximately one mm spacing. Rain intensity must be great enough to accumulate water across the spacing before the collector is activated and the wet bucket exposed to the rain. Therefore, the initial portion of a rain event may not be collected. When light showers occur, the portion of rain not collected represents a significant fraction of the total amount.

Evaluation of Factors Which Contribute to the Determined Composition of Samples

The methodology used to investigate several factors which may influence the measured composition of precipitation samples was described in the experimental section. The following describes the contribution which collector operation and sample bucket condition, the chemical analysis program, and natural variations in composition due to meteorological conditions have on the reported concentrations of individual ionic species.

Contamination. A series of experiments was performed to determine whether significant contamination of the sample bucket can occur when the bucket remains in a closed collector for various periods of time. During the first week of February 1978, and again during the first week of March 1978, an experiment (as described in the experimental section) was performed. Chemical analysis of the deionized water rinse from each bucket confirmed that the wet/dry collector will satisfactorily preclude the intrusion of contaminants into the sample bucket. The ionic composition of the deionized wate rinse

solution was negligibly low and conductivity was below 1.0 umho/cm. Should circumstances require that a sample bucket not be replaced with a clean one for an extended period, contamination is unlikely unless the collector lid opens to expose the sample bucket. The study periods utilized in this experiment were selected because strong winds typically occur during these months and might be expected to cause contamination problems. Significant rainfall occurred during both study periods and may have helped minimize airborne contaminant levels which could have been introduced into the sample bucket.

Evaluation of the Reliability of Chemical Analysis Procedures. The results obtained in the evaluation of analytical variability are presented in the next section where evaluation of sampling variability and spatial variability are considered.

Typical results obtained in a spike recovery experiment are summarized in Table 2. The recoveries range from 80 to 120 percent. The magnitude of variability for the spike recovery determinations for

Table 2. Typical spike recovery study on precipitation sample

	PPM				
	Sample	Spike	Recovery of Spike*	Anal. Var.**	% Recovery

*Mean + average deviation of triplicate determinations. Relative average deviation is shown in parenthesis.

**Analytical variability from Table 3.

Note: Na and K determined by flame emission, Ca and Mg determined by atomic absorption, and NH_4, Cl, NO_3, SO_4 determined by ion chromatography.

cations is comparable to the variability or precision associated with the analytical methods used to determine concentrations for these analyses as summarized in Table 3. These data lend support to the hypothesis that errors introduced in the chemical analysis of samples contribute little to the variability associated with the determined concentrations of various species in rainfall.

We participated in the "MAP3S Precipitation Intercomparison Study" during summer of 1978. The study involved determining the chemical composition of eight precipitation samples. Approximately 35 private, state, university, federal government, and foreign laboratories submitted results. The program was conducted by the U.S. Department of Energy. Our results, which were not submitted in time for inclusion in the interim report (Bogen, et al., 1978), will be included in a final report from DOE. Our results agreed with those reported by several other program participants.

Stability of Ionic Components Present in Precipitation. One source of error in precipitation chemistry is associated with the ionic composition instability of dilute aqueous solutions. All procedures involved in the collection, handling, storage, and chemical analysis of precipitation samples can introduce contaminants or lead to loss of certain ionic components in precipitation samples through decomposition or other chemical processes such as absorption. Maienthal and Becker (1976) conducted an extensive literature review on sampling and storage of environmental water samples. Batley and Gardner (1977) critically reviewed sampling and storage of natural waters for trace metal analysis. These studies present many conflicting views. Studies directed specifically at precipition samples have been cited (Galloway and Likens, 1976, 1978; Peden and Skowron, 1978).

The contribution of the sampling bucket and collector as a source of contamination has been described. Contamination introduced through sample handling is most difficult to evaluate. It is possible to evaluate the effect that storage conditions have on sample compositional changes. It is likely that the presence of fine particulate matter or other debris that may enter a collected precipitation sample during the actual rain occurrence will contaminate the sample, will act as a surface upon which absorption and accompanying chemical change can occur, or can react with other components in the sample. Unless a precipitation sample can be obtained and all debris removed simultaneously with the occurrence of precipitation, it must be assumed that compositional changes are likely. When sampling locations are remote from the laboratory, it is not possible to collect samples and analyze in realtime. Typically, samples were received in the laboratory within 24 hours of precipitation. Compositional changes which may have occurred during this time period could not be avoided. Once samples reached the laboratory, procedures were employed to minimize further change. Various studies were performed to evaluate the ionic composition stability of samples once they were received in the laboratory. For those species which were part of the routine chemical analysis program, only pH, NO_3^- and NH_4^+ were observed to change concentration by an amount that could not be accounted for by

Table 3. Magnitude of sources of variability in Kennedy Space Center precipitation composition

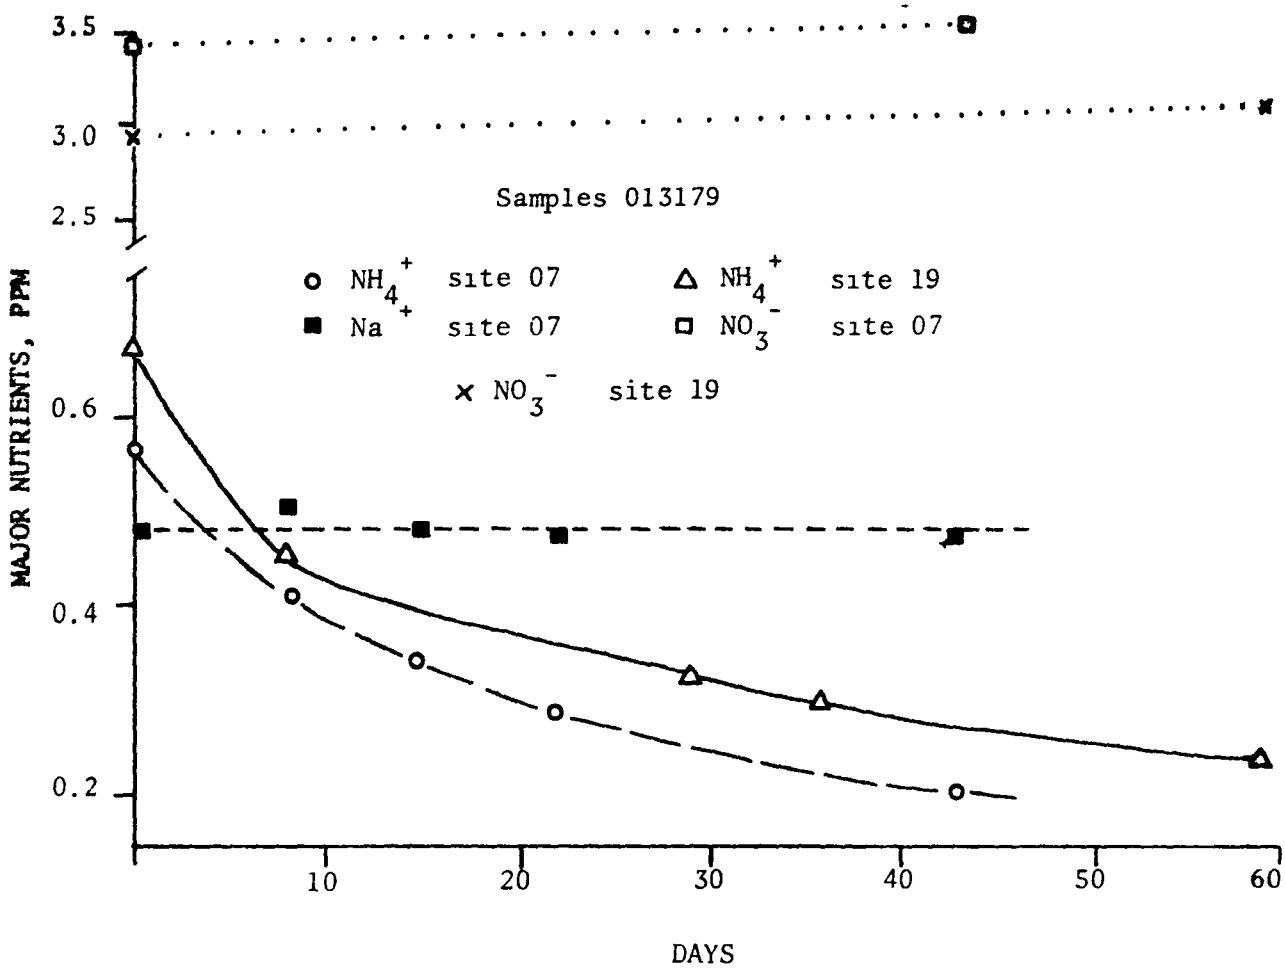
Variability is as previously described (Galloway and Likens, 1978). Sampling variability is based on data from five or six collectors located five meters apart at Site 14. The November-December 1977 Spatial Variability Study is based on the same 11 precipitation events that were sampled for the Sampling Variability Study. The June-July 1978 Sampling Variability and Spatial Variability studies are based on data from 10 precipitation events that occured during late June and early July 1978. Five sites (01, 12, 13, 14, 19) which cover 200 km^2 or 12 sites (01, 03, 05, 06, 08, 10, 11, 12, 13, 14, 16, 19) which cover 600 km^2 were utilized. Sampling Variability and Spatial Variability were calculated by summing the standard deviation/mean (relative standard deviation) for each parameter per event then dividing by the number of events. Analytical Variability is the relative standard deviation based on six to ten separate measurements.

analytical error. Stabilization of NO_3^- and NH_4^+ concentrations was accomplished in most cases by storing the samples at 4°C until chemical analysis was complete. This procedure appears satisfactory for at least 60 days. Long-term stabilization and storage was accomplished by freezing the sample. Stabilization of sample acidity or pH could not generally be accomplished at either 4°C or by freezing of the samples. Those samples which were quite acidic with pH 4.2-4.3 or below were generally but not always self-stabilizing. Results of several sample stability studies are shown in Figure 7.

Analytical, Sampling, and Spatial Variability. Since the measured concentrations of chemical species present in precipitation may vary due to several factors, factors which can be controlled and minimized were continually evaluated. Three specific factors were documented: analytical variability, sampling variability, and spatial variability. These factors have been defined in the experimental section of this report. Every effort was made to insure that results obtained did indeed reflect the actual composition of precipitation and were influenced only slightly, if at all, by controllable factors. Results obtained for analytical variability, sampling variability, and spatial variability are presented in Table 3. Specific experiments which were designed to evaluate both analytical variability and sampling variability were performed durng November-December 1977, and again during June-July 1978. These time periods were selected because meteorological conditions would be at extremes during the two time periods and variability in precipitation composition could, therefore, be significantly different. Because precipitation composition data were available for the entire operational network, spatial variability was determined for comparable time periods to aid in the evaluation of the major sources of variability in measured precipitation composition. The results presented in Table 3 indicate that analytical variability did not change significantly during the two different time periods and probably contributed only a small amount to any variations observed in precipitation composition. Analytical variability was determined for each chemical species by performing each determination six to ten times on fresh portions of the same sample.

Sampling variability was determined from samples collected 5 meters apart at Site 14. Six collectors were used for the November-December 1977 study while five collectors were used for the June-July 1978 study. Samples from 11 precipitation events were analyzed to determine sampling variability in the November-December 1977 study. Samples from ten precipitation events were analyzed to determine sampling variability in the June-July 1978 study. Variation in precipitation composition that results from sampling as determined here also includes analytical variability. However, the magnitude of analytical variability has been shown to be considerably less that that observed for sampling variability. Only minor differences in sampling variability were observed between the two time periods evaluated. The 11 precipitation events which occurred during November-December 1977 were generated by movement of a cold front through central Florida and were generally characterized by strong gusty winds and precipitation which occurred during periods that ranged from about 1 hour to more than 24 hours of continuous



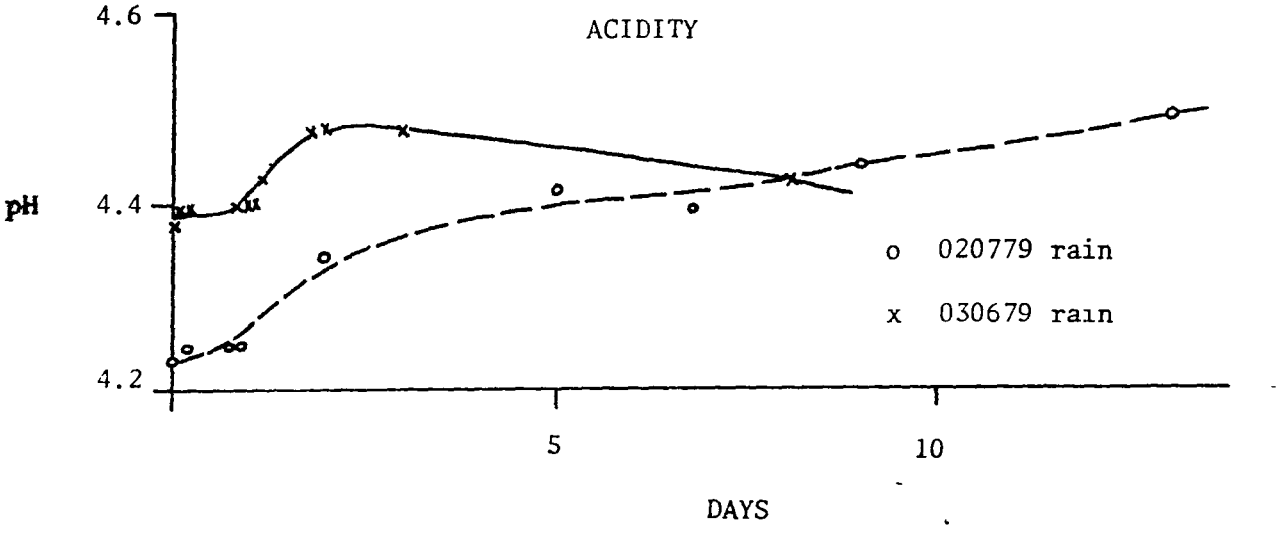


Figure 7. Changes in the chemical composition of precipitation samples with time when stored at room temperature

rain and mist. The ten precipitation events from June-July 1978 were a result of convective-type weather activity. Strong gusty winds usually occur during periods of convectional storm activity. Precipitation usually occurs over a short time period of two hours or less.

Spatial variability associated with precipitation composition which occurred during the same time periods utilized to evaluate analytical and sampling variability are also presented in Table 3. Spatial variability inherently includes both analytical varability and sampling variability. Results obtained for both the November-December 1977 and June-July 1978 periods show significant variations in precipitation composition. These variations cannot be accounted for by a consideration of analytical and sampling variability. The observed spatial variability in the concentration for each chemical species, as reported in Table 3, is quite typical of what occurs even on an event-by-event basis.

Chemical Composition of Precipitation Which Occurred from July 1977 to March 1979

Precipitation chemistry data were collected for several sites on KSC and on the UCF campus for a 21-month period. Ionic composition data were obtained from precipitation samples for the last 17 months while acidity, conductivity, and volume measurements were made during the entire 21-month period. In the following narrative, general observations based on data collected are described. No attempt is made to present all results available on a site and chemical parameter basis. Instead, representative data from selected sites which involve only a few of the more important chemical parameters will be utilized. Trends and variations in volume weighted average concentrations which occurred during the 21-month study for several chemical parameters will be considered. The term "volume weighted average" (VWA) or "weighted average" will be used when concentration data for individual chemical species are to be reported as averages and when precipitation sample sizes were not identical. Larger samples exert a greater influence on weighted average concentration. The weighted average is determined as follows:

$$VWA = \frac{\sum_i C_i V_i}{\sum_i V_i}$$

where C_i represents the concentration and V_i represents the volume of the ith sample. The weighted average for most situations is calculated as described. However, parameters which are logarithmic functions of concentration cannot be treated directly. For example, pH values must be converted to hydrogen ion concentrations, then the weighted average hydrogen ion concentration is calculated and used to calculate weighted average pH.

Monthly weighted average pH, amount of precipitation, major ion concentrations as microequivalents/liter and total deposition amount of free acid measured as microequivalents/square meter are summarized for six individual sites located at KSC, the UCF site, and an average of all KSC sites in Tables 4-12. The values reported in Table 4 include contributions from all KSC sites. The units microequivalents/liter were selected for reporting of results in preference to units of parts per million (ppm) because the former allow direct intercomparison of acidity with other ionic concentrations. Units of ppm are based on weight and thus do not allow direct comparisons to be made. For example, in a dilute solution of sulfuric acid, one microequivalent of acid is present for each microequivalent of sulfate. By comparison, 1 ppm of acid (hydrogen ion) is present for each 48 ppm sulfate.

Results from both "clean" and "slightly dirty" samples are included in the average values reported. Clean samples were those which were colorless and contained no visible contamination such as dirt or insect remains. Slightly dirty samples contained dirt, insect remains, or other foreign matter while the liquid portion of the sample remained colorless. Results obtained as averages for "clean only" samples are reported for comparison purposes in Table 5. The weighted average concentrations based on clean and slightly dirty samples agree with the corresponding averages based on results from clean only samples except during the period December 1978, and January 1979. Clean samples accounted for less than ten percent of all samples collected during this two-month period. No clean samples were collected during February and March 1979. The variations in monthly weighted average pH for all KSC sites based on clean plus slightly dirty and for clean only samples is shown in Figure 8. The variations apparent in the December 1978, to March 1979, data have been explained above.

Tables 6 to 12 summarize the monthly averages considered previously in Tables 4 and 5 for individual KSC sites 01, 11, 12, 13, 14, and 19, and UCF Site 18. In all cases, considerable variation between months is observed for the chemical species measured. Site-to-site variations for individual chemical species is not as great as monthly variations. Figures 9 and 10 show variations observed when weighted average pH based on all KSC sites is compared to the UCF site and when weighted average pH at KSC sites 01, 12, and 14 are compared. The variation in the chemical composition of precipitation has been considered previously. The variation in measured sample pH based on all samples collected at a single site within a specified time period is substantial. Monthly and quarterly pH summaries presented as weighted averages are shown in Figure 11. The distribution and variability of sample pH is shown in Figure 12 and in Appendix Tables 1-21. Because of the variability in the chemical composition of rain monthly weighted averages should be utilized with caution and then only to indicate the relative average composition on a month-to-month basis.

All concentrations are microequivalents/liter except pH, Cmppt, and AMTH. The latter represents the amount of acid deposited (microequivalents/square meter). AMTH is calculated from pH and the amount of precipitation which occurred.

Characterization of Precipitation Composition

Results of precipitation chemistry measurements based on monthly averages were presented previously. The trends in precipitation composition from month to month are not clearly defined in most cases; significant correlations do exist, however, among several of the chemical species present. Many of these correlations exist on a sample-by-sample and event-by-event basis as well. The results summarized below will emphasize those correlations which are useful in defining the composition of precipitation.

Acidity. The free acidity of samples was determined by converting the measured pH value to the corresponding hydrogen ion concentration which has units of microequivalents/liter. The pH of dilute aqueous samples which contain strong acids such as HNO_3, H_2SO_4, and/or HCl is determined by the total acid concentration present unless acid neutralizing species or partially dissociated weak acids are present. The actual strong acid acidity can be determined by titration and Gran plot treatment of the titration data (Galloway and Likens, 1979). Total titratable acidity can be evaluated from the same titration data and includes the contribution of all acidic species (Galloway and Likens, 1979). Rain samples which gave initial pH readings of less than 4.7 were titrated to determine the total acidity and strong acid acidity. Figures 13 and 14 show the relationships that were observed between HNV (non-volatile free acidity) and strong acid acidity in precipitation samples that were collected at KSC site 01 and for all KSC samples collected from July to September 1978. The relationship which exists between HNV and strong acid acidity for samples collected at KSC site 01 and at all KSC sites indicate that strong acids in the samples account for sample free acidity once volatile acids have been removed and, therefore, are responsible for pH values which have been observed. Similar behavior has been observed during other time periods. Titratable acidity for samples collected during July to September 1978, is compared to sample acidity based on the initial pH measurement in Figure 15.

The free acidity of rainfall at KSC can be totally accounted for by the presence of H_2SO_4, and HNO_3^- when monthly averages are considered. This observation has also been made when only individual samples are considered. The actual concentrations of free acidity, NO_3^-, and excess SO_4^{2-} (sulfate not of sea salt origin) in individual samples collected at KSC site 01 and UCF site 18 during July 1978, are shown in Figures 16 and 17, respectively. The additive concentrations of NO_3^- plus excess SO_4^{2-} account for the acidity observed even when sample acidity changed drastically. Concentrations of NH_4^+ were very low in samples collected during July 1978.

The excess SO_4^{2-} concentrations and NO_3^- concentrations in rain samples expressed as monthly weighted averages are included in Tables 4 to 12. from Figures 18 and 19, it is apparent that the monthly weighted average acidity in samples corresponds closely to observed weighted average concentrations for both excess SO_4^{2-} and NO_3^-. Only during April 1978, do these comparisons not hold. The concentrations of NH_4^+ in precipitation samples from April 1978,

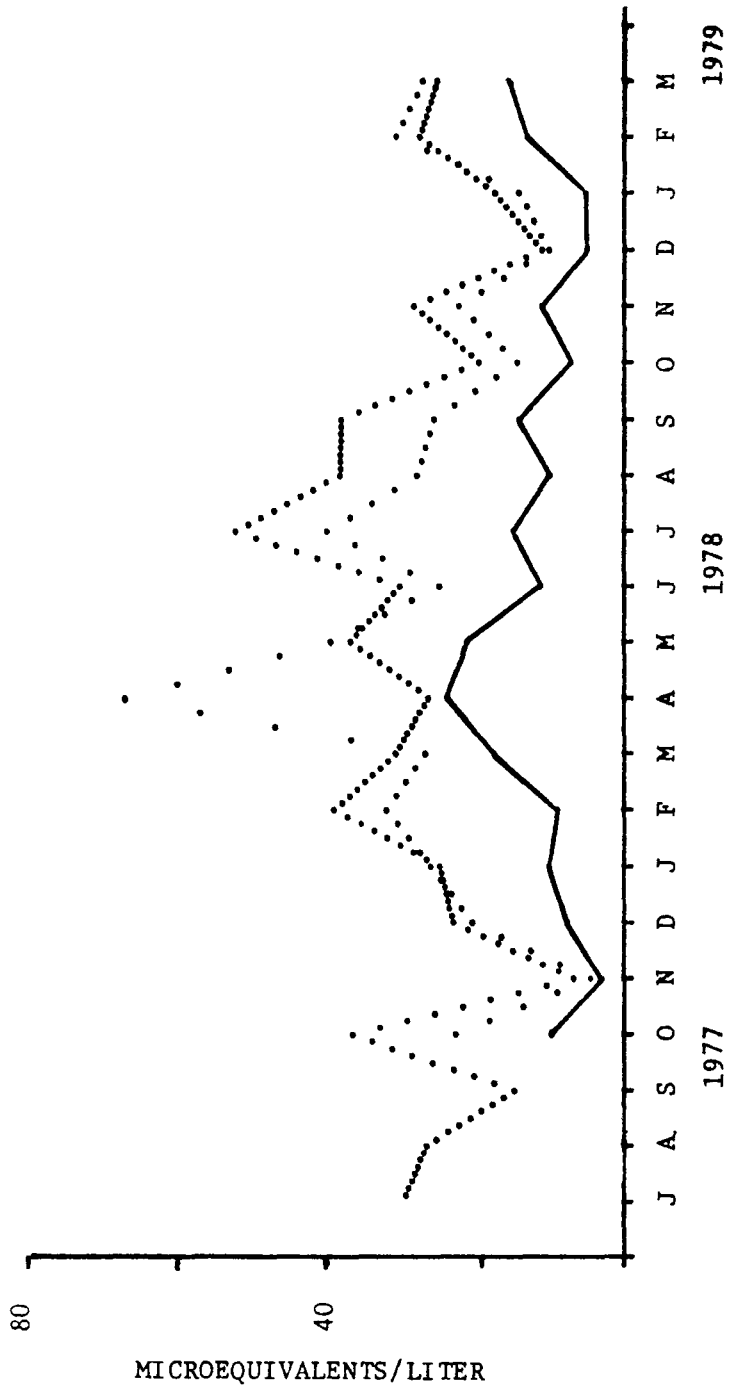

Figure 19. Comparison of Monthly Volume Weighted Average Free Acidity (.....), Nitrate Concentration (_____), and Excess Sulfate Concentration (. . . . . .) for Precipitation Samples Collected at All KSC Sites

The excess SO_4^{2-} concentrations and NO_3^- concentrations in rain samples expressed as monthly weighted averages are included in Tables 4 to 12. From Figures 18 and 19, it is apparent that the monthly weighted average acidity in samples corresponds closely to observed weighted average concentrations for both excess SO_4^{2-} and NO_3^-. Only during April 1978, do these comparisons not hold. The concentrations of NH_4^+ in precipitation samples from April 1978, were typically 2 to 50 times greater than those measured during other months in the study period. No conclusive reasons for this increase can be given. Atmospheric ammonia neutralizes acids in the atmosphere and this may account for the fact that acidity did not increase as in other months in proportion to the excess SO_4^{2-} or NO_3^- concentration.

When all samples collected at KSC during July to September 1978, are considered and the dependence of sample acidity on NO_3^- or excess SO_4^{2-} concentrations is evaluated, evidence as shown in Figures 20 and 21 indicates that both NO_3^- and excess SO_4^{2-} are significant contributors. The correlations of free acidity with NO_3^- and excess SO_4^{2-} concentrations from individual samples when evaluated on a month-by-month basis are presented in Table 13.

Figures 22 and 23, respectively, show the dependence of free acidity in samples collected at KSC site 01 on NO_3^- and excess SO_4^{2-} when monthly volume weighted average concentrations are considered. The reported correlation coefficients emphasize the existence of a strong dependence and lead to the conclusion that H_2SO_4 and HNO_3^- are indeed responsible for the acidic character of precipitation. When the influences of excess SO_4^{2-} and NO_3^- are combined with the acid neutralization by ammonia, an even stronger correlation is observed--Figure 24. The relationship between free acidity and NO_3^- plus excess SO_4^{2-} minus NH_4^+ also holds when the average results obtained from samples collected at all KSC sites are considered--Figure 25.

Sample free acidity also appears to be dependent upon the amount of precipitation that occurs. Typical behavior that has been observed is shown in Figure 26. The total amount of acid deposited is also related to the amount of precipitation that occurs as shown in Figure 27 for KSC Site 01. The same general agreement is observed when the amount of free acid deposited and amount of precipitation are compared on a sample-by-sample basis. Typical results for samples collected at KSC from July to September 1978, are shown in Figure 28. A comparison by month between the amount of free acid deposited at KSC Site 01 and UCF Site 18 is shown in Figure 29.

Sea Salts. "Rainout of pollutants" refers to incorporation of the pollutant into the rain during formation of precipitation in a cloud. "Washout of pollutants" refers to the scavenging action of rain droplets as the travel through a mass of polluted air and dissolve or wash the pollutant from the air. Many pollutants exist as stoichiometric compounds in the atmosphere. The compounds thought to account for increased acidity of rain include H_2SO_4 and HNO_3^-. Variations in sample acidity, whether occurring from rainout or washout of pollutants, should come about due to the presence of specific compounds. If H_2SO_4 and HNO_3^- are responsible for increased acidity, then the concentrations of SO_4^{-2} and NO_3^- in the precipitation samples should be indirect indicators of sample acidity provided other nonacidic sources of NO_3^- and SO_4^{-2} do not exist. Sea salt contains considerable SO_4^{-2} and precipitation collected where the marine influence is strong will contain considerable nonacidic SO_4^{-2} which arises from this influence. The SO_4^{-2} which exceeds the sea salt contribution may, therefore, be an indication of acidic SO_4^{-2}. If Na^+ and Cl^- concentrations in precipitation are determined, then the concentration of excess SO_4^{-2} in the sample can be determined (Granat, 1972). The determination of excess sulfate assumes that the concentration ratio of SO_4^{-2}:Na^+ or SO_4^{-2}:Cl^- in precipitation is the same as that in sea water. It is common to assume that the only source of Na^+ in precipitation is the sea. Therefore, the sea salt origin of K^+, Ca^{+2}, Mg^{+2}, Cl^-, and SO_4^{-2} in precipitation can be determined from the measured Na concentration and appropriate element:Na^+ ratio. For situations where Cl^- has no other source except the ocean it can be used to determine the sea salt contribution of each element when used in place of Na^+ in the previous discussion. As will be shown later, it appears that sea salt contributes all of the Na^+ and Cl^- determined to be present in precipitation at KSC. Therefore, either Na^+ or Cl^- can be used to determine the sea salt contribution. Because slight variations were observed in the Cl^-:Na^+ ratio from sample to sample, all calculations of total sea salt concentration and excess SO_4^{-2}, etc. were based on the sea salt ratio of 1.165 which represents microequivalents Cl^-/microequivalents Na^+. Chloride was used if the ratio was less than 1.165 which indicates excess Na^+ and vice versa. The presence of sea salt in rain is due primarily to washout. The concentrations of sea salt in precipitation has been included in Tables 4-12.

The ionic species which have their origin in the ocean have been observed to account for a significant portion of the total ionic composition of precipitation samples collected at KSC. Sea salts represent about 75 percent of the total ionic composition in all rain samples collected when pH values are relatively high (low acidity) and as much as 25 percent to 35 percent when sample acidity is high. These observations can be drawn from results presented in Table 4. These same contributions are approximately 90 percent and 40 percent, respectively, at KSC Site 11 [on a beach dune (Table 7)] and are much lower at UCF Site 18 (Table 12). The effect of proximity to the ocean as it influences sea salt concentrations in the rain samples is shown in Figure 30, where monthly volume weighted average sea salt concentrations that were determined for samples collected at KSC sites 01, 11, 12, and 14 are presented. These four sites describe a progressively increasing distance from the ocean. The decrease in sea salt effect is apparent.

The ratios of Cl^-:Na^+ and Cl^-:Mg^{+2} have been observed to approximate closely the corresponding ratios as they exist in sea water. These ratios hold when individual samples are considered and variations typically are less than $\pm$ 10% from the 1.165 ratio for Cl^-:Na^+. Typical behavior is shown in Figures 31 and 32. Agreement between measured Cl^- and Mg^{+2} with the theoretical ratio of 5.11 is shown in Figure 33. These observations are important for several reasons. Because existing Cl^- concentrations can be accounted for by considering sea salt alone, it is apparent that HCl does not contribute to the observed acidity in rain. If no other sources of Na^+ and/or Mg^{+2} exist, then either can be used in determining excess SO_4^{-2} concentrations and excess Cl^- concentrations should the latter become significant in the future. Terrestrial sources may account for up to 10 percent of the Mg^{+2} present in samples.

Correlation Among Species. The coefficients of linear correlation which have been determined for selected pairs of ionic species from samples collected during the 21-month period covered by this study are summarized by month in Table 13. The relationships that exist between selected species from July to September 1978, have already been described and presented graphically in Figures 20, 21, 31, 32, and 33. The results presented in Table 13 show that the pairs, acidity:nitrate, acidity:excess SO_4^{-2}, Cl^-:Na^+, Mg^{+2}:Na^+, NH_4^+:SO_4^{-2}, and the amount of free acid:amount of precipitation, are generally highly correlated with few exceptions during individual months and, therefore, support the discussion presented in the previous section. For comparison purposes, the linear correlation behavior between acidity:F and sea salt:acidity are also presented in Table 13. These pairs are not significantly correlated.

Only during April 1978, May 1978, and March 1979, were significant correlations lacking for acidity:NO_3^- and acidity:excess SO_4^{-2}. Samples collected during these periods tended to contain greater quantities of foreign matter and the frequency of precipitation was much lower. Precipitation only occurred on two days in April 1978, and three days in March 1979. There were six days when precipitation occurred during May 1978. The presence of NH_4^+ in precipitation in amounts proportional to excess SO_4^{-2} was observed during these months of infrequent precipitation. As previously reported (Figures 24 and 25), the NH^+_4 is probably the neutralization product of the reaction between ammonia and acidity, due to HNO_3 and H_2SO_4. Excellent correlation was observed between ionic species of sea salt origin. Specifically, Cl^-:Na^+ and Mg^{+2}:Na^+ correlations (Table 13) and, indirectly, Cl^-:Mg^{+2}, are important because they indicate no significant contribution by other sources of Na^+, Mg^{+2}, or Cl^- to the ionic composition of collected precipitation. Determination of excess Cl^- is feasible based on the measurement of Cl^- and either Na^+ or Mg^{+2} concentrations. More extensive monthly weighted average concentrations, range of concentrations, and statistical summaries by month and for individual sites are presented in Appendix Tables 22-203. Evaluation of correlations which may exist among various species concentrations are summarized by month for individual sites in Appendix Tables 204-381.

Evaluation of Factors Which Contribute to the Composition of Precipitation.

Evaluation of the existing quality of rain which fell during the time period included for this study can be made based on volume weighted average concentrations for chemical species of interest and the time interval desired. Before conclusions can be drawn, several factors that must be evaluated include: 1) Sources of variability in measured rainfall composition 2) Influence of foreign matter which may be present in the sample, e.g. insects and vegetation 3) Site selection and biases introduced 4) Period of time utilized for presentation of results 5) Meteorological conditions. Each of these factors was studied or evaluated to determine the influence that each could have when results of sampling and chemical analysis are reported.

Sources of Variability. The variability associated with measured rainfall composition can be accounted for by a number of factors. Analytical variability refers to the precision associated with the chemical methods of analysis that are utilized to determine individual ion concentrations. The analytical precision depends on the method of analysis utilized. It also depends on the concentration of the chemical species to be measured. When methods which are characterized by relatively poor sensitivity are utilized in attempts to measure small concentrations or when methods of high sensitivity are utilized to measure extremely low concentrations then precision is expected to be poor. When a sample is subjected to chemical analysis, precision may be good or poor for individual components based on selection of method and the actual concentration present for each individual chemical species. Results presented in Table 2 indicate relatively large ranges in precision for some individual species. Under the conditions utilized for routine chemical analysis of precipitation samples, concentrations of 0.01 ppm were typical of the lower concentration limits that were considered significant; no attempt was made to measure concentrations lower than this value. Certain species were typically present in samples at low concentrations. for example, many F^-, K^+, Ca^{+2}, Mg^{+2}, and NH_4^+ concentrations were determined to be less than 0.1 ppm. Typical concentrations for other species were 2 ppm Na^+, 3 ppm Cl^-, 0.5 ppm NO_3^-, and 1.5 ppm SO_4^{-2}. For those species which were present at less than 0.1 ppm., an analytical variability of 0.01 (10 percent) was common and aceptable based on methodology used to determine concentration. The analytical variability observed for determining concentrations of other ions present at higher concentrations should be considerably less. These observations were verified; results are presented in Table 3.

Sampling variability is a measure of variability introduced into the measured precipitation composition due to the method of sample collection. This factor was evaluated by placing identical collectors side-by-side--simultaneously collecting precipitation from the same event in each and performing routine chemical analysis on each sample to determine any variability which may be present.

There is no way to physically separate variability due exclusively to sampling from that introduced by analytical variability. A qualitative comparison of the magnitude of analytical variability with that of sampling variability (Table 3) shows that sampling of precipitation does introduce variation into the measured chemical composition which cannot be accounted for by the analytical variability. Only small differences are observed when these comparisons are made between the two different time periods used to study these factors.

Spatial variability refers to the differences observed in measured precipitation composition from samples collected over a specified area. Evaluation of the magnitude of spatial variability is presented in Table 3 for time periods which coincided with those used to evaluate sampling variability. Five sites were utilized for the initial evaluation of spatial variability which occurred during November and December 1977. During June and July 1978, the same 5 sites were again utilized as well as a 12-site network. Variations measured for precipitation composition over the network are only somewhat accounted for by analytical and sampling variability. These observations hold for both time periods. Only minor differences are observed between variability in data from the 5-site and 12-site networks. Several factors account for the relatively large spatial variations observed and probably include local, regional, and long-range origin, meteorology, and transport of various chemical species. The variations in site-by-site and event-by-event precipitation composition are real and complicate assessment of origin and long-term trends associated with precipitation composition.

Analytical, sampling, and spatial variability have been evaluated by others (Galloway and Likens, 1978). The analytical variability for individual chemical species as determined in this study are similar to those reported previously (Galloway and Likens, 1978). The sampling variability associated with collection of bulk precipitation (Galloway and Likens, 1978) is similar to results obtained here for H^+, K^+, Ca^{+2}, NO_3^-, and SO_4^{2-}. Sampling variability associated with the determination of Na^+, Mg^{+2}, and Cl^- in this study were considerably lower than those previously reported, that for NH_4^+ was considerably larger. These differences can be explained when the actual concentrations are considered. KSC precipitation contains much higher concentrations of Na^+, Mg^{+2}, and Cl^- because of proximity to the ocean. KSC precipitation has generally been characterized by very low NH_4^+ concentrations.

When comparisons are made between the observed spatial variability in precipitation composition at KSC with results of similar studies, several conclusions can be drawn. Galloway and Likens (1978) measured spatial variabilities of less than 15 percent for precipitation amount, H^+, Ca^{+2}, Mg^{+2}, NO_3^-, and SO_4^{2-} and up to 90 percent variability for other species. From a three- site network which covered approximately 20 km^2, sampling and spatial variability were essentially the same. They also reported results from an European study which was based on a 50-site network which

covered an area of 7600 km^2. Variability for precipitation amount, Na^+, NH_4^+, NO_3^-, and SO_4^{-2} were 33 percent, 61 percent, 87 percent, 32 percent, and 29 percent, respectively, and was attributed to the much larger area covered. Greater variability was observed for most individual component concentrations in precipitation collected at KSC.

Analytical, sampling, and spatial variability studies were performed during two different time periods. It was initially believed that seasonal changes in precipitation composition and the different meteorological conditions which result in precipitation during two seasons would significantly alter any variability in composition. This apparently is not the case. Sampling variability was not significantly different when results obtained from samples collected during November-December 1977, are compared with those obtained during June-July, 1978. Similar observations were made for spatial variability. Although the composition of precipitation which occurred during these two time periods was dramatically different, variations due to sampling error and variations observed among individual sites were relatively unchanged. Apparently, complex local and regional meteorology and the processes which result in precipitation are extremely variable and result in significantly different precipitation composition even on a relatively small areal scale.

In addition to reporting sampling and spatial variability for individual chemical parameters or species, Table 2 also includes results for variabilities associated with determination of excess SO_4^{-2}, sum of anions, and amount of free acid deposition. These three parameters are calculated by incorporating combinations of previously measured properties. Variability in determination of these parameters, therefore, reflects on any propagation of errors which may occur due to measured chemical composition. Excess SO_4^{-2} values were determined from measured concentrations of SO_4^{-2} and either Na^+ or Cl^-. The sum of anions includes the contribution of all measured anions and includes F^-, Cl^-, NO_3^-, and SO_4^{-2}. The amount of free acid was determined from measuring the amount of precipitation and the measured sample acidity based on pH. The magnitude of sampling variability expressed in terms of its influence on these three parameters is no greater than that observed for individual parameters. Spatial variability for excess SO_4^{-2} and sum of the anions is no greater than the variability associated with the parameters used to calculate each. The spatial variability for amount of free acid deposited is considerably greater than that determined for either amount of precipitation or acidity. This result is expected because of the large observed variations in both parameters from which amount of free acid is determined.

The chemical analysis and sampling programs utilized have proved reliable, relatively efficient for handling a moderate number of samples, and do not contribute significantly to variability of precipitation composition. The results of the analytical variability and sampling variability studies, combined with other studies designed to evaluate quality of data and results, indicate that data used for interpretation of precipitation can be used with confidence.

Sample Contamination. The presence of foreign matter in the form of particulate washout from the atmosphere, wind-blown dust, soil, vegetation, and insect or bird droppings will alter the composition of individual precipitation samples. Samples which were seriously contaminated were discarded. Those which contained small amounts of debris were analyzed. On several occasions, only a few samples collected from a single event were contaminated to some degree. Comparisons were made between individual chemical species concentrations in clean and dirty samples. In most cases where contamination was not severe, differences in concentrations between samples were small. Monthly volume weighted average concentrations for clean and dirty samples and clean only samples are presented in Tables 4 and 5, respectively. During most months, 50-70 percent of all samples collected were clean. However, during December 1978, and January 1979, only 5-10 percent of the samples were clean; during February and March 1979, no totally clean samples were collected. Figure 8 compares monthly volume weighted pH based on clean and dirty samples with clean only samples. During the first three months of this study, clean samples were somewhat more acidic. Clean samples were somewhat less acidic during the middle months of the study. Because so few clean samples were collected from December 1978, to March 1979, comparisons are not justified. When individual comparisons are made for specific chemical species using results presented in Tables 4 and 5, small amounts of foreign matter do not appreciably influence the reported monthly average concentrations in most cases.

Based on these observations, subsequent discussions focus on results obtained from clean and dirty samples because they provide a larger and, hopefully, more representative data base.

The compositional stability of precipitation depends on several factors. As previously described, the presence of foreign matter can contribute to composition in several ways. Changes do occur which influence the concentration of several chemical species present in precipitation. Most notably, pH, NH_4^+, and NO_3^- values seem susceptible to change with time as shown in Figure 7. Sample treatment and storage conditions can stabilize some of these changes to a certain extent. Refrigeration or freezing of samples is effective for all but pH.

Vegetation and insect contamination has been observed to increase concentrations of K^+ and NH_4^+. It is likely that results presented and discussed here represent a small underestimate of sample acidity because of time dependent decreases in sample acidity which may be due to the presence of foreign matter or to other processes which neutralize a portion of the acidity.

Site Selection. The selection of individual sites can be important because localized sources of pollutants may influence composition of precipitation samples. Although this factor may contribute to some

extent to the observed spatial variability, it appears not to be a serious problem except at a few sites. The presence of sea salt in precipitation is influenced in large measure by proximity to the ocean and to meteorology. These cause "natural" variations and should not be considered a serious problem when site selection is determined. At least two sites utilized in this study have been found to yield results for certain species concentrations which can be considered somewhat different. Site 03, located at Ti-Co Airport, showed significantly elevated excess SO_4^{-2} concentrations and significantly lower pH values than other sites when the low altitude winds blow from the southeast during precipitation. Under these conditions, the stack plumes from the FPL and OU power plants will cover this site. Washout of acidic material from the power plant plume may contribute to the increased acidity. At site 06, located near Port Canaveral, elevated Ca^{+2} and Mg^{+2} concentrations in samples were sometimes observed along with higher pH values. These variations may indicate the influence of nearby cement plants. Other sites including those located near heavily traveled roads do not show extreme variations in the concentration of the major ionic species. The overall site selection plan has been judged to be acceptable to allow precipitation of representative composition to be collected.

Presentation of Results. Extreme variations in sample composition from event-to-event and site-to-site make it difficult to assess long-term behavior or changes which may occur. Therefore, one month has been selected as the minimum data resolution period for use in documenting precipitation composition. Samples collected from individual events are analyzed and these individual results are used to calculate monthly weighted average concentrations. This approach has been used to obtain results presented in Tables 4-12. Selected portions of these results are plotted for easy comparison in Figures 8-10, 18, and 19. The extreme variations that are observed in event sample compositions are smoothed by this approach. However, it is possible to evaluate average seasonal variations in results. Compositional variability between months and seasons and for individual events and sites is discussed in more detail in later sections.

Meteorology. Local and regional meteorology has been observed to influence the composition of precipitation. The influence of proximity to the ocean is very apparent when concentrations of Na^{+}, Mg^{+2}, and Cl^{-} in precipitation are evaluated. Onshore or offshore breezes can dramatically influence the concentration measured for these three species. The anomolous behavior observed for pH and SO_4^{-2} concentrations in some samples collected at site 03 can be explained because of the location of site 03 with respect to the power plants and low altitude wind directions. The effect that regional and/or long- range atmospheric transport of pollutants produces cannot easily be analyzed. It is believed that most contributions to the deteriorating quality of precipitation arise from atmospheric transport of pollutants followed by rainout or washout

during the precipitation event. This conclusion is partially supported by results obtained from samples collected at the UCF site and from results obtained from samples collected in Gainesville, Florida during the same time period (Brezonik and Edgerton, 1979). Rainfall is definitely acidic at KSC, Orlando, and Gainesville.

Chemical Composition of Precipitation

General Composition. The composition of rainfall collected at KSC and on the UCF campus near Orlando, Florida has been presented in Tables 4-12. Tables 6-12 present the results for individual KSC sites and the UCF site. The major differences observed in composition of rainfall at the various sites occurs for Na^+, Mg^{+2}, and Cl^-. Sea salts are the principal source of these species and site distance from the ocean is very important when sea salt input into rainfall composition is considered. Appendix Tables 22-203 include more detailed statistical summaries of rainfall composition by month combining results from all KSC sites, and treating selected KSC sites and the UCF site individually.

The composition of rainfall determined in this study is similar to that determined for precipitation which occurs in other parts of the U.S. The major differences occur in the acid composition. Likens (1976) has reported the composition of precipitation which occurred during 1963-74 at the Hubbard Brook Experimental Forest, N.H. Liljestrand and Morgan (1978) reported the composition of precipitation based on 15 events which occurred during 1976-77 at Pasadena, Calif. The present acidity of rainfall at KSC is about one-third that reported at Hubbard Brook and Pasadena. Acidity at Pasadena is due to H_2SO_4 and HNO_3^- in a 1:2 ratio. At KSC and in the northeastern U.S., acidity is due to H_2SO_4 and HNO_3^- in a 2:1 ratio. The concentrations of K^+, Ca^{+2}, and NH_4^+ are comparable in all areas. Concentrations of Na^+, Mg^{+2}, and Cl^- are two to ten times greater at KSC than at Hubbard Brook or Pasadena. This is due to proximity of KSC sites to the ocean.

Acidity. The arithmetic means of monthly volume weighted acidity of precipitation samples collected at KSC and UCF during the 21 months yield mean pH values of 4.56 and 4.50, respectively. These values agree closely with pH values of 4.55 reported at Tallahassee, Florida, for 1974-76 and 4.53 at Gainesville, Florida, for 1976 (see Likens, 1976). The weighted mean pH for rainfall collected on an event basis in Gainesville, Florida, during late 1977 and the first 8 months of 1978 was 4.64 while rainfall collected on a weekly basis in west Orlando during the same time period was 4.62 (Brezonik and Edgerton, 1979). Wisnewski and Cotton reported the collection of rain in the Miami, Florida area during the summer of 1973 and measured pH values near 5.9. Using limited data from the southeastern U.S., Likens (1976) concluded that rainfall pH in central Florida was greater than 5.6 in 1966 and greater than 5.0 in 1972-73.these estimates are correct, then the acidity of rainfall in central Florida has increased at least three-fold in the past six years.

The monthly weighted average pH of rain collected at UCF Site 18 compared in Figure 9 with pH determined as a weighted average for all operational KSC sites. The variations from month to month are more severe at UCF Site 18. This may occur because far fewer samples contributed to the reported value. It is apparent that the acidity of rainfall in east central Florida undergoes variations which may be related to seasons of the year. Summertime acidity is as much as 10 times greater than that measured during early winter. For example, July 1978, compared to November 1977, yielded pH values of approximately 4.3 and 5.2 respectively.

Variations in monthly weighted average pH at KSC sites located relatively close together were most severe during spring and fall, 1978. These variations are compared in Figure 10 for Sites 01, 12, and 14. These three sites are located on a line which runs west-northwest from near the ocean (Figure 1). The distance separating Sites 01 and 14 is approximately 10 km. Site 12 is located approximately midway between Sites 01 and 14.

Although the use of monthly or quarterly weighted average pH is convenient when large amounts of data are to be compared for purposes of evaluating the changing composition of precipitation by season, it appears that they should be used with caution. Monthly and quarterly weighted average pH values are compared in Figure 11. The behavior exhibited stresses the smoothing effect that weighted averages have on results that are quite variable. It appears that the only strong seasonal (quarterly) patterns associated with precipitation acidity during the time period covered by this study occurs in the last quarters of 1977 and 1978 where pH was relatively high followed by decreases in subsequent quarters. The monthly weighted average pH for the individual months of October, November, and December which comprise the last quarter show greater variations than any other consecutive three-month period with the possible exception of the September-November 1977, time period. When monthly weighted average pH is considered, there is a pronounced decrease in pH which continues from November 1977, through September 1978. This may be indicative of a yearly cycle. More data are necessary before this tendency can be verified.

The variability in pH for individual samples collected in September 1978, at KSC Site 01 is also presented in Figure 11. These demonstrate the variability associated with acidity of samples which are used to calculate monthly or quarterly weighted averages. Individual pH values obtained from samples collected at individual sites and tabulated by month are presented in Appendix Tables 1-21. These results can be used to evaluate variability as in Figure 11.

The variability that was observed in individual sample pH is summarized in Figure 12. The frequency of occurrence for pH values within a specified range and expressed as a percentage are presented for individual three-month periods. The pH ranges were selected to represent approximately equal ranges of acidity for pH values

greater than 4.0. These results are based on the sites specified because these five sites were operational during most of the 21-month period. Samples with pH greater than 4.7 (acidity of less than 20 microequivalents/l) occur with highest frequency in all time periods and the frequency of occurrence then decreases as pH decreases. Typically, there are 20-50 percent of the samples that have pH less than 4.4.

Characterization of Acidity. In attempts to characterize the acidity of rainfall samples, several measurements that would add insight into acid composition were made on each sample. Measurement of sample pH was used as an indicator of sample free acidity. If volatile acids which contribute to sample acidity are present, it is sometimes possible to effect their removal by bubbling an inert gas such as nitrogen through the sample prior to measuring pH. Carbonic acid is a volatile weak acid which behaves in this manner. When the initial sample acidity is high, any contribution from H_2CO_3 should be minimal because it is a weak acid; it should not undergo significant ionization, therefore. If sample acidity is low, e.g. pH greater than 5.0, then H_2CO_3 may have a more important contribution. Reuss (1975) has discussed the effect that varying CO_2 partial pressures have on pH. When pH is measured after removing CO_2 from the sample, the pH change compared to initial pH measurement will depend on the initial sample pH and the CO_2 partial pressure associated with the original sample. Initial sample pH was always measured with the sample at approximately 25°C. No attempt was made to control CO_2 partial pressure. Sample pH (PHNV) measured after purging with nitrogen gas was made under an inert nitrogen atmosphere and hopefully under conditions where CO_2 removal from the sample was significant. The difference between the two measured pH values was small, typically less than 0.05 units when sample acidity was relatively high; the difference increased significantly in several cases when initial sample pH was greater than 5.0. It is felt that the removal of CO_2 is largely responsible for the differences observed.

Further characterization of sample acidity was carried out on many samples which had initial pH values below 4.7. These samples were titrated as described previously to characterize both the strong acid component and total titratable acidity which include strong acids and weak acids which titrate under the conditions utilized. A typical though somewhat more detailed than usual titration curve obtained for a sample collected in February 1978, is shown in Figure 4. The initial sample pH was 4.38, while the pH after bubbling nitrogen through the sample was 4.44. Typical acid-base titration behavior is observed. It would be extremely difficult, however, to determine an equivalence point from the titration curve because of the gradual "break" which corresponds to the equivalence point. This is characteristic of titrations which involve dilute reagents. Titration data of this type have been treated by Gran theory (Gran, 1952, Rossotti and Rossotti, 1965). The Gran functions that were generated from the titration data are also shown in Figure 4. Comparison of sample acidity based on measurement of pH, pHNV, strong acidity, and total titratable acidity yield values

of 41.6, 36.3, 38.4, and 57.0 microequivalents/liter respectively. The agreement between the first three values indicates that the acidity of this sample which determines initial pH is due primarily to strong acids, and the contribution of volatile acids is quite small. The result for titratable acidity is considerably higher than the other values. This indicates that undissociated acids are present in the sample at a concentration of about one-half that of strong or dissociated acids.

Relationships that have been observed between acidity as determined from measured pH, PHNV, and the Gran functions are displayed in Figures 13, 14, and 15. Although only data for samples collected from July to September 1978 have been included, the results are typical of what was observed during the entire 21 months of the study. The slopes of the least squares correlation lines shown in Figures 13 and 14 are approximately 1.00 and the correlation coefficients approach 1.00 as well. Slopes of 1.00 are expected if the acidity is of common origin. Because data points are approximately equally scattered and the slope is near 1.00, it is believed that experimental error in measuring pH probably accounts for most deviations. An error of 0.01 units in the measurement of pH results in an error of 1.7 percent in acidity determinations. Several sources that may have contributed to an error of this magnitude have been described (Galloway and Likens, 1979). Much greater variability is observed when data obtained as a measure of initial sample acidity are compared to titratable acidity. Results presented in figure 15, which compare measured free acid concentration and titratable acidity, show this greater variability. Variations from a one-to-one correlation are apparent and generally range between 10 and 50 percent. These variations indicate the presence of weak acids in addition to strong acids in the precipitation samples. Several anions which are conjugate bases of weak acids were determined in some of the precipitation samples collected. These include fluoride, orthophosphate, formate, and nitrite. No attempt was made to quantify all these anions in the precipitation samples nor to determine whether they constituted the full complement of weak acids in the samples. Ammonium ion titrates as a weak acid in titrations carried to a pH above 9.0. Rain sample titratable acidity consisted of approximately 65 percent strong acid free acidity and 35 percent weak acids. The latter did not contribute to the initial pH value. Ammonium ion concentrations were not large enough to account for the weak acid component as reported by Liljestrand and Morgan (1978).

Good agreement has been observed between acidity values determined from pH, pHNV, and strong acid determinations for individual precipitation samples. These results indicate that strong acids such as H_2SO_4, HNO_3^-, and/or HCl are responsible for the acidic properties which influence the pH of these samples. It is possible to assess the importance of each strong acid if detailed measurements are performed to determine concentrations for NO_3^-, excess SO_4^{-2}, and excess Cl^-. Excess Cl^- levels are of little consequence (to be discussed later). Concentrations of free acidity, NO_3^-, and excess SO_4^{-2} are compared in figures 16 and 17 for samples collected at KSC Site 01 and UCF Site 18 in July 1978. The behavior is similar to

that observed in Figures 18 and 19 when monthly volume weighted averages are utilized. Data for individual samples are considerably more variable than monthly volume weighted averages. Changes in free acidity from sample to sample are followed closely by changes in NO_3^- and excess SO_4^{-2} concentrations.

When the dependence of free acidity on either NO_3^- or excess SO_4^{-2} concentrations is evaluated (Figures 20 and 21 respectively), some scatter is shown. In data collected from July to September 1978, free acidity is more closely related to excess SO_4^{-2} concentrations than to nitrate, the least square line in each case has a high correlation coefficient significant at $\alpha<0.001$ in each case. These correlations are summarized by month for individual KSC sites and the UCF site in Appendix Tables 204-381. Correlations between free acidity and nitrate and excess SO_4^{-2} are summarized by month in Table 13. The free acidity:NO_3^- and free acidity:excess SO_4^{-2} ratios are typically 2:1 and 5:4, respectively. There is sufficient NO_3^- and excess SO_4^{-2} present to account for the entire sample free acidity. The presence of neutralizing cations is obviously important. Their presence indicates that portions of the $NO^-_3$and excess SO_4^{-2} were initially present as neutral salts of the neutralizing cations or were formed by partial neutralization of sample acidity. These results lead to the conclusion that present free acidity can be accounted for by the presence of HNO_3^- and H_2SO_4 in the samples.

The observed acidity of precipitation is quite variable. This is particulary true when comparisons are made between individual events.

The presentation of results as monthly volume weighted averages tends to smooth the extreme variations to a considerable extent. However, significant differences have still been observed between individual months and particularly between seasons. If the presence of NO_3^-, excess SO_4^{-2}, and/or Cl^- are verified at concentrations which exceed those expected from introduction of sea salts and if the neutralizing cation concentrations are too low to account for the concentrations of excess SO_4^{-2}, NO_3^-, and Cl^- and the sample is acidic, it is highly probable that sample acidity is due to the presence of at least one of the three strong acids. Neutralizing cations include Na^+, K^+, Ca^{+2}, Mg^{+2}, and NH^+_4 which are present in the sample and have origins other than sea salt. They can be considered indicators of basic compounds e.g. CaO, NH_3, which have neutralized some of the initial sample acidity. The Cl^- concentrations in precipitation samples are due to the presence of sea salt. There is considerable excess SO_4^{-2} and NO_3^- in samples. If monthly weighted average free acidity variations are compared to the changing concentrations of excess SO_4^{-2} and NO_3^- as shown in Figures 18 and 19, it appears that the monthly changes in free acidity are followed by similar changes in both excess SO_4^{-2} and NO_3^- concentrations. The behavior is similar when only samples from a single site (Figure 18) or when samples from all KSC sites (Figure 19) are compared. For the time period studied, NO_3^- concentrations were typically less than one-half the free acidity concentrations, excess SO_4^{-2} concentrations tended to vary between 70 and 120 percent of the free acidity except

during April 1978, and to a lesser extent, May 1978. During these two months, the neutralizing cation concentrations and, in particular, NH^+_4 concentrations, were quite large and can account for the deviant behavior observed.

The results presented in Figure 18 for KSC Site 01 are displayed in somewhat different fashion in Figures 22 and 23. Figure 22 shows the dependence of free acidity on the concentration of NO^-_3 and, assumably, HNO^-_3. When data for April and May 1978 are excluded, the least square line has a slope of 1.96. This indicates that free acidity is only partially accounted for by NO^-_3. The correlation coefficient of 0.735 is significant at $\alpha<0.01$. Figure 23 shows the dependence of free acidity on excess SO^{-2}_4 concentration and, assumably, H_2SO_4. The least square line data fit has a slope of 0.886. This indicates that all free acidity can be accounted for by excess SO^{-2}_4 were it all present as H_2SO_4. The correlation coefficient of 0.832 is significant at $\alpha<0.001$. The total amounts of NO^-_3 and excess SO^{-2}_4 are more than adequate to account for all free acidity observed.

The combined influence of concentrations of NO^-_3, excess SO^{-2}_4, and NH_4 on free acidity (where NH_4 is considered to be a neutralizing cation) is shown for KSC Site 01 and all KSC sites in figures 24 and 25, respectively. The correlation coefficients are significant at $\alpha<0.001$ in both cases. The slopes of the least square lines are greater than 0.8 in each case and indicate that free acidity would generally be overestimated from monthly volume weighted average NO^-_3 + excess SO^{-2}_4 - NH^+_4 by about 20 percent.

The lack of any significant excess Cl^- in KSC rainfall samples and the presence of ample NO^-_3 and excess SO^{-2}_4 can be interpreted to mean that present free acidity is due exclusively to the strong acids HNO^-_3 and H_2SO_4. The relative concentrations of NO^-_3 and excess SO^{-2}_4 indicate that these two acids are present in an approximate 1:2 ratio.

Deposition of Acid. In addition to showing strong dependence on measured NO^-_3, excess SO^{-2}_4 and NH^+_4 concentrations, free acidity is also influenced by the amount of precipitation that occurs. By either rainout or washout, it would be expected that the initial rain will contain higher concentrations of pollutants. As the precipitation event continues, the pollutant content will decrease because rainout and washout will make the atmosphere cleaner. Therefore, it is expected that the initial portion of a rain sample or the entire volume will contain higher concentrations of pollutants when only small amounts of rain are received. Figure 26 shows the comparison of the free acidity behavior of rain samples with the total monthly amounts of rain received at KSC Site 01. Monthly weighted acidity is generally inversely related to total amount of rain during most months. Exceptions are the summer months in 1978 where high acidity and large amounts of rain occurred.

When assessing the long-term environmental impact of acid rain on soils and other terrestrial ecosystem parameters, the amount of acid deposited is probably more important than acidity associated with individual precipitation events. The total amount of free acid deposited for each month at six KSC sites and UCF Site 18 are presented in tables 6-12. Total free acid deposited related closely to the amounts of rain received. The only exceptions to this behavior occurred in November 1977, when all KSC sites received large amounts of high pH precipitation. Similarly, UCF Site 18 did not show the parallel increase in free acid deposited with the very large amount of rain received in July 1978. The behavior observed between total amount of free acid deposited and the amount of rain is significant because it appears that central Florida ecosystem loading with acid is related directly to the amount of rain received.

Although a small amount of rainfall generally results in a higher concentration of pollutants, the amount of each pollutant deposited is also a function of the amount of rain received. Results that support this observation can be seen in Figure 27 which compares the amount of free acid deposited per month to the amount of rain received. Individual sample behavior in Figure 28 also supports this observation. The deposits of free acid by month at KSC Site 01 and UCF Site 18 are compared in Figure 29.

Reported deposits are probably underestimated because contributions from very contaminated samples were not included. The total acidity deposited due to both strong and weak acids may be as much as 50 percent greater than amounts reported for free acidity.

Chloride, Sea Salt, and Assessment of Acid Rain. The presence of many ionic species in rain is not directly related to acidity. Specific examples include those ions commonly found in sea salt, including Na^+, K^+, Ca^{+2}, Mg^{+2}, Cl^-, and SO^{-2}_4. Major terrestrial and anthropogenic sources of K^+, Ca^{+2}, Mg^{+2}, SO^{-2}_4, and to a lesser degree Cl^-, have been documented. When the acidity of precipitation is evaluated, concentrations of the anions SO^{-2}_4, Cl^-, and NO^-_3 become important. For most studies, sea salts in precipitation are of little significance. When the assessment and evaluation of Cl^- levels are important, however, Cl^- which originates in the oceans must be carefully determined before the presence of excess Cl^- can be ascertained. The generation of HCl as an exhaust product from utilization of SRM boosters on Space Shuttle launch vehicles will provide a source of acid and Cl^-. To determine increased concentrations of Cl^- in precipitation which are not due to sea salts (a greatly variable entity in precipitation) several assumptions and careful measurements must be made. Determination of total sea salt concentrations in rainfall were made by assuming that the contribution of sea salt can be based on the limiting concentration of Cl^- or Na+ compared to the measured Cl/Na ratio in sea water. This implies that sea water is the only source of the limiting species, either Cl^- or Na^+. The sea salt contribution to total ionic composition of precipitation then can be assessed. Monthly variations for sea salt concentrations in rain at four KSC sites are shown in

Figure 30. Tabulated summaries are presented in Tables 4-12. The behavior shows considerable variability which can be accounted for when proximity to the ocean is considered. Diverse meteorology accounts for month to month variations at individual sites. Any episodic introduction of HCl into rainfall probably will not increase Cl^- levels enough to allow precise determination of excess Cl^- to be made when monthly averages are considered. However, as will be discussed later, it is possible to determine the presence of excess Cl^- on a sample by sample basis, if the assumption is made that the only Na^+ in the precipitation sample is of sea salt origin.

The direct impact that SRM launches will have on the acidity of rain will be due to the presence of HCl in the exhaust. Should acid rain occur, increased concentrations of acid and Cl^- will be present. Present Cl^- concentrations in individual samples, if they originated exclusively from HCl with no other acids present, would yield acidities of 1-1000 and 5-4000 microequivalents/liter at UCF Site 18 and at KSC, respectively. These describe pH ranges of 6.0-3.0 and 5.3-2.4 respectively. Because of the tremendous variability associated with Cl^- concentrations due solely to sea salt, sample-by-sample determination of Cl^- due to sea salt must be possible before the acidity of rain in the form of HCl, HNO_3^-, or H_2SO_4 can be accounted for. It appears that sea salts provide nearly 100 percent of the Na^+, Mg^{+2}, and Cl^- present in rain. This conclusion is supported by ratios and correlation behavior of Cl/Na, Mg/Na, and Cl/Mg presented in Table 13 and figures 31, 32, 33. In addition, Appendix Tables 22-203 and 204-381 include both monthly ratios and linear correlations based on individual samples.

If increased acidity is observed in rain collected after a SRM firing, it should be possible to determine the Cl^- concentration due to sea salts. Excess Cl^- can then be attributed to HCl from the SRM exhaust if concentrations of NO_3^- and excess SO_4^{-2} are not elevated enough to account for the increase in acidity.

Although correlation coefficients (Table 13) which relate the dependence of Na^+, Mg^{+2}, and Cl^- are very high, it is important to consider the ratio of concentrations for individual species. The sea water ratios (eq/eq) of Cl/Na, Mg/Na, and Cl/Mg are 1.165, 0.243, and 5.11, respectively. Actual ratios can be calculated from results presented in tables 4-12 and also are included for a limited set of data in figures 31, 32, and 33. Ratios for Cl/Na and Cl/Mg determined from monthly weighted average concentrations of Na^+, Mg^{+2}, and Cl^- are generally somewhat lower than those reported for sea water. The majority of values for the Cl/Na ratio are 1.0-1.1, for the Cl/Mg ratio, they are 4.0-4.7. Each indicates the presence of small amounts of Na^+ and Mg^{+2} in rain, which may be due to a source other than sea salt. when excess Cl^- is present, the presence of Cl^- due to sea salt can only be determined by assuming that the presence of Na^+ and/or Mg^{+2} is due exclusively to sea salt as follows:

$$\text{Excess } Cl^- = \text{total } [Cl^-] - 1.165\ [Na^+] \text{ or}$$

$$\text{Excess } Cl^- = \text{total } [Cl^-] - 5.11\ [Mg^{+2}]$$

The error introduced into the determination of excess Cl^- may be significant when the excess Cl^- concentration is expected to be small. The calculation based on measured Na^+ concentration may yield a value for sea salt Cl^- which is 10-20 percent higher while the calculation based on Mg^{+2} concentration may yield a value for sea salt Cl^- which is 25 percent higher. These errors are probably only significant when the total Cl^- concentration and the Cl^- concentration due to sea salt are similar.

Typical precipitation concentrations for Na^+, Mg^{+2}, and Cl^- are 50, 12, and 55 microequivalents/liter (Table 4). Values of 58.2 and 61.3 are obtained when the values for Na^+ and Mg^{+2} are used to calculate the Cl^- concentration due to sea salt. If a precipitation event of pH 3.0 due to HCl (1000 microequivalents Cl^-/liter) occurs and also contains sea salt as just described, the excess Cl^- based on measured Na^+ and Mg^{+2} is 997 and 994 microequivalents/liter, respectively. Error of less than -1 percent occurs in the determinations. Even when the concentration for sea salts is ten times greater than in the previous example, the error introduced into determination of excess Cl^- will be -2.2 percent based on Na^+ and -6.3 percent based on Mg^{+2}. These examples show the utility of using measured Na^+ or Mg^{+2} concentrations in individual samples for determining the presence of excess Cl^-. Should increased acidity occur due to the presence of HCl, the acidity can be accounted for based on excess Cl^- (if present), NO_3^-, and excess SO_4^{-2}. There is no evidence to show that existing Cl^- concentrations in rain exceed those due to sea salt effects. There may be minor sources for Na^+ and Mg^{+2} in precipitation in addition to sea salts.

Increases in HCl concentrations in individual rainfall samples can be determined with very little error. Increases in HCl concentrations which may occur during extended time periods (weeks to months to years) will be much more difficult to determine. Should increases cause the lowering from existing levels of precipitation pH by several tenths of a unit, then these increases should be measurable if accompanied by HCl concentrations which increase total Cl^- concentrations by at least 10-20 percent above levels due to sea salt.

Summary and Conclusions

The following conclusions can be drawn from nearly two years of activity in the collection and chemical analysis of rainfall:

1. A network for the collection of precipitation samples has been established and demonstrated to be effective and satisfactory.

2. The acidity of precipitation in east central Florida is moderately high; individual rain events can be very acidic. Acidity cannot be associated with operations at KSC.

3. Extensive day-to-day and site-to-site variation in precipitation occurs. Analytical and sampling variability do not contribute significantly to the observed spatial variability in rain composition.

4. Sulfuric and nitric acids account for the observed acidity of precipitation at the present time.

5. Sea salt represents a significant portion of the total ionic composition of precipitation at KSC. Because sea salt contains high concentrations of chloride, the sea salt contribution to precipitation composition must be determined and used to evaluate increased acidity if the presence of hydrochloric acid becomes an issue.

6. Use of monthly volume weighted averages for analysis of general trends associated with changes in precipitation composition can be beneficial. However, to evaluate local perturbations which may influence precipitation composition, event sampling is necessary.

7. Contamination of rain samples occurs; however, it was not a severe problem because the usual sampling period was 24 hours. Sample pickup at less frequent intervals will greatly increase the likelihood of many samples becoming too contaminated for meaningful chemical analysis.

8. The chemistry of rain falling in the vicinity of KSC has been characterized sufficiently to allow detection of changes in the future.

SOIL CHEMISTRY

Introduction

This study was designed to evaluate certain chemical parameters associated with representative soils collected at selected sites on Merritt Island and the Kennedy Space Center. The results of this study will be useful when attempts are made to evaluate effects of SRM exhaust on the terrestrial ecosystem. The 10 sites utilized were designated as reference stands in the terrestrial community analysis program (Stout, 1979). Soil samples were analyzed on a routine basis to establish the concentration of certain elements which are essential for plant growth. Samples were assayed for pH, Ca^{+2}, Mg^{+2}, Na^{+}, K^{+}, NH_4^{+}, Al^{+3}, NO_3^{-}, Cl^{-}, SO_4^{-2}, P, ion exchange capacity, total nitrogen, and organic matter.

Leaching studies were performed on the same representative soil samples. Dilute solutions of HCl were used to leach cations from the soils. Total concentrations of leachable cations and concentrations leached were determined. The extent of acid leaching on the various soils which support the various plant communities was evaluated from the data obtained.

Reseach directed toward evaluation of pollution on soils and resulting changes in fertility and ability to support and sustain plant life is a relatively recent activity. The changing acidity of precipitation has been evaluated in Europe since the 1950's. Oden (1976) has summarized the results of selected studies and presented evidence to show that movements of air masses across the entire European continent complicate evaluation of the origin of the acidity. Oden also summarized the acid impact on surface waters. In general, pH of freshwaters is characterized by random, seasonal, and yearly variations and time trends. Parallel studies of the acid impact on soils included consideration of ground and surface water runoff and ultimate mixing in lakes. Increased soil acidity will lead to exchange of absorbed cations which will leach from the soil, and base saturation will decrease. Decreases in cation nutrients can lead in the long-term to changes in the plant community supported on the soil.

Norton (1978) has evaluated changes in chemical processes in soils caused by acid precipitation. These include pH insensitive reactions, pH sensitive reactions, E_h sensitive reactions, and the relative mobility of elements. Increased mobility of Al^{+3} and consequential destruction of clay materials may decrease ion exchange capacity. In other situations, ion exchange capacity may increase. The general rate of removal of all cations including trace metals will increase, and this nutrient flux will result in increased nutrient concentrations in aquatic ecosystems below the soil zone.

Frick and Voight (1976) described the nature of acidity and potential effects of acid precipitation on soils in the humid temperate zone. As chemical weathering of soils become more complete and Na^{+}, K^{+}, Ca^{+2}, and Mg^{+2} are removed, hydrogen and aluminum ions begin to dominate.

Soil acidity then is controlled by hydrolysis of Al^{+3} and soil pH can be represented by

$$pH = 5.0 + pAlOH - pAl$$

and soils become buffered near pH 5. The relationship between soil pH and ion exchange capacity also was considered but interpretation is complex. They also described the role that the nitrogen cycle and sulfides have in production of acids in the soil. Oden (1976) showed a time sequence which illustrates soil acidification due to biological action, man-made acidity, and excess mineral acids. Mineral acids which contributed less than 20 percent to total acidification in the early 1950's, contributed about 50 percent in the early 1970's.

McFee, Kelly, and Beck (1977) described the effects of acid precipitation on soil pH and base saturation of exchange sites. Noting the resistance of most soil systems to pH change, they conclude that acid precipitation should not cause rapid soil degradation. They point out that it is difficult to evaluate these phenomena in the short-term. They present an example for 100 years of pH 4.0 acid precipitation (100 cm/year) and conclude that percent base saturation within the top 20 cm of a typical midwestern soil with 20 meq/100g ion exchange capacity will decrease by 20 percent. A pH decrease of 0.6 units would occur if no acid neutralizing materials were introduced by other deposition processes.

Overrein (1972) reported the effect of acid precipitation on Ca^{+2} levels in a Norwegian forest soil and considered the nutritional status of forest soils based on lysimeter studies. The leaching to Ca^{+2} from different soil types increased rapidly when the acidity of precipitation increased. Soil acidity was dependent on the amount and concentration of acid added, the nutrient element considered, and soil ion exchange capacity. In general, the leaching of Ca^{+2} was significantly greater at pH 3.0, compared to leaching at pH 4.3 which showed effects similar to those of distilled water. Below pH 3.0, greatly accelerated leaching occurred. All leaching of Ca^{+2} was characterized by a time delay of several days following acid treatment of soil.

The U.S. Environmental Protection Agency has supported studies to evaluate acid effects on soils. Reuss (1978) performed a simulation study to evaluate nutrient loss from non-calcareous soils due to acid rainfall. A model which predicts the most likely effect of acid precipitation on the leaching of cations was developed.

NASA has supported studies to characterize soil from a Cape Canaveral launch complex, post-launch pad debris particulates, and interaction of soil with aqueous HCl. Pellett, et al. (1979) will report results based on Titan III launches from Launch Complex 40 at KSC on March 11-12, 1975, and August 20, 1977. Soil composition near complex 40 contains considerable Ca^{+2} and Mg^{+2}, occuring as carbonates from sea shells. Considerable acid neutralization should be provided in this soil. Soil slurries, which were titrated with HCl, were shown to consume considerable acid on a time-delay basis.

Sampling and Sample Preparation

Collection of soil samples was accomplished during mid-July, early September, and early December of 1976 and during mid-March of 1977. Samples were collected from sites identified as reference stands in the Terrestrial Plant Community Analysis Program (Stout, 1979). Each sample consisted of between 30 and 40 cores, 15 cm deep by 2 cm in diameter, obtained with LaMotte, Hankinson-Hester type soil sampling tubes (Welcher, 1962). Samples were collected in random fashion along transects within each sampling area. The layer of ground litter was scraped away before each soil core was taken. The March sampling consisted of four independently collected subsamples, of 20-30 cores, from each site. Each subsample was processed as a separate entity. Samples were collected in zip-lok polyethylene bags for transport to the laboratory.

The soil samples were air-dried in the laboratory by spreading them on aluminum trays. Large clods of air-dried soils were broken up before samples were sieved through a 2.0 mm nylon sieve. Subsamples for all subsequent determinations were obtained by the technique of coning and quartering. Chemical analyses were performed. They are summarized in Figure 34, and are described below.

Double Acid Extraction Procedure and Analysis

Determination of Na^+, K^+, Ca^{+2}, Mg^{+2}, Al^{+3}, and P in the soil samples was accomplished by using a double acid (0.05N HCl in 0.025N H_2SO_4) extraction reagent, followed by appropriate chemical methods (Soil Testing Lab, 1974). The K^+ and Na^+ were determined by flame emission spectroscopy, Ca^{+2}, Mg^{+2}, and Al^{+3} by flame atomic absorption spectroscopy, and phosphorus by the Vanado-molybdophosphoric acid colorimetric procedure. These determinations were performed by the Soil Testing Laboratory, University of Florida, Gainesville, under the direction of Dr. H. L. Breland. Air dried and sieved samples were submitted for analysis.

Organic Matter

Organic matter content of samples was determined by a gravimetric weight loss procedure. Five gram samples were placed in porcelain crucibles and ignited to constant weight at 900°C by heating initially for two hours, followed by subsequent heating for 30 minutes. Organic matter was determined from the following equation:

$$\text{Organic Matter, \%} = \frac{\text{g loss on ignition}}{\text{g sample}} \times 100$$

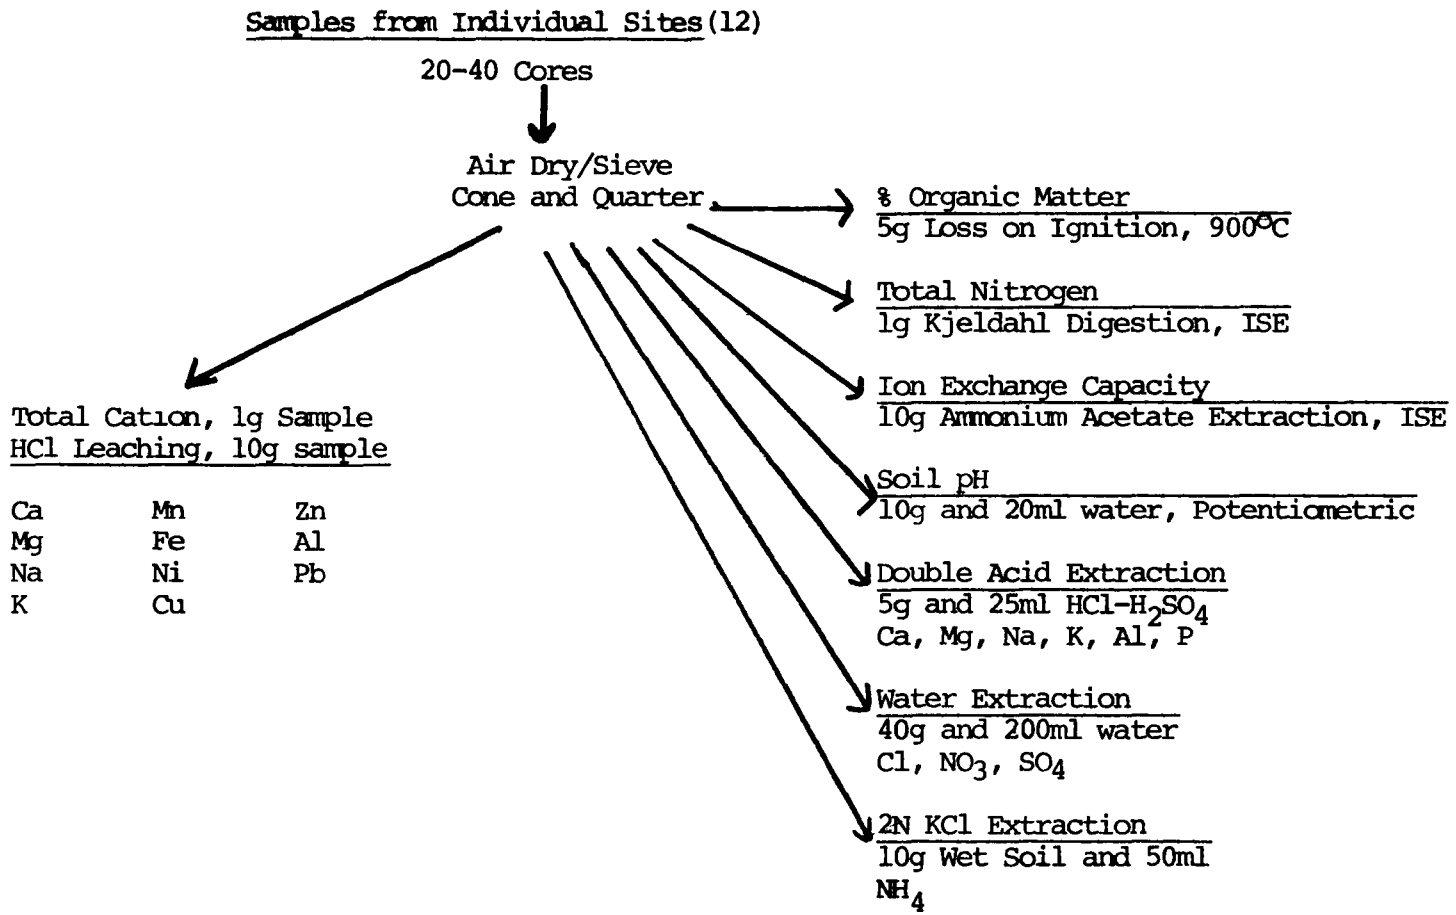

Figure 34. Flow Diagram Showing the Sampling and Analysis Sequence Utilized in the Soil Studies.

Soil pH, Chloride, Nitrate, Sulfate and Ammonia Determinations

Soil pH was determined by the soil Testing Laboratory, University of Florida. The pH was measured potentiometrically in a slurry prepared to contain a 1:2 ratio of soil:water.

The Cl^-, NO_3^-, SO_4^{-2}, and NH_4^+ concentrations were determined after extraction of the soils with deionized water. Forty grams of air-dried soil was extracted by shaking the soil with 200 ml of deionized water in a 250 ml widemouth polyethylene bottle. Soil and extracting solution was thoroughly mixed, allowed to stand overnight then mixed again before gravity filtering through Whatman #42 filterpaper. Separate portions of the extract were analyzed for each species.

Chloride was determined potentiometrically with a chloride ion-selective electrode prepared as described by Olson et al. (1974) and Czaban and Rechnitz (1973). An Orion double junction reference electrode, model 90-02 was used. The method of standard additions (Eynon, 1970; Beckman, EC-7633; Beckman, EC-8148) was used to overcome possible matrix interference problems. A Beckman Expandomatic pH meter operated in the expanded scale millivolt mode was used. This procedure was used for samples collected during July, September, and December, 1976. The determination of chloride in samples collected in March, 1977 was accomplished through use of the $Hg(SCN)_2$ - FE(III) method (Vogel, 1961).

Sulfate was determined turbidimetrically by following standard procedures (Standard Methods, 1975). Soil extract turbidity was compensated for by using a blank which contained all reagents except the $BaCl_2$ precipitating reagent. A spectronic 20 colorimeter, equipped with 1.17 cm lightpath cells and set to 420 nm, was used.

Nitrate was determined spectrophotometrically by using a method adapted from the Cd reduction standard procedure (Standard Methods, 1975a). Nitrate was determined by using Hach reagents. The procedure is outlined in a methods manual (Hach 1975).

A nitrate ion-selective electrode, Orion 93-07, was evaluated for use in the determination of soil nitrate concentrations. However, performance was not reliable even though several applications have been published (Smith, 1975; Orion, 1975a; Raveh, 1973; Mack and Sanderson, 1971, Olen and Selmer-Olsen, 1969, Mahendrappa, 1969; Myers and Paul, 1968; Bremner et al., 1968; Standard Methods, 1975).

Determination of NH_4^+, reported as NH_3, in the soil extract was performed with an Orion 95-10 ammonia electrode. (Orion, 1975a, McKenzie and Young, 1975, Beckett and Wilson, 1974; Banwart et al., 1972).

Ion Exchange Capacity

Ion exchange capacity of soil samples was determined by the ammonium acetate pH 7.0 procedure (Soil Survey Staff, 1972), except

that the NH_4^+ present in the NaCl-HCl leachate was determined using an Orion 95-10 ammonia electrode (Orion, 1975a, Busenberg, E., and Clemency, C. V., 1973).

Total Nitrogen

Semimicro Kjeldahl digestion of samples and measurement of generated ammonium ion with an Orion 95-10 ammonia electrode (Soil Staff Survey, 1972a; Bremner and Tabatabai, 1972; Orion, 1975a) was utilized to determine total nitrogen content of the soil samples.

Determination of Total Cations in Soils

A 3 g subsample of the air-dried and sieved soil sample from each site was taken for determination of total cations. Each sample was ground, using an agate mortar and pestle, until a fine powder was obtained. Separate one-gram subsamples were taken for subsequent treatment. Twelve elements were determined to be present in the soil samples. Silica was removed, and each sample was dissolved by treatment with hydrofluoric acid, usually in combination with a mineral acid, followed by heating to volatilize SiF_4 (Dolezal, J. et al. 1968). Dissolution of silica samples in HF prior to extraction and atomic absorption spectrophotometry is commonly used (Sanzolone and Chao, 1976; Fuller and Whitehead, 1974; Fuller, 1973; Fuller, 1972, Ward, 1969). Treatment of soil samples involved ignition of the one gram samples at 900°C for 2 hours to remove organic matter, followed by treatment with HCl and HF in 20 ml teflon beakers. The procedure followed is described by Pawluk (1967).

Initially, the solutions obtained from the HCl/HF treatment of the soils were subjected to flame atomic absorption analysis for determination of Na^+, K^+, Ca^{+2}, Mg^{+2}, Mn^{+2}, and Zn^{+2}. The elements Al^{+2}, Cu^{+2}, Mo^{+2}, Ni^{+2}, Mn^{+2}, and Pb^{+2} were determined by flameless atomization atomic absorption spectroscopy. A Perkin-Elmer 305B atomic absorption spectrophotometer, operated according to manufacturer directions, was used. An air-acetylene flame and a Perkin-Elmer HGA-2100 heated graphite atomization (HGA) sources were used. Flame absorption results were obtained from calibration curves generated from standard solutions and run under identical experimental conditions. Flameless atomic absorption results were obtained by using the method of standard additions. Ultimately, all samples were analyzed by plasma spectroscopy at the Institute of Ecology, University of Georgia. The laboratory was under the direction of Dr. Frank Golly.

Hydrochloric Acid Leaching of Cations from Soils

Samples of the air-dried and sieved soil samples were used to assess the extent to which various cations could be leached by HCl. Five 10 g subsamples, obtained by coning and quartering, were taken for soil subsamples from each site. These samples were placed in 25 ml-capacity gooch filtering crucibles with fine porosity fritted discs. Leaching was accomplished by adding 20 ml portions of 1.0, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4} M HCl (pH range 0 to 4) to separate portions

of each sample. The solution was allowed to percolate through the soil using sufficient vacuum to require a minimum of 25 minutes for the leaching. Additional 20 ml portions of acid were added to each soil, until a total of 100 ml had been used and a minimum total leaching time of 2 hours had elapsed. Concentrations of metals in the HCl leachates were determined as described above for total cations.

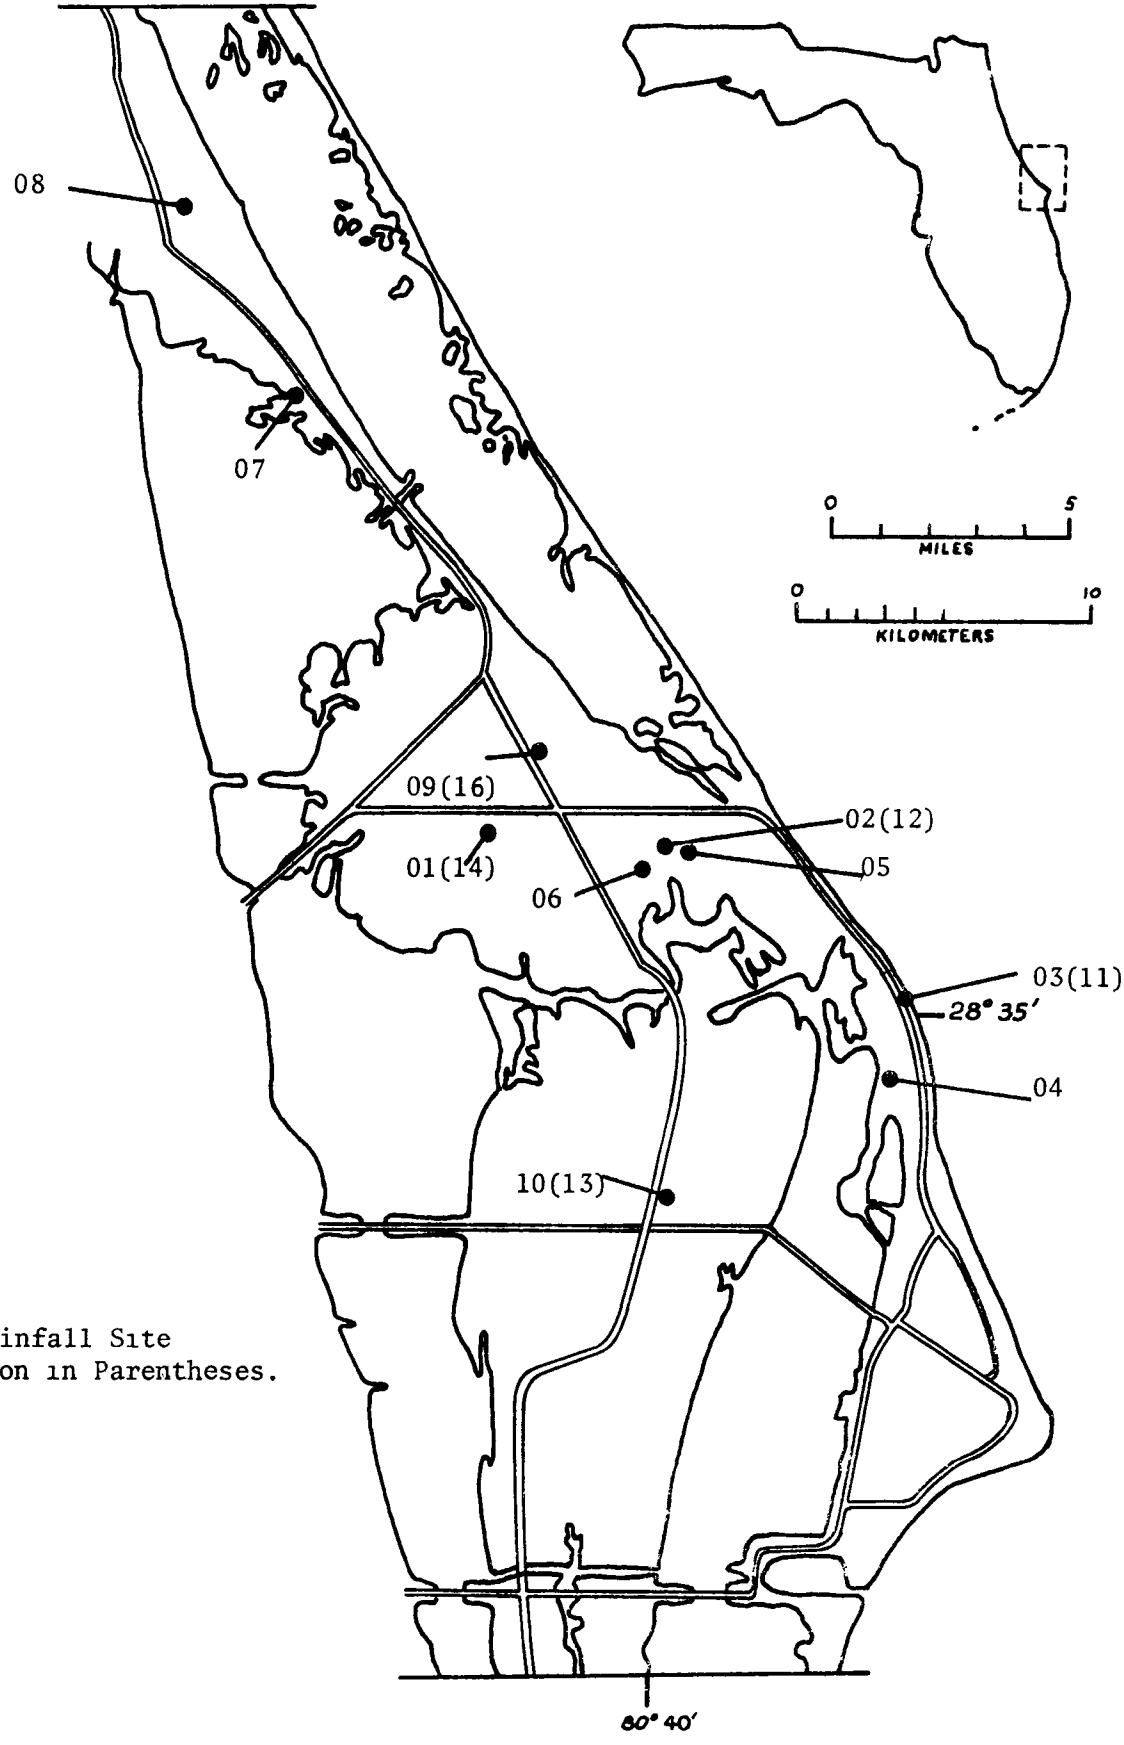
Results

Ten primary sites were established as part of the Terrestrial Plant Community Analysis Program (Stout, 1979). Figure 35 shows the location of plant communities where soil samples were taken. Site number designation in Figure 35 is that used for the reporting of all subsequent soil results. Nearby sites where collection of precipitation samples was performed are noted. Soil types and descriptions for each of the sites are presented in Table 14.

Results from the Quarterly Soil Sampling Program

Samples were collected from the ten primary areas identified in Figure 35 in mid-July 1976, early September 1976, early December 1976, and mid-March 1977. Appendix Table 382 summarizes the data from individual sampling sites and sampling periods for the determination of pH, Na^{+}, K^{+}, Ca^{+2}, Mg^{+2}, Al^{+3}, NH_3, P, Cl^{-}, NO_3^{-}, SO_4^{-2}, organic matter, ion exchange capacity, and total nitrogen. The mean annual concentration of individual soil nutrients, by site, is presented in Figures 36-49. These results are indicative of changes that may be occurring for the varous nutrients. However, presentations of mean and standard deviation are not sufficient for establishing trends. No attempt has been made to establish any seasonal trends, because of the limited data available and, in some cases, because of less than adequate analytical methods for determination of very low concentration levels for some of the nutrients. Figures 36-49 also show the mean and standard deviation for individual nutrient concentrations in the soil samples collected during March 1977. These results were obtained from quadruplicate sampling, sample processing, and sample analysis for the 14 nutrients as outlined in Figure 34. The precision associated with the measurement of concentration for each of the nutrients in the different soils represent contributions from collection of sample cores, coning and quartering to obtain subsamples of suitable size for each extraction and/or determination, and the analytical method itself. Comparisons based on the annual and March 1977 sampling have been presented for the 10 primary soils. In a few cases, no information is reported. This occurs when data for certain nutrients is reported as greater than a specified value but no actual concentration is reported. Nutrients involved are Ca^{+2} and, occasionally, Mg^{+2}, P, and NO_3^{-}.

Site selection resulted in the inclusion of several different soil types. For purposes of sampling, the single beach site was subdivided into three separate sections, based on dune profile and vegetation cover. Designations used are: front dune, middle dune, and back dune, based on proximity to the ocean. Two sites are located on Immokalee Sand and a third, the Pine Flatwoods, is of similar soil type. Three sites are located on Pomello Sand and three are supported on soils referred to as "Swamps" or "Copeland Complex". The latter are complex soils, and complete description of soil type has not been attempted. Sites designated as hammocks are supported on these soils.



Nearby Rainfall Site
Designation in Parentheses.

Figure 35. Locations of Soil Sampling Sites. Site Descriptions are Included in Table 14.

Site No.	Name	Soil Type[a]	Plant Community Description
01	Wisconsin Village	Immokalee sand -- This is a nearly level, poorly drained sandy soil in broad areas in the flatwoods, on low ridges between sloughs, and in low, narrow areas between sand ridges and lakes and ponds. It has a dark-colored, weakly cemented layer below a depth of 30 inches. This layer is dark colored because the sand grains are coated with organic matter. In most years the water table is within a depth of 10 inches for 1 to 2 months. It is between 10 and 40 inches more than half the time, and during short, dry periods it is below 40 inches. The soil is flooded for 2 to 7 days once in 1 to 5 years	The vegetative cover of the grid may best be referred to as Flatwoods without pines The dominant element in the ground cover is wiregrass Aristida Stricta Smaller woody plants include St. Johns wort Hypericum reductum, Gaylussacia dumosa, and Vaccinium myrsinites. Taller shrubs (1-2 meters in height) are Quercus myrtifolia, Q. chapmanii, Lyonia lucida, L. fruticosa, Ilex glabra, Befaria racmosa, and Serenoa repens. A smaller oak Quercus minima is also very common.
02	Happy Hammock	Swamp -- consists of nearly level, poorly drained and very poorly drained areas of soils that have a dense cover of wetland hardwoods, cypress trees, vines, and shrubs. Swamp is in poorly defined natural drainage-ways in depressions, and in large bay heads. It is flooded with fresh water most of the time. The soil pattern in the swamps is intricate and varied The dense vegetation makes it impractical to map the soils separately. On Merritt Island are the deep sandy Anclote, Pompano, Basinger, Terra Ceia, and Tomoka soils.	Large live oaks Quercus virginiana var. virginiana are scattered throughout the hammock. Other canopy dominants include Sabal palmetto, Quercus laurifolia, red maple Acer rubrum; and elm Ulmus americana var. floridana. Subcanopy trees include hackberry Celtis laevigata, mulberry Morus rubra and lancewood Nectandra coriacea. Common shrubs are coffee Psychotria nervosa and P. sulzneri, Myrsine guianensis, and Ardisia escallonioides.

Table 14. Soil Sampling Site Numbers and name designation, soil type, and plant community description for sites selected for use in the soil analysis program and Plant Community Analysis Program.

Site No	Name	Soil Type[a]	Plant Community Description
04	Dune Scrubb	Pomello sand -- This is a nearly level, moderately well drained sandy soil on broad low ridges and low knolls. The water table is 30 to 40 inches below the surface for 2 to 4 months in most years and between 40 to 60 inches for more than 6 months. During dry periods, it is below 60 inches for short periods. Included with this soil in mapping are a few areas of Myakka and Immokalee soils. Also included are areas of fine sand, small sloping areas, and areas on the Atlantic Coastal Ridge where shell fragments are mixed with the sand beneath the weakly cemented, dark-colored layer is within a depth of 30 inches.	A dense shrub cover 1-2 meters in height covers the area. Essentially no ground level cover is present, but a heavy litter layer has developed beneath the shrubs. Rosemary Ceratiola ericoides forms extensive, almost pure stands. Three oaks, live oak Quercus virginiana var. maritima, chapman oak, and myrtle oak are common. Spanish plum Imenia americana, Lyonia ferruginea, and saw palmetto are scattered throughout the grid.

Site No.	Name	Soil Type[a]	Plant Community Description
09	Rt. 3 Hammock	Copeland complex -- This complex consists of several nearly level, very poorly drained soils on low flats. In most years the water table is within a depth of 10 inches for more than 6 months. In dry seasons it is between 10 and 30 inches. This soil is flooded for 7 days to a month once in 5 to 20 years. Some areas are underlain by copuina rock instead of limestone. The soils in this complex are so intermixed that it was impractical to map them separately. About 6 percent is Copeland loamy fine sand; 55 percent is a soil that is similar to Copeland loamy fine sand, but has limestone at a depth of about 20 inches and a subsoil of sandy loam; about 8 percent is an area where the black surface layer is underlain by hard limestone, generally within a depth of 10 inches; about 5 percent is a Wabasso soil; 10 percent is a soil similar to the Wabasso soil, but has limestone beneath the loamy layers; and 16 percent is scattered spots of Bradenton shallow variant, Chobee, Felda, Myakka, and St. Johns soils.	
10	Headquarters Pinelands	Immokalee Sand - See Site 01	
03	Beach Grid	Palm Beach sand -- This is a nearly level and gently sloping excessively drained soil on dunelike ridges that roughly parallel the Atlantic Ocean. It consists of mixed sand and shell fragments. Slopes are mostly 2 to 5 percent. The water table is at a depth of more than 10 feet. Included with this soil in mapping are narrow areas that have slopes of 5 to 8 percent and lead to included narrow low sloughs. Also included are areas of soils that contain only a very few shells in the upper 20 to 40 inches and that are brownish yellow to	Three obvious zones of vegetation run parallel with the beach and dune lines. The first zone and most seaward is covered with sea oats Uniola paniculata, Heterotheca hyssopifolia, and Ipomoea stolonifera and I. Pes-caprae. Some 14 other species of plants occur in zone 1. Zone 2 is between the beach and the major dune line. Much of this area is bare sand with clumps of palmetto Sarenoa repens, occassional sea grape Coccoloba uvifera, and buckthorn Bumelia tenax. Gopher apple Licania michauxii forms extensive

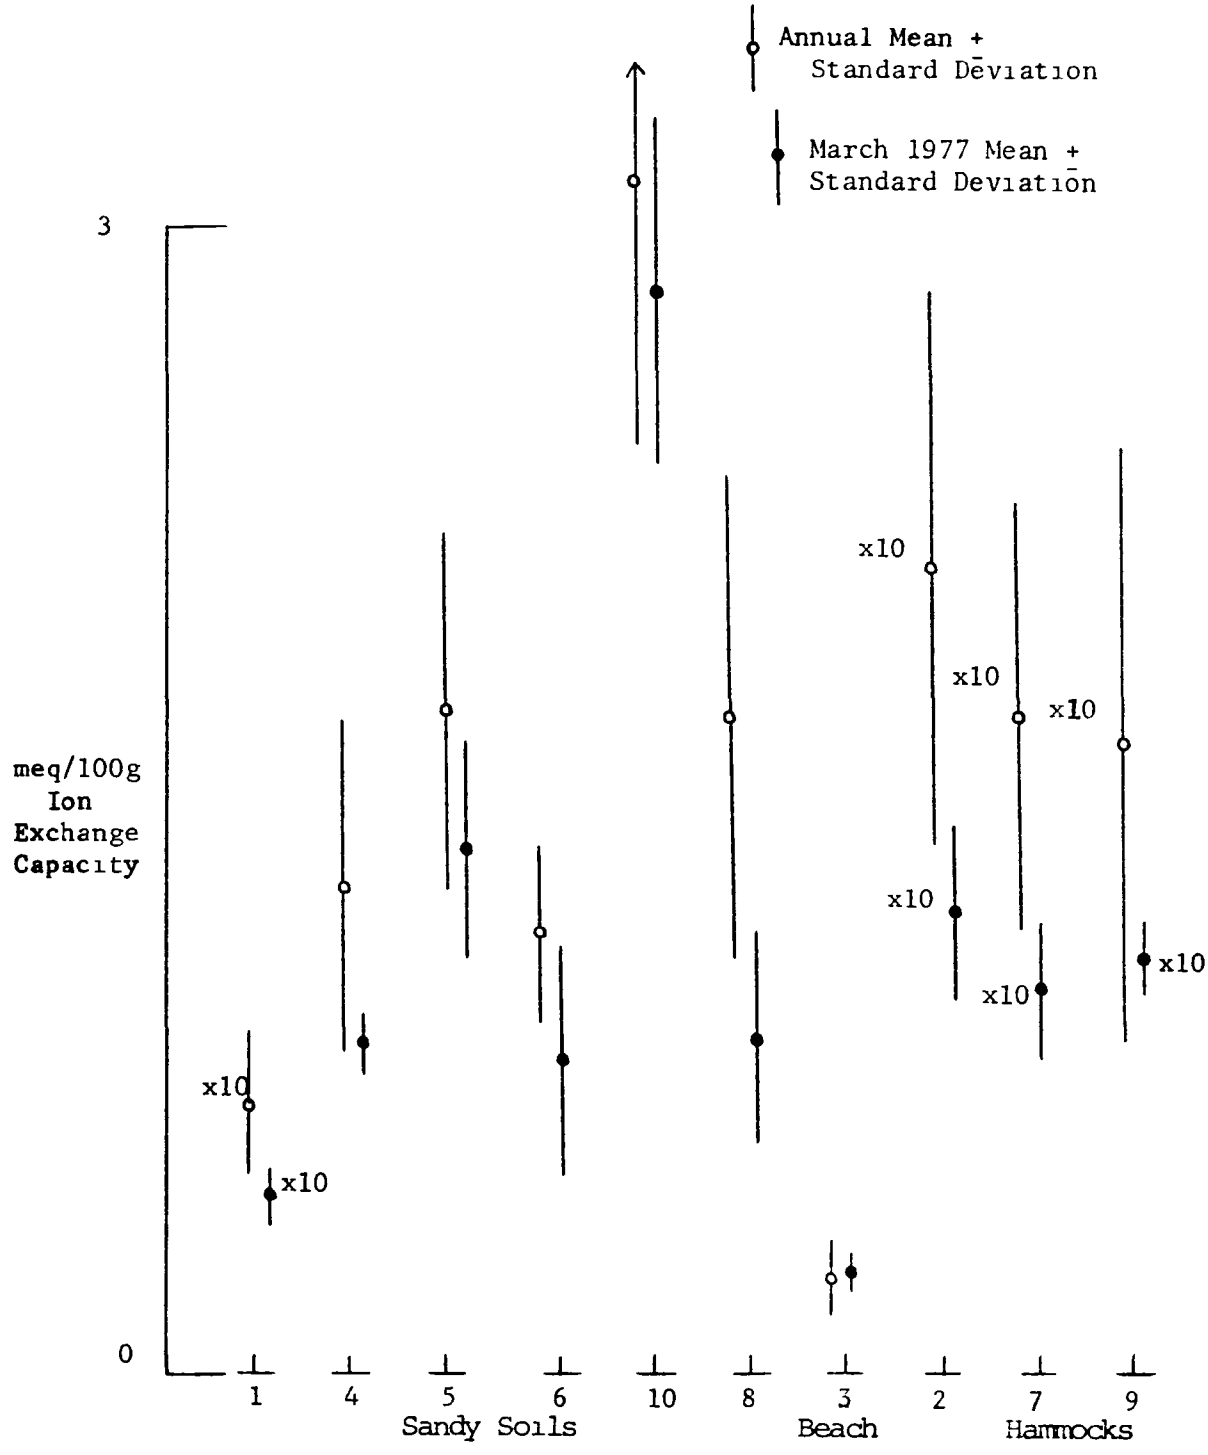

Figure 48. Comparison of Ion Exchange Capacity in Merritt Island Soils

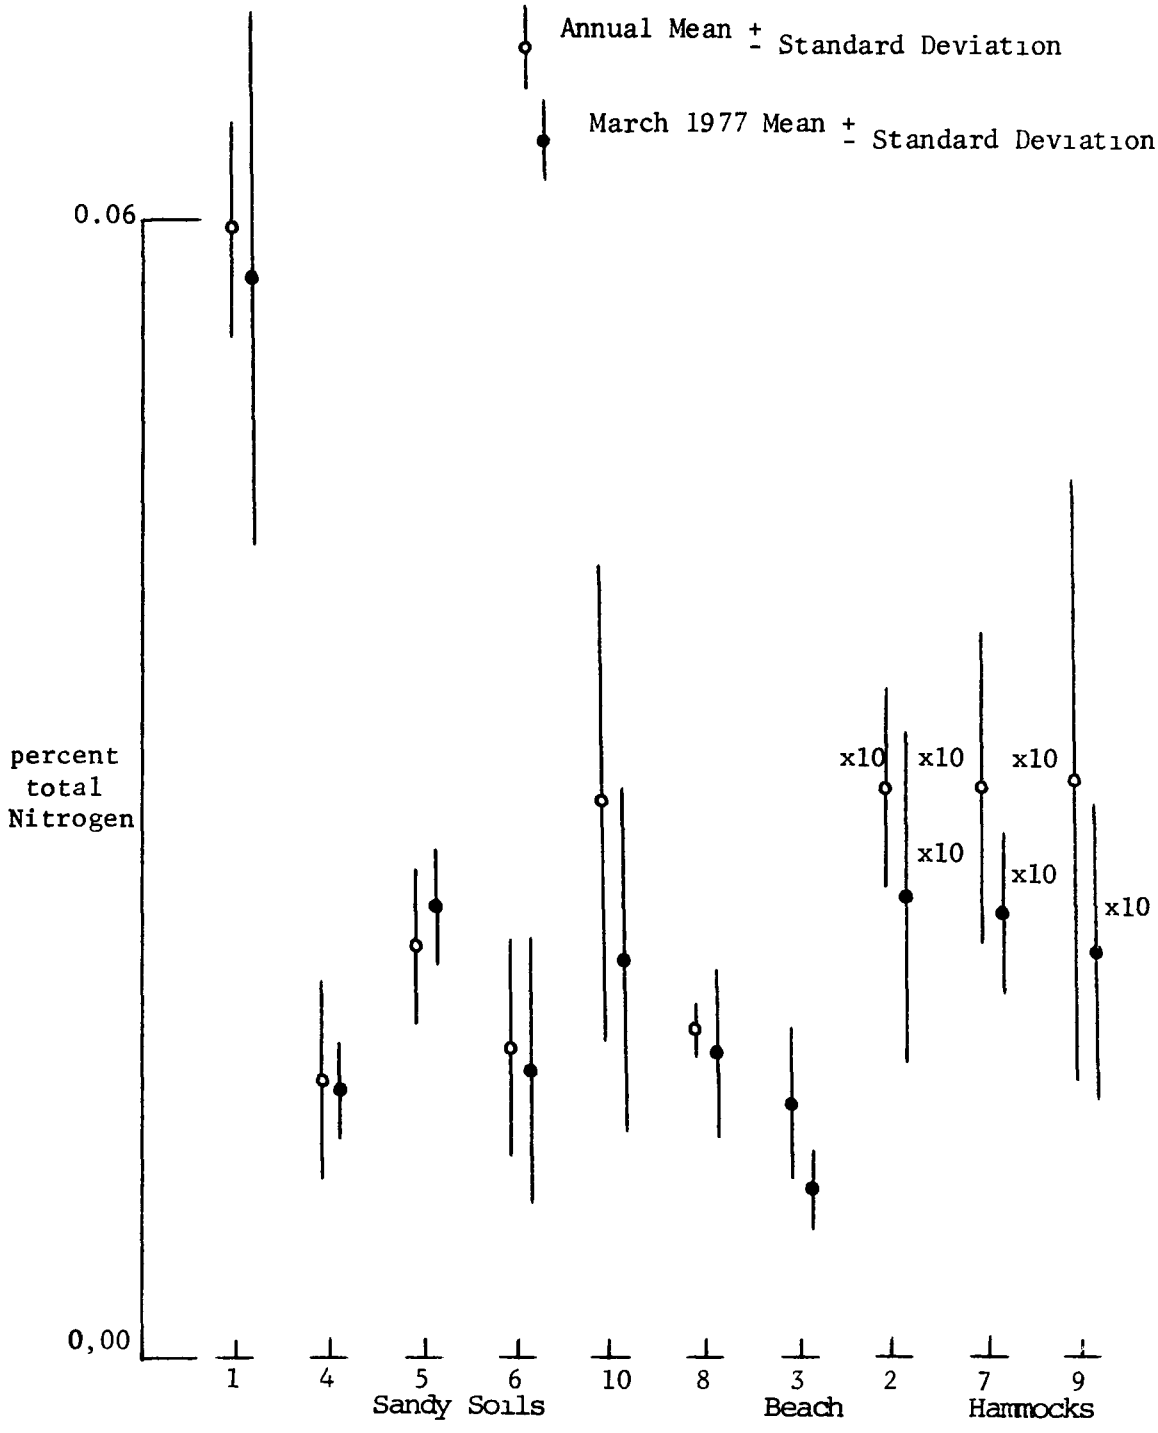

Figure 49. Comparison of Nitrogen Concentrations in Merritt Island Soils

The results presented in Appendix Table 382 and Figures 36-49, which summarize the routine monitoring of nutrients in soils, generally are what would be expected. the soils can be grouped on the basis of concentration levels of several of the nutrients monitored. Some variability of results is observed. However, the following parameters generally are useful for gross differentiation of soils based on chemical differences: pH, ion exchange capacity, total nitrogen, organic matter, calcium, sodium, and chloride. A summary of the concentrations found for these nutrients is presented in Table 15. The most logical grouping of sites is: sandy soils, 6 different sites; beach soils, one site; and hammock soils, 3 sites. The comparison of nutrient results presented in Figures 36-49 are arranged to reflect this grouping. Large amounts of calcium present in the hammock and beach soils and the relatively large ion exchange capacity for the hammocks undoubtedly explain higher pH values associated with these soil types. The hammocks are quite rich with respect to most nutrients monitored, while the sandy soils and beach soil are quite deficient. Figure 50 shows the observed annual mean pH at each site, compared to ion exchange capacity and organic matter content.

Table 16 lists the various analytical techniques and associated detection limits utilized for nutrient measurements. The detection limits represent the practical lower concentration limit measurable with each experimental procedure and analytical technique. Values generally correspond to measurements made at twice the background or noise level for each measurement.

Table 17 lists the precision of analytical measurements performed in the UCF laboratories. The degree of precision associated with the analytical measurements performed in the Soil Testing Laboratory, University of Florida, is not available.

Results presented in Figures 42 for NH_3, 43 for P, 45 for NO_3^-, and 46 for SO_4^{2-} show extremely large standard deviations for both the mean annual and quadruplicate March results. Detection limits presented in Table 16 show that when measurements are made at or near these limits, and on a relative basis, more error is likely for these four nutrients. Measurements for the other nutrients are made considerably above the detection limits of the various methods employed, and the deviations that can be attributed, at least in part, to the analytical method have been minimized.

Total Cation Concentrations of Soils

The total cation concentration for individual metals in the soil samples based on triplicate determinations are presented in Table 18. In general, these results differ from those obtained initially by atomic absorption spectroscopy by as much as 100 percent. The specific reason for these differences is not known, however, several of the samples submitted to the University of Georgia for plasma spectroscopic determination of metals actually were replicates (same sample; different bottle), spiked samples, and standard solutions

Table 15.
Summary Results for Selected Nutrients
Based on General Soil Type.

Chemical Parameter	General Soil Type		
	Hammock	Sandy	Beach
pH	5.8-8.5	4.0-5.5	8.0-8.5
Ion Exchange Capacity (milliequivalents/100g)	10-30	1-8	0.1-0.8
Total Nitrogen (percent)	0.2-0.4	0.1-0.6	.01
Organic Matter (percent carbon)	10-30	1-5	6
Calcium (parts per million)	>7000	100-300	>7000
Sodium (parts per million)	100-500	10-30	100
Chloride (parts per million)	100-500	6-20	10

5.0	2.8, 5	6.1, 7	15, 5
10.0	0.3, 2		18, 5

Note: Precision expressed as 3.7, 6 represents 3.7% R.S.D. based on 6 measurements.

prepared in the UCF laboratory. Results obtained from these "control" samples also showed considerable variation. It should be concluded that results presented here are, at best, semi-quantitative.

Hammock sites 02, 07, and 09 and beach site 03 consistently show higher total metal concentrations. Results presented in Table 18 show how total cation concentrations vary from site to site. Results from sites which have very sandy soil indicate that the total cation composition of these soils is similar. Hammock soils which differ significantly in concentration for individual metals also show significant variation from hammock to hammock.

Hydrochloric Acid Leaching of Cations from Soils

Results from the HCl leaching experiments are summarized graphically in Figures 51-59. Appendix Tables 383-474 provide a complete record pertaining to results for total cation and leaching experiments. Figures 51-59 show the leaching behavior of the 9 metals Na^{+}, Ca^{+2}, Mg^{+2}, Al^{+3}, Fe^{+3}, Mn^{+4}, Ni^{+2}, Zn^{+2}, Co^{+2}, from KSC soils. The leaching behavior of K^{+}, Cu^{+2}, Cr^{+2}, and Pb^{+2} has not been presented. Concentrations of K^{+}, Cr^{+2}, and Pb^{+2} in the HCl leachates were generally lower than could be measured routinely with accuracy, and Cu concentration in the HCl leachate was typically 100 percent of the total concentration present. Limits of detection associated with the analytical methods used to determine metals are shown in Table 19. Because of the relatively large deviations in the data, these results should also be interpreted semi-quantitatively.

Discussion

Two distinct studies were performed to evaluate soil composition and to assess the effect that HCl will have as a leaching agent for cations from soils. Both studies were performed on soil samples that were collected from reference sites in the Terrestrial Community Analysis Program (Stout, 1979). The soil composition studies initially were intended to continue for the entire three year contract period. Because of funding limitations and a NASA decision to emphasize precipitation chemistry studies, soil studies were terminated after the initial year of the contract. Soil composition results have been reported, but because of the short-term nature of collected data and, in some cases, because of resource and equipment limitations which restrict the usefulness of the results, detailed interpretation cannot be attempted. Results of the leaching experiments should be utilized in a semi-quantitative fashion. The reasons for this previously were explained in the results section.

Soil Composition, and Major Nutrients Based on One Year of Quarterly Soil Sampling.

Only limited results are available to use for evaluation of soil composition. Only the stationary pool of nutrients in the surface 15 cm of soil were considered. A more complete soil study should include determination of base-saturation of ion exchange sites and the assay of soil water based on lysimeter sampling, in addition to those determinations which were performed. The availability of more reliable instrumentation and a more frequent sampling program also could provide additional insight into the total nutrient status of Merritt Island soils.

Soil composition is summarized in Table 15 and Figures 36-49. The summary results shown in Table 15 demonstrate the variability associated with soil composition. When the results shown graphically in Figures 36-49 are evaluated, while simultaneously considering analytical method sensitivity (Table 16) and precision (Table 17), it is difficult to unequivocally locate the major source(s) of error or variation. In general, variation in results is smaller for the quadruplicate March 1977 sampling of soils. Relative standard deviations are typically 10 percent or less, and reflect contributions due to soil sampling in the field, sample processing in the laboratory, and chemical analysis. Relative standard deviations for the annual mean concentrations based on quarterly values range from 10-100 percent. Concentrations for Na^+, K^+, Ca^{+2}, Mg^{+2}, Al^{+3}, Cl^-, ion exchange capacity, organic matter, and nitrogen concentration probably remained relatively constant. Sampling and chemical analysis variability probably accounted for variations observed. The variability in quarterly concentrations for NH_3 (Figure 42) may be real. Variability in sampling and chemical analysis procedures based on quadruplicate samples collected in March, 1977, is considerably smaller than the variability in quarterly concentrations. Soil handling and treatment after collection of the sample can result in loss of NH_3. Air- drying, the procedure used in this study, can result in NH_3 loss from soils and lead to incorrect results. Similarly, P, NO_3^-, and SO_4^{-2} concentration variability is extremely large. Concentrations for these species were low and approached the lower practical concentration range for meaningful chemical analysis. This fact, even in the absence of other sources of error, could account for the variability observed. The concentrations reported for P, NO_3^-, and SO_4^{-2} are not totally reliable for purposes of interpretation.

Soil pH, Figure 36, is related to other properties of individual soils. When sandy soils and hammock soils are considered, pH is related to both ion exchange capacity and organic matter content, Figure 50. Soil pH generally increases as values for these two parameters increase when hammock and sandy soils, but not the beach soil, are considered.

Total Cation Concentrations

The total concentrations of several cations which are present in Merritt Island soils are presented in Table 18. Average deviations in reported mean concentrations are presented for each. The reported mean concentrations were used to determine the extent to which leaching of each individual cation was achieved by HCl, as discussed in the next section.

Hydrochloric Acid Leaching of Cations from Soils and Evaluation of Leaching by Acid Rain from SRM Exhaust.

The leaching of Na^+ from the soil samples collected and treated as described in the experimental section (Figure 51) was generally less than 100 percent efficient and showed a strong dependence on HCl concentration only for the soil sample collected from beach site 03. The leaching behavior of Na^+ closely parallels that of Ca^{+2} in the site 03 soil, as will be described later. For hammock soils 10-70 percent of the Na^+ can be lost regardless of HCl concentration, while less than 20 percent of the Na^+ is lost from the sandy soil samples studied. Except in the HCl

leachate from samples collected at sites 07 and 09, both hammocks, the concentrations of K^+ were below the reliable analysis sensitivity limit of 35 ppm and, therefore, provided no data to evaluate.

The leaching behavior observed for calcium, Figure 52, and for magnesium, Figure 53, are similar. Leaching of calcium and magnesium is nearly 100 percent efficient at the higher HCl concentrations, and decreases as the HCl concentration decreases. This would indicate that the calcium and magnesium present in the Merritt Island soils exist in an easily exchangeable form in the soils, or they are present as calcareous material that readily dissolves in mineral acids such as HCl. The latter reaction was observed readily during sample preparation. A significant decrease in the fraction of calcium or magnesium leached occurs as the HCl concentration decreases. For soil samples which have relatively large amounts of calcareous matter present (Hammocks and Beach) there was insufficient HCl present when a low HCl concentration leachate was used to result in 100 percent reaction with calcareous material. These soils exhibit very large capacity to neutralize added HCl, and the Ca^{+2} present in the beach, hammock, and three sandy soils are 100 percent leached as HCl concentration approaches 1.0 M. However, soils 04, 06, and 08, which contain 200-300 ppm total Ca^{+2}, lose less than 50 percent of the Ca^{+2} originally present. Soils from sites 04, 06, and 08 consistently show greater resistance to leaching by HCl for all cations investigated. Hammock soil 02 and beach soil 03 contain enough calcareous material, based on total Ca^{+2} content, to consume all the HCl added until the HCl concentration exceeds 0.25 M. Hammock soil 07 could consume all the 0.1 M HCl (pH 1) added in this experiment. The Ca^{+2} leaching behavior shown in Figure 52 reflects the acid neutralizing capabilities of these soil samples.

Aluminum is partially leached from all soils at HCl solution pH of 0.0, and decreases to zero as the HCl solution pH increases to 3 or 4 (Figure 54). Aluminum is known to become more readily available and toxic to plants as soil pH decreases. It would, therefore, be expected that the presence of strong acids such as HCl could alter availability of Al^{+3} significantly and, consequently, alter plant growth.

In addition to Na^+, K^+, Ca^{+2}, Mg^{+2}, and Al^{+3}, Fe is the only metal measured in this study consistently having a total concentration in Merritt Island soils greater than 100 ppm. The fraction of Fe leached, Figure 55, is small, and does not occur to any appreciable extent when the HCl concentration decreases below 10^{-2} M (pH 2).

Manganese also is leached by HCl. Results shown in Figure 56 generally indicate less than 50 percent of the total amount of manganese is leached. There is no significant occurence of leaching below 10^{-1} M HCl (pH 1).

For the metals Ni^{+2}, Zn^{+2}, Co^{+2}, Cr^{+2}, Pb^{+2}, and Mo^{+2}, leaching behavior becomes more erratic. Leaching characteristics for Ni^{+2}, Zn^{+2}, and Co^{+2} are shown in Figures 57-59, respectively. The erratic behavior probably results because the actual concentrations of metals in the soils is quite small, and even smaller in leachate samples. Absolute precision

associated with analytical techniques begins to become more important at these low concentrations. In addition, the possibility of sample contamination becomes more likely. On a fractional basis, it appears that the leaching of these metals is similar to that of Fe and Mn at high HCl concentrations, but Ni^{+2}, Zn^{+2}, and Co^{+2} continue to leach at lower HCl concentrations.

It may be stated that under the experimental conditions utilized in this sequence of experiments, considerable leaching of metals did occur. Experimentally, 10 grams of soil was leached with 100 ml of acid added slowly over a period of two hours. In general, the extent of leaching was small until the pH of leachate decreased to below 3.0 and occured in very large volume. Even then, the relatively large amounts of calcareous material in some soils should be quite effective in neutralizing the acid, which, in turn, should inhibit the leaching effect.

The results of the leaching experiments can be evaluated to determine the effect that the occurrence of acid introduction into the soils would have on leachability of cations. If an area 1.0 m^2 is used as the basis for discussion, then 10g of soil, the sample size used in the leaching experiments, will represent a soil depth of 0.000074 cm based on soil density of 1.35 g/cc. The experimental 100 ml HCl treatment of soils would correspond to 0.01 cm of HCl solution, distributed equally over the 1.0 m^2 area. This corresponds to the addition of 100 meq. HCl. If a more convenient soil depth of 1.0 cm were considered, then scale-up of experimental conditions would correspond to 135 equiv. HCl/m^2. Existing deposition of acids due to acid precipitation presently amounts to .03-.05 eq./m^2/yr., based on results presented in Tables 6, 7, 9, and 10. The occurrence of acid rain from an SRM firing might, in a severe case, produce 1.0 cm of pH 1.0 precipitation (Pellett, 1977). This corresponds to the deposition of 1.0 equiv./m^2 of HCl. Therefore, 130-140 cm of pH 1.0 precipitation would be required to correspond to our worst case experimental leaching experiment, or 1-2 cm of pH 1.0 precipitation would correspond to the experimental leaching of 10 g soil with 100 ml of 0.01 M HCl (pH 2).

The yearly background deposition of acid at present is insignificant compared to that which could potentially be introduced from acid precipitation which might occur during or shortly after a SRM firing. Under the conditions described above leaching of Na^{+}, K^{+}, Ca^{+2}, Mg^{+2}, Al^{+3}, Fe, Ni^{+2}, Zn^{+2}, and Co^{+2} could occur as previously summarized. Leaching of most cations decreases significantly when the concentration of HCl leachate decreased to 0.01 M. This amount of acid more realistically corresponds to a single worst case acid rain event, and should initially result in only small amounts of leaching of most cations. Many of the soils on Merritt Island contain calcareous material which will consume considerable amounts of acid. The hammock soils have relatively high ion exchange capacity and organic matter content as well. While no attempt has been made to completely characterize these soil properties, it is possible that they may act further to neutralize or buffer the effect of added acid.

Summary and Conclusions

1. The leaching experiments were designed to evaluate very severe stress to soils due to the addition of HCl. The mobilization and subsequent loss of cations from the soils due to interaction with HCl can occur. Evaluation of leaching under laboratory conditions cannot duplicate *in situ* soil experiments or actual processes, and probably does not reflect the complex nature by which mobilization of ions in soils can occur.

2. No attempt was made to evaluate the role that soil properties such as organic matter content, or ion exchange capability have in influencing ion mobility. These considerations, when combined with the fact that the analytical data are of a semiquantitative nature in many cases, limit the extension of these results to interpretation of actual interactions between HCl and soils.

3. Based on experimental observations, projected acid rain occurrence, and limitations cited above which have the effect of tempering conclusion, leaching should not be severe in the short-term. Should several rain events with pH 1.0 occur on the same soil, then leaching, which amounts to greater than 30 percent of the original cation concentrations in the top 1.0 cm of soil, can occur.

4. It is not possible to predict whether the effect of several cumulative exposures of lower concentrations of HCl to soils will produce the same effect that a single high concentration treatment produced in this study.

5. It would only be possible to fully measure and understand the effect of acidification on Merritt Island soils following several years of exposure to SRM exhaust, if a long-term program were initiated to continuously study both the stationary and mobilized pool of nutrients and cations present.

Acknowledgements

Initial evaluation of the precipitation chemistry program and several valuable suggestions by Dr. James Galloway, University of Virginia, were extremely beneficial. Dr. Robert Todd, University of Georgia, made useful suggestions in the area of soil chemistry.

Most chemical analyses were performed by John Hogsett, Leonard Hutto, and Mark Carter. Students who provided assistance in sample collection and chemical analysis include Jim Hood, Chris Kohl, Anthony Mancusi, Karin Moore, and Charles Otis. Sandra Watson assisted in data processing. The reliable and conscientious efforts expended by each were vital to accomplishments achieved. The efficiency and organizational capabilities provided by Rosalie Creamer, who typed this report, is appreciated. Development of all computer software and considerable data processing were accomplished by Farley Place. His never-ending enthusiasm and achievements proved to be indispensable.

Assistance provided by the NASA Booster Exhaust Study Test (BEST) program directed by Mr. Hans Rudolph is acknowledged.

Table 382. (cont.) Concentration of Various Nutrients Present in Soil Samples collected in July, 1976, September, 1976, December, 1976, and March, 1977, from Merritt Island Plant Communities. Concentrations reported are parts per million(ppm) except for percent Organic matter, Ion Exchange Capacity in milliequivalents per 100g, and percent Nitrogen.

15 Abstract

The first part of the document reports the results of a study which was designed to monitor, characterize, and evaluate the chemical composition of precipitation (rain) which fell at the Kennedy Space Center, Florida (KSC) during the period July 1977 to March 1979. In the second section, the results which were obtained from a soil sampling and associated chemical analysis are discussed. The purpose of these studies was to determine the environmental perturbations which might be caused by NASA space activities.

Note: This document was prepared under the sponsorship of the Biomedical Office, Bioscience Operations, Dr. William M. Knott and Dr. Paul Buchanan.

16 Key Words

Acid rain; rain chemistry; hydrochloric acid; soil chemistry; soil leachates
