Sumário/Notas <i>The following three experiments were conducted on corn (Zea mays L.) plants using a calibrated Exotech Model 20C spectroradiometer under field conditions in the indium antimonide channel (InSb, 2.8 to 5.6 μm) and mercury cadmium telluride channel (HgCdTe, 7 to 14 μm): (1) ground cover experiment (2) experiment on non-systemic stressed corn plants and (3) experiment on systemic-stressed corn plants. In the first experiment, average spectral radiance temperature, $\bar{T}_s(\lambda)$, for the four healthy corn plant populations (15, 30, 60 and 90 thousand per hectare) were found to be statistically significantly different (level of significance 0.05). In the second experiment, $\bar{T}_s(\lambda)$ of the corn plants increased with increase in blight severity. In the third experiment, $\bar{T}_s(\lambda)$ of the corn having different rates of nitrogen applications (0 kg/hectare, 67 kg/hectare and 201 kg/hectare) were found to be statistically significantly different.</i> | | | |
| 17. Observações <i>Submitted to Agronomy Journal for publication.</i> | | | |

1 each of the selected wavelength regions of the indium antimonide
2 channel. In the second experiment, $\bar{T}_s(\lambda)$ of the corn plants increased
3 with the increase of blight severity in each of the selected
4 wavelength regions of the InSb as well as the HgCdTe channel. The
5 contact temperatures of the healthy and blighted spots of corn leaves
6 were not found to be statistically significantly different. A tentative
7 conclusion is that the percentage of the soil, especially sunlit soil,
8 visible from the spectroradiometer is the predominant factor causing
9 differences between $\bar{T}_s(\lambda)$ of the healthy and blighted corn plants. In
10 the third experiment, $\bar{T}_s(\lambda)$ of the corn having different rates of
11 nitrogen application (0 kg/hectare, 67 kg/hectare and 201 kg/hectare) -
12 were found to be statistically significantly different in each of the
13 selected wavelength regions of indium antimonide channel.

INTRODUCTION

1
2
3 Remote sensing is beginning to provide tools and
4 techniques with which agronomists and plant pathologists can rapidly
5 observe crop conditions. Detection of crop diseases is but one of many
6 possible applications of remote sensing technology (Bauer, 1976). The
7 interpretation of multispectral scanner data is enhanced by the use of
8 spectral data taken under field conditions. The application of such
9 field data to the analysis of multispectral information may allow the
10 interpretation of second-order differences in the airborne observations
11 (Silva et al., 1971; Hoffer, 1971).

12
13 The field van system of the Laboratory for
14 Applications of Remote Sensing (LARS), of Purdue University, was used
15 extensively in the 1968 growing season, to record the spectra from
16 natural scenes with the Block 195 T Michelson Interferometer
17 spectrometer in the region of 5 to 15 μm (LARS Annual Report, 1968).

18
19 However, much of the research on the reflective and
20 thermal properties of plants and soils has been done in the laboratory
21 (Kumar, 1972). Field studies have been hampered by the lack of suitable
22 instrumentation for obtaining reliable spectral measurements (Silva et
23 al., 1971). Consequently, there has been increased reliance on
24 laboratory instruments and spectral measurements of individual leaves
25 or small soil samples. Such techniques have been used effectively, but
26 the resulting spectra lack the interrelationships between green leaves,
27 dead leaves, the soil itself and shadows for the entire scene as

1 measured by an airborne remote sensing system. Further, most previous
2 researchers made multispectral measurements of the plants in the
3 visible, near-and middle-infrared wavelength regions. This is due to
4 the lack of suitable instrumentation for obtaining reliable spectral
5 measurements in the thermal infrared wavelength region.

6
7 Gates (1970) pointed out that the chemical status of
8 plants determines normality or abnormality of growth. A chemical
9 excess or deficiency for a plant may cause chlorosis, premature
10 yellowing and abscission of leaves, burning of leaf tips, bronzing,
11 wilting, mottling, necrosis, water stress, cupping of leaves, flower-
12 color changes or other abnormalities. A change in the spectral
13 properties causes changes in the energy balance of the leaf and hence
14 its temperature.

15
16 He found the temperatures of potassium-deficient
17 sugarcane leaves to be 0.5° to 1.5°C warmer than normal leaves exposed
18 to sunlight. Silva et al. (1972) reported that a sulfur-deficient corn
19 plant, in an ambient temperature of 24°C , and a nitrogen-deficient corn
20 plant, in an ambient temperature of 23°C , were 1°C cooler and 2°C cooler,
21 respectively, as compared to the healthy controlled plant, when the
22 surface located immediately behind the plants, in both cases, was
23 16.5°C . The preliminary conclusion made was that nutritionally stressed
24 plants are not always hotter than a controlled plant, but are
25 apparently influenced more strongly by environment.

26

27

1 In the analysis of multispectral scanner data of the
2 Corn Blight Watch Experiment, almost all the LARS analysts found the
3 thermal channel (9.30 to 11.70 μm) to be one of the best four channels,
4 out of twelve available channels, using a feature selection algorithm.
5 This finding created interest among the staff members of LARS, to find
6 the reasons for this and was an additional impetus for performing field
7 experiments in the thermal infrared wavelength region using long
8 wavelength spectroradiometer. Kumar and Silva (1974, 1977), analyzed
9 multispectral scanner data in the twelve spectral channels for three
10 flightlines. They found thermal channel to be one of the best ones in
11 the subsets of four or more spectral channels for getting good overall
12 statistical separability of agriculture cover types.

13
14 Cipra et al. (1971) measured the radiance
15 characteristics of soil with an Exotech Field Spectroradiometer; the
16 authors used a modified version of this spectroradiometer for the
17 experiments described here.

18
19 The purpose of this study was to determine the effect
20 of systemic and non systemic stresses on the spectral response of corn
21 plants in the thermal infrared wavelength region, using the
22 longwavelength head of the Exotech Model 20C spectroradiometer. This
23 model has wavelength ranges of 2.8 to 5.6 μm and 7 to 14 μm . The
24 specific objectives of the study were:

- 25
26 (1) To determine in what wavelength regions the
27 spectral radiance temperature of the stressed

1 plants is statistically significantly different
2 from the healthy ones;

3 (2) to try to determine predominant variables that
4 cause the differences between the spectral
5 radiance temperature of healthy and stressed
6 plants, using statistical analysis of
7 spectroradiometric data and ground observations;
8 and

9 (3) to try to explain the results of these
10 experiments on a physical basis.

METHODS AND MATERIALS

1
2
3 The Exotech Model 20C spectroradiometer was used to
4 conduct three experiments: (1) ground-cover experiment, (2) experiment
5 on non systemic stressed corn plants and (3) experiment on systemic
6 stressed corn plants. The Exotech Model 20C spectroradiometer is a
7 rugged field instrument that has four circular-variable-filters to
8 provide spectral resolution of approximately 2%. This instrument is
9 ideally suited to the rigors of a field environment, embodying sealed
10 circuits for protection against dust and condensation, modular
11 construction for simplified maintenance, and operational features
12 designed to reduce data acquisition time. This instrument can be
13 operated as two separate units. The short wavelength (SWL) unit is
14 responsive to radiation in the wavelength range from 0.38 to 2.5 μm
15 and the long wavelength unit (LWL) is responsive to radiation in the
16 wavelength range 2.8 to 5.6 μm (indium antimonide channel) and 7 to
17 14 μm (mercury cadmium telluride channel). Further details of an
18 earlier version of the instrument can be found in Leamer et al. (1973).
19 In this paper, only the results with the long wavelength head are
20 presented.

21
22 A LARS Hi-Ranger mobile aerial tower is used to lift
23 the optical heads to the desired position relative to the target
24 scene (Figure 1). The optical heads may be lifted to a height of 15.3 m
25 above the ground and may be suspended as far as 6.4 m from the edge of
26 the Hi-Ranger at a height of 9.15 m. The control electronics, recording
27 equipment, and other data-recording instruments are located in the

1 instrument van. A power unit towed behind the instrument van provides
2 electrical power for both the instrument van and the spectroradiometer.
3 Normally, a technician operates the equipment while the natural
4 scientist directs the experiment. Further details of "The LARS Extended
5 Wavelength Spectroradiometer" are available: Kumar & Silva (1973),
6 Robinson et al. (In preparation).

7
8 The wavelength calibration for both the indium
9 antimonide (InSb) and mercury cadmium telluride (HgCdTe) channels was
10 done by finding the pulse number corresponding to the sharp and
11 accurately known absorption bands of polystyrene, atmospheric carbon
12 dioxide and methyl cyclohexane. A copper cone having an apex angle of
13 15° and a diameter of about 16.5 cm was painted with Parson's Optical Black
14 Lacquer and fitted into a fiberglass covered foam box. This was used
15 as a blackbody for calibration of spectral radiance of the
16 spectroradiometer. Two such blackbodies were used in the field
17 experiments; one kept well above the ambient temperature (called hot
18 blackbody) and the other kept well below the ambient temperature
19 (called cold blackbody). Spectral radiance calibration of the
20 instrument was done in the field with the help of hot blackbody and
21 cold blackbody before starting an experiment. Further details
22 concerning the calibration of the instrument can be found in Kumar and
23 Silva (1973) and Robinson et al. (In preparation).

24
25 In all of the experiments, spectroradiometric scan of
26 each of the corn (*Zea mays* L.) plots was accomplished in the InSb and
27 the HgCdTe channels on relatively cloud-free days (i.e., sky radiant

1 temperature $< -5^{\circ}\text{C}$), from a height of about nine meters. Ground
2 observations of sky radiant temperature, sunlit soil temperature, shaded
3 soil temperature and air temperature etc., were generally made with
4 each spectroradiometric scan. A portable radiation thermometer (PRT-5)
5 was used to determine the radiant temperature of the sky. Calibrated
6 probes types 709 and 705, manufactured by Yellow Springs Instruments,
7 were used to measure the contact temperatures of soil and air
8 respectively.

9
10 Data of spectral scans of the targets, hot blackbody
11 and cold blackbody were stored on magnetic tapes. In addition, the ground
12 observations were also stored on the same tapes. These tapes are
13 digitized. A data processing software system has been developed at
14 the LARS to calibrate the spectroradiometric scans for spectral
15 radiance (L_{λ}) and spectral radiance temperature ($T_s(\lambda)$) of the target in
16 InSb and HgCdTe channels at a wavelength interval of about $0.03\ \mu\text{m}$ and
17 $0.07\ \mu\text{m}$ respectively.

18
19 The data in the wavelength regions 2.6 to $3.6\ \mu\text{m}$, 4.15
20 to $4.50\ \mu\text{m}$ and 5.40 to $5.60\ \mu\text{m}$ were not analyzed due to problems of low
21 signal-to-noise ratio, of strong absorption by carbon dioxide, and of
22 being close to the end of the circular variable filter wheel
23 respectively. The spectral radiance temperature, calculated at
24 wavelength interval of about $0.03\ \mu\text{m}$ in InSb channel, was averaged over
25 each of the wavelength regions mentioned above and is denoted by
26 $\bar{T}_s(\lambda)$.

27

1 Similarly, HgCdTe channel (7 to 14 μm) was divided into
2 the following seven wavelength regions for analyzing the data: 7.5 to
3 8.2 μm ; 8.2 to 8.9 μm ; 8.9 to 9.6 μm ; 9.6 to 10.3 μm ; 10.3 to 11.0
4 μm ; 11.0 to 11.7 μm ; and, 11.7 to 12.4 μm .

5
6 The data in the wavelength regions 7.0 to 7.5 μm and
7 12.40 to 14.00 μm were not analyzed because the signal-to-noise ratio
8 can be low in these wavelength regions (as these correspond to near the
9 start of and near the end of the circular variable filter wheel
10 respectively). The spectral radiance and spectral radiance temperature
11 of the target were calculated at a wavelength interval of about 0.07 μm
12 in the HgCdTe channel. This calculated spectral radiance temperature
13 was averaged over each of the wavelength regions mentioned above and is
14 denoted by $\bar{T}_s(\lambda)$.

15
16 As pointed out above, three experiments were conducted.
17 The method of these experiments is described briefly under their
18 respective headings.

19
20 I. Ground-Cover Experiment

21
22 The experiment was conducted on the Purdue University
23 Agronomy Farm in the summer of 1972. Corn (*Zea mays* L.) plants were
24 grown in the plots in 6-76 cm rows, 4.6 meters long. Fertilizer and
25 herbicides were applied prior to planting on 25 May 1972. The
26 planting was done by hand in order to obtain uniform spacing between
27 plants. Plots with varying amounts of ground cover were established

1 by having five different plant populations: 0, 15, 30, 60 and 120
2 thousand plants per hectare, each plant population being replicated
3 twice in a randomized complete block design.

4
5 Spectroradiometric scan of each of the plot numbers one
6 to ten was accomplished in the Indium Antimonide Channel (2.8 to 5.6 μm)
7 with the Exotech Model 20C spectroradiometer on 18 August 1972, which
8 was a relatively cloud-free day (sky radiant temperature was less than
9 -5°C).

10

11 II. Experiment on Non Systemic Stressed Corn Plants

12

13 This experiment was designed to study the effect of
14 non systemic stresses on the spectral response of corn plants in the
15 long wavelength thermal infrared wavelength region. The experiment was
16 conducted for the southern corn leaf blight (Ullstrup et al., 1945)
17 because corn blight is representative of the problems of non systemic
18 stresses.

19

20 The field experiments were conducted on the Purdue
21 University Agronomy Farm in the summer of 1972. Corn (*Zea mays* L.)
22 plants of row width 76 cm, plant population 52500 plants per hectare,
23 were planted 18 May on the silty clay loam chalmers soil.

24

25 Two hybrids, Pioneer 3306 and Pioneer 3571, were chosen
26 for growing corn of normal (N) as well as Texas male-sterile cytoplasm.
27 One of the objectives of the experiment was to determine if there was

1 any statistically significant difference in the spectral radiance
2 temperature of the Pioneer 3306 corn (healthy as well as blighted) and
3 Pioneer 3571 corn. *Helminthosporium maydis* (*H. maydis*) causes
4 relatively mild infection on corn of N cytoplasm, but it attacks corn
5 in TMS cytoplasm with unusual virulence which causes southern corn
6 leaf blight. Half of TMS corn plots were inoculated with *H. maydis* on
7 28 June; whereas, the other half were inoculated with *H. maydis* on
8 14 July. The whole experiment (N + TMS cytoplasm) was replicated twice
9 on 9 August as well as 17 August 1972 under relatively clear-sky
10 conditions.

11
12 III. Experiment on Systemic Stressed Corn Plants

13
14 The purpose of this experiment was to study the effect
15 of systemic stresses on the spectral response of corn plants in the
16 long wavelength thermal infrared wavelength region. Nitrogen deficient
17 plants were used in the experiment because nitrogen deficiency is
18 representative of the problems of systemic stresses.

19
20 The field experiments were conducted on the Purdue
21 University Agronomy Farm where long-term fertility experiments are
22 available. These are replicated experiments with varying rates of
23 nutrient application. Corn plants of row width 71 cm, plant population
24 54,500 plants per hectare, were planted on 18 May 1972, on the chalmers
25 soil having a smooth surface and a silty clay loam texture. The
26 experiment was conducted on three rates of nitrogen application: (the
27 nitrogen application was given in the form of ammonium nitrate in

1 spring) 0 kg/hectare, 67 kg/hectare and 201 kg/hectare (healthy).

2

3 Two measurements (spectroradiometric scans) for each
4 of the three nitrogen treatments were done in the Indium Antimonide
5 Channel (2.8 to 5.6 μm) on 18 August, which was a relatively cloud-
6 free day.

27

RESULTS AND DISCUSSION

A level of significance (α level) of 0.05 was used in all of the experiments for statistical analysis of data. Bartlett's Test (Ostle, 1969) was used individually in each of the wavelength regions of InSb and HgCdTe channels mentioned above, to test for the homogeneity of the variances of the average spectral radiance temperature $\bar{T}_s(\lambda)$ of: (A) four corn plant populations (15, 30, 60 and 90 thousands per hectare) in experiment (1); (B) healthy, early inoculated (28 June) with Southern corn leaf blight (SCLB), and late inoculated (14 July) with SCLB corn in experiment (2), and (C) corn plots with different rates of nitrogen application (0 kg/hectare, 67 kg/hectare and 201 kg/hectare-healthy) in experiment (3).

Soil plots (plant population = 0) were not included in the statistical analysis because the spectral radiance temperature of the soil throughout 3.60 to 5.40 μm was considerably higher than the spectral radiance temperature of any of the other plant populations (Table 1).

No evidence was found to reject the hypothesis of homogeneous variances in *each* of the wavelength regions of InSb and HgCdTe channels mentioned above in *each* of the three experiments.

For each of the three experiments, the analysis of variance was used individually in each of the wavelength regions of InSb and HgCdTe channels mentioned above to test for the homogeneity

1 of the means of $\bar{T}_s(\lambda)$. The results and discussion of the three
2 experiments are given below under their respective headings.

3
4 In all of the three experiments, $\bar{T}_s(\lambda)$ in 3.6 to 3.9
5 μm and 3.9 to 4.15 μm was significantly higher than $\bar{T}_s(\lambda)$ in 4.50 to
6 4.80 μm and beyond. The reason for this result is that there was a
7 significant amount of solar radiation reflected from the target in
8 3.6 to 3.9 μm and 3.9 to 4.15 μm . This result also shows that the
9 plants were not perfect blackbodies in these wavelength intervals,
10 because $\bar{T}_s(\lambda)$ for a blackbody is constant with respect to wavelength.
11 The details of this explanation are given in the ground-cover
12 experiment.

13
14 I. Ground-Cover Experiment

15
16 The means of $\bar{T}_s(\lambda)$ for the four plant populations were
17 found to be statistically significantly different for each of the five
18 wavelength regions of InSb channel and are given in Table 1.

19
20 The spectral radiance temperature of a plant depends
21 upon its spectral emittance and temperature. Table 1 shows that $\bar{T}_s(\lambda)$
22 of the soil is considerably higher than $\bar{T}_s(\lambda)$ of any of the plant
23 populations. This resulted because contact temperature of the sunlit
24 bare soil was found to be 8 to 12^oC higher than the temperature of the
25 shaded soil under the plant. The temperature of the sunlit bare soil
26 was also considerably higher than the temperature of the leaves. Sunlit
27 soils have generally higher temperatures than plants because of their

1 greater absorption of the solar energy. Thus, percentage of sunlit soil
2 visible from the spectroradiometer is an important factor determining
3 its spectral radiance temperature. Table 1 shows that $\bar{T}_s(\lambda)$ of the
4 plants decreases significantly as we go from plant population zero
5 (soil) to the plant population 30,000 plants per hectare in all
6 wavelength regions shown in the table. This decrease is probably due
7 to a significant decrease in the percentage of sunlit soil between
8 plant population 0 to 15,000 and 15,000 to 30,000. The differences
9 between $\bar{T}_s(\lambda)$ in plant populations of 30,000, 60,000 and 90,000 plants
10 per hectare are rather small. These small differences probably occurred,
11 because there were relatively small differences in the percentage of
12 sunlit soil of plant populations 30,000, 60,000 and 90,000 plants per
13 hectare. Most of the soil under the plants of population 30,000 and
14 60,000 plants per hectare was shaded. There was no sunlit soil under
15 the plants of population 90,000 plants per hectare.

16
17 Table 1 shows that $\bar{T}_s(\lambda)$ of the plants and soil
18 decreases significantly with the increase in wavelength from 3.6 to
19 4.80 μm . This is because the solar irradiance reflected from the target
20 decreases with increasing wavelength.

21
22 Calibrated spectroradiometer data of Exotech Model 20C
23 spectroradiometer, on Russell Silt Loam Soil, in the Purdue University
24 Agronomy Farm, W. Lafayette, Indiana were available for comparing
25 experimental results with theoretical calculations. Using the emittance
26 and contact temperature of the soil and the calculated value of solar
27 irradiance, calculations of radiant flux density, reflected as well as

1 emitted from the soil, were done using Kirchoff's law and assuming
2 the target to be lambertian in both reflecting and emitting modes.
3 Table 2 is a comparison of the experimental results with the
4 theoretical calculations. It indicates that the radiant flux density
5 reflected from the target from 3.6 to 4.5 μm cannot be neglected, as
6 compared to the radiant flux density emitted by it. The table also
7 shows that experimental results agree reasonably well with the
8 theoretical calculations, except in 4.8 to 5.1 μm and 5.1 to 5.4 μm .
9 This is because atmospheric (emitted) exitance reflected from the
10 target is not likely to be negligible in these wavelength regions
11 (Kumar, 1976, 1977).

12
13 It should be noted that due to significant
14 contributions of radiant flux density reflected from the target, average
15 spectral radiance temperature in the wavelength ranges 3.6 to 3.9 μm
16 and 3.9 to 4.15 μm is higher than the contact temperature of the
17 target. This illustration (Table 2) is created because Table 1 might
18 give misleading indication to many readers that emittance of the
19 targets decreases with increasing wavelengths.

20
21 II. Experiment on Non Systemic Stressed Corn Plants

22
23 From the analysis of variance for factorial design,
24 the following conclusions were obtained: (1) $\bar{T}_s(\lambda)$ of the corn Pioneer
25 3306 was not found to be statistically significantly different from
26 $\bar{T}_s(\lambda)$ of the corn Pioneer 3571. This means that although the
27 experiment was conducted for only two hybrids of corn-Pioneer 3306 and

1 Pioneer 3571--the results obtained from this analysis may well be
2 applicable to many other corn hybrids. (2) $\bar{T}_s(\lambda)$ of the healthy corn,
3 blighted corn inoculated on 14 July (average blight level³ = 1.40) and
4 blighted corn inoculated on 28 June (average blight level³ = 3.4) were
5 found to be statistically significantly different (3) $\bar{T}_s(\lambda)$ of the
6 corn (healthy and blighted), on 9 August, was found to be statistically
7 significantly different from $\bar{T}_s(\lambda)$ of the corn on 17 August.

8
9 Values of $\bar{T}_s(\lambda)$ of the healthy, late inoculated
10 blighted corn and early inoculated blighted corn are given in Table 3.

11
12 The variables which can cause differences in the
13 average spectral radiance temperature of the healthy and blighted corn
14 are given by Kumar & Silva (1973, p. 161). Based on limited
15 measurement of the emittance of the healthy and blighted leaves, it was
16 concluded that there was no significant difference in the emittance of
17 healthy and blighted leaves. From fifty readings of the temperature of
18 the healthy spots of leaves, blighted spots of leaves and air
19 temperature near leaves, no statistical significant difference between
20 the temperatures of healthy spots and the blighted spots of leaves was
21 found.

22 From these experiments, it seems that neither the
23 difference in contact temperature nor the difference in emittance is a

24
25 ³ Average blight level of the blighted corn inoculated on July 14 is
26 defined as the average of the blight levels of four plots, inoculated
27 on July 14, from which the spectroradiometric data was taken. The
average blight level of the blighted corn inoculated on June 28 is
defined similarly.

1 predominant factor causing the differences in the spectral response of
2 the healthy and blighted plants. The percentage of ground cover of a
3 corn plant decreases as the blight level increases. It was found
4 during the ground observations that the temperature of the shaded as
5 well as sunlit soil decreases as the percentage of ground cover
6 increases. The preliminary conclusion, yet to be confirmed by further
7 experiments, is that the percentage of soil visible from the
8 spectroradiometer, especially the sunlit soil is the predominant factor
9 causing the differences in the average spectral radiance temperature of
10 the healthy and blighted corn plants. The results of the ground-cover
11 experiment support this conclusion. $\bar{T}_s(\lambda)$ of the blighted corn plants
12 was found to be higher than $\bar{T}_s(\lambda)$ of the healthy corn plants because
13 there was relatively more percentage of soil visible from the
14 spectroradiometer under the blighted plants than under the healthy
15 plants and the average spectral radiance temperature of the soil was
16 higher than that of the leaves. Kumar and Silva (1973) found, from a
17 detailed analysis of aircraft twelve channel MSS data in the 0.46 to
18 11.7 μm of ten flightlines, that the spectral classes of healthy and
19 blighted corn are most separable in the wavelength range 1.00 to 1.40 μm .
20 Again, the reason for this is probably that the percentage of soil
21 visible from multispectral scanner is a predominant factor causing
22 differences in spectral response of healthy and blighted plants and
23 there is much contrast between the reflectance of the soil and the
24 plant leaves in this wavelength region (Myers et al. 1964).

25

26

27

1 II. Experiment on Systemic Stressed Corn Plants

2
3 The means of $\bar{T}_s(\lambda)$ of the three corn plots with
4 different nitrogen application, (0, 67 and 201 kg/hectare), were found
5 to be statistically significantly different and are given in Table 4.

6
7 It shows that $\bar{T}_s(\lambda)$ of nitrogen deficient plants (0
8 and 67 kg/hectare) was significantly higher than $\bar{T}_s(\lambda)$ of healthy
9 plants. In the wavelength ranges 3.6 to 3.9 μm and 3.9 to 4.15 μm ,
10 $\bar{T}_s(\lambda)$ of the plants having nitrogen application of 67 kg/hectare was
11 higher than the $\bar{T}_s(\lambda)$ of plants having nitrogen application of 0 kg/hec
12 tare. However, this difference is small and is of the order of
13 experimental errors involved in determining $\bar{T}_s(\lambda)$. Although no detailed
14 measurements of emittance and contact temperature of the leaves were
15 made, based on the results of experiments nos 1 and 2, the percentage
16 of soil, especially the sunlit soil, is an important factor causing the
17 differences between the spectral response of the healthy and
18 nutritionally stressed plants. The higher $\bar{T}_s(\lambda)$ of the nutritionally
19 stressed plants can be explained by the fact that they had a
20 significantly greater percentage of soil visible from the
21 spectroradiometer, as compared to the healthy plants.

ACKNOWLEDGEMENTS

We gratefully acknowledge the assistance of Messrs. R. Haselby, B. Robinson and W. Simmons of the Laboratory for Applications of Remote Sensing (LARS), Purdue University in the calibration of the spectroradiometer. We also wish to thank Dr. J. Cipra for his assistance in the design of the experiment and Miss Marilēa Lopes Garcia for typing this manuscript. We are deeply indebted to Dr. Nelson de Jesus Parada (Director), Dr. Derli Chaves Machado da Silva and Dr. Celso de Renna e Souza of the Instituto de Pesquisas Espaciais (INPE/CNPq) for providing facilities for the completion of this manuscript at INPE.
