FOREWORD

This memorandum presents information acquired in preparation for conducting a test to validate plume simulation procedures for Shuttle (Test FA-17). This work was performed for the Systems Dynamics Laboratory of MSFC under Contract NAS8-32128. The NASA Technical Coordinator for this work is Mr. Kenneth L. Blackwell of ED32. Appreciation is extended to Dr. W. A. Foster, Jr., of Auburn University, for the elevon balance design and analysis efforts.

1. INTRODUCTION

The Space Shuttle Launch Vehicle (SSLV) configuration exhibits significant interaction between the main propulsion plumes and the vehicle aerodynamics. Exhaust plumes from the Space Shuttle Main Engines (SSME) and Solid Rocket Boosters (SRB) interact among themselves and with the external flowfield. This interaction establishes the base environment on the Orbiter, SRB, and External Tank (ET); affects aerodynamic stability and control (via flow separation); and affects the aerodynamic control surface effectiveness.

A comprehensive study keyed to analysis of well-chosen experiments has been in progress for some time, Ref. 1. The ultimate goal is to base the SSLV aerodynamics upon measured values from a subscale model test in a wind tunnel, while using proper simulation of the propulsion plumes. To meet that goal requires validation of this simulation procedure.

Simulation of a model to a prototype plume has been considered by many (Refs. 2-13), and it appears sufficient to match shape and edge viscous effects, Fig. 1. A simple concept to achieve this match would use a geometrically scaled nozzle flowing the prototype plume gas. However, matching of γ and temperature is not available at this time by means other than use of subscale rockets. It would have been very complicated and expensive to base the complete SSLV development program on such subscale rockets. Therefore, a simpler technique was sought; use air jets and match some appropriate simulation criteria. Review of prior work indicated that matching Herron's parameters (Ref. 10) might be adequate simulation.

An investigatory test (MA-10F) initiated the experimental effort in mid 1973. Subsequently, an extensive program has been performed. The bulk of

1

testing has involved a simple ogive-cylinder body, with limited investigations of the SRB flare effect and the SRB+ET combination. Parallel to the experiments has been analytical effort aimed at verifying the applicability of Herron's parameters (Ref. 10), especially δ_j , or finding other adequate correlators (Refs. 14, 15).

More recently the parameter $\delta_{j\gamma}\xi$ (where ξ is a function of M_{∞}) has been recommended to provide adequate correlation between gas-only and solid-propellant exhaust (Ref. 16).

This memo presents the results of an effort to plan a final verification wind tunnel test (FA17) to validate the recommended correlation parameters and application techniques. The test planning effort is complete except for test site finalization and the associated coordination. Two suitable test sites are identified. Desired test conditions are shown in Table 1. Subsequent sections of this memo present the selected model and test site, instrumentation of this model, planned test operations, and some concluding remarks.

2. MODEL DESCRIPTION

For this test program, the model must simulate all SSLV ascent propulsion plumes while maintaining geometric similitude to the SSLV vehicle shape. The effect of these ambitious constraints upon model selection are detailed in the first section below, followed by description of the physical and operational aspects of the selected model.

<u>2.1 Selection</u> - There are two basic approaches generally available: either adapt existing hardware to the specific needs of the contemplated test, or build new test-specific hardware. Both approaches were considered. The desired model features were:

- 1. Match external mold lines of SSLV ascent configuration.
- 2. Simulate hot, reacting exhausts of SSLV ascent configuration: a. SSME - O_2/H_2 at $P_C \approx 3000$ psia, $T_C \approx XXXX^\circ R$
 - b. SRB 16% A& solid propellant $@P_c \approx 600$ psia, $T_c \approx XXXX^{\circ}R$
- 3. Match P_c/P_m in transonic range.

The existing models that might be considered are of three general categories. First are those built under MSFC initiative for the plume technology program. Those described in Refs. 17 - 19 feature plume simulation via cold or warm (1000 °R) gas, and model shapes that are only generally similar to SSLV. Those described in Refs. 20 and 21 have solid propellant rocket motors for either a single body (Ref. 20) or for the SRB+ET combination (Ref. 21). Second are the Rockwell International (RI) models built for vehicle aerodynamic test which match the SSLV configuration and use cold air plume simulation, Refs. 22 and 23. Third is a single model built for RI and used for base heating tests, Refs. 24 and 25. This model, denoted 19-OTS, generally matches SSLV shape and features near duplication of SSLV plumes via O_2-H_2 combustion products for SSME and solid propellants for SRB.

Most of the models in the first two categories are designed for the plume simulation gas to be supplied from a source outside the model. It was judged impractical to attempt to pipe gases at 5000° R. Moreover these models would not have adequate structural integrity for such gases. The rocket models (Refs. 20 and 21) are akin to the SRB but quite different from the SSME. Furthermore, neither is very representative of the SSLV mold lines. Therefore, all models in the first two categories were eliminated. However, the 19-OTS model appeared very attractive for this application and was selected for adaption.

S.t.

This model is 2.25% scale, and is very close to the current SSLV configuration except that the ET is one diameter longer and the O/ET attachment structure is not to scale; it has about 0.6 sq. ft. of frontal area. The plume simulation operates at 50% of nominal flight P_C values, for 30 - 60 msec. For this size model to present only 0.5% blockage requires a tunnel of 120 sq. ft. cross-section. A 0.5% blockage value is suggested as appropriate for transonic testing, especially when considering that the plumes increase the effective blockage. The available model P_C level would require a variable-density tunnel to match flight values of P_C/P_{∞} . The impact of the short duration of plume simulation upon instrumentation is detailed in Section 4, below. The impact of the overlong ET is discussed in Section 6, below.

Consideration was also given to building new test-specific hardware. Three features of such a new model could be more attractive than the 19-OTS model:

- 1. Smaller size so that a smaller, less expensive tunnel could be used.
- 2. Higher P_{C} so that a variable density tunnel would not be needed.
- 3. A simpler SSME simulation might be devised probably a solid propellant rocket.

Investigation of these ideas did not indicate that a new model would be justified. First, it was assumed that any new model would cost at least as much as duplicating the current 19-OTS model. Although the new smaller model would use less material, considerable engineering effort would be required to design any smaller O_2/H_2 valving or alternate SSME simulation technique. Such a cost would probably not be recovered from tunnel costs savings for any fore-seeable test program even if the new model were small enough to be tested in 4x4 or 6x6 foot tunnels. Moreover a 50% reduction (which might fit a 6x6 foot tunnel) would likely result in a significant reduction of plume simulation duration, probably as much as 50%. Although a duration of 30 msec is probably acceptable, 15 msec is probably not - see Section 4 below. Therefore, a smaller model was eliminated from further consideration.

Second, the provision of higher P_C was investigated. If such could be incorporated into the extant 19-OTS then a real savings could be realized. However, it was evident that this model was designed for the current pressure levels, and a factor of 2 increase could not be applied without complete

redesign. Thus higher P_C would mean a new model. As above, the cost of a new model could not be expected to be recovered from tunnel cost savings. Third, a simpler (i.e., solid propellant) SSME simulation would not be worthwhile by itself, but only in combination with either a smaller model and/or higher P_C capabilities. The high P_C capability would be for 3000 psia, and satisfactory current solid propellant model technology is not known. Therefore, further consideration of any new model was terminated.

Thus the 19-OTS model was selected for this program with certain instrumentation additions described in Section 4 below.

<u>2.2 Description</u> - The 19-OTS model was developed by Calspan Corporation during 1972-73, Refs. 24 and 25. Two test programs - IH5 and IH34 - were performed during 1974-75; the model was refurbished, improved and updated for the 1976-77 IH39 test (Refs. 26 and 27); and is now in use on IH75A. Thus this model represents mature design for which a considerable amount of experience is available. Fig. 2 depicts the model. Table 2 gives detailed dimensional data and Table 3 lists the associated drawings. The model ET mounts to a thin blade strut which attaches to a sting, and all instrumentation, control, and pneumatic lines are routed internally through them.

<u>Model</u> - This model operates on short-duration firing principles. Combustion products of H_2 and O_2 are provided to the three SSME nozzles, and 15% aluminum solid propellant combustion products to the two SRB nozzles, for near duplication of the SSLV. SSME and SRB nozzle internal surfaces are geometrically duplicated; external surfaces are smooth. These nozzle walls are structurally thickened to withstand heating. The skirt curtain between the SRB shroud and nozzle is simulated. The OMS nozzles are simulated externally and internally, although there are no flow provisions, and are positioned in their "stowed" ascent position (6° pitch down and 7° yaw outboard from null). A non-scale adapter connects the orbiter to the ET, containing propulsion supply lines, autovalve control lines, charge tube thermocouples, and cooling lines. It also provides a mounting surface for the orbiter wing. Flanges and a small strut connect the SRB's to the ET. The ET is one diameter longer than correct scale.

Model 19-OTS was built to the Space Shuttle Vehicle 5 lines and conforms to the following Rockwell International Space Division Drawings:

Considerable complexity is associated with H_2/O_2 combustion process. This system consists of H_2 and O_2 charge tubes, a fast-acting bi-propellant valve (autovalve), H_2 and O_2 metering venturis, an injector, a combustion chamber, and the three SSME nozzle assemblies. The charge tubes are arranged spirally in the ET; all other items are in the orbiter. These charge tubes supply gases at approximately 3000 psia through the autovalve to the venturis. When the autovalve opens, the gases are supplied to the venturis at constant conditions for the expansion wave time of the charge tubes. The autovalve is a pneumatically operated piston-type valve, Fig. 3. Two electrical solenoid (Valcor) valves, when energized, permit high pressure N_2 (approximately 3000 psia) to enter chambers within the autovalve and move the piston to open or close the O_2 and H_2 ports. The autovalve is probably the most complex item associated with this model, initiating then terminating the SSME nozzle flows

Fig. 3 Autovalve Concept

RM 024-1

within controllable periods as brief as 30 msec. The venturis operate under choked flow conditions, and are designed for an O/F ratio of 6.0. The single injector is composed of twelve doublets designed to impinge on a diameter equivalent to the combustion chamber area mean diameter. Doublet holes are equal in size, angled to balance the radial momentum of H_2 and O_2 streams. The single combustion chamber provides the necessary volume for the gases to mix and burn, and is common to all three SSME nozzles. A pyrotechnic ignition source is located in the chamber. Nominal P_c is 1500 psia and is controlled by charge tube pressure and losses in the autovalve, venturi, and injector. Nominal run time is 30 msec. Up to 60 msec can be readily obtained but leads to some hardware deterioration (one inadvertant 150 msec run resulted in a hole being burned in the combustion chamber wall).

In effect, the SSME exhaust simulation involves all of the aspects of the NASA/MSFC Impulse Base Flow Facility except for the IBFF's vacuum cell feature.

In addition, this model has solid propellant charges for the SRB simulation. These items are similar to the Calspan-developed motors used on the MAIIF, FA7, and FA22 tests, (Refs. 28-30), and are essentially identical to those used on the FA23 test (Ref. 21). Each consists of a propellant holder, ignition gas system, diaphragm, and nozzle assembly. SRB flow is controlled by the amount of solid propellant used. The propellant holder is a cylindrical casing which fits inside the SRB. Solid propellant is glued to a thin aluminum sheet (0.011 in. thick) and rolled to fit inside the holder. GN_2 coolant is flowed through the propellant holder to maintain the propellant at a constant temperature during the wind tunnel run before ignition. To insure rapid and simultaneous ignition of the two SRB's, both are filled with a mixture of ethylene (C_2H_6) and oxygen immediately before the desired firing time. A pyrotechnic source ignites this gas mixture which in turn ignites the propellant. A single igniter is used for both SRB's. The diaphragm is contained in the aft propellant holder and cap. It is made of thin sheets of Mylar sized to burst slightly above the desired P_c . An 0.063 in. diameter hole is at the center of the diaphragm to permit the N_2 coolant flow to exit. The solid propellant is ANB-3066B, a 15% AL/AP/CTPB composition which is an ICC Class B explosive that functions by rapid combustion rather than detonation. Burning rate is a function of pressure, temperature, and humidity. Nominal P_{c} is 290 psia and nominal duration is 100 msec.

Data typical of model operation is shown in Fig. 4.

<u>Gas Supply and Control</u> - Considerable effort was expended by NASA-Lewis to design and build gas supply and control systems for the IH-39 test. The concept is sketched in Fig. 5. The detailed schematics are presented in NASA-Lewis drawings MDS-945 Revision K and MDS-945A, Revision G (Fig. 6). Five plumbing panels were built: one each for SSME O_2 , H_2 , 6000 psi N_2 , cooling/purge N_2 , and ethylene/oxygen for SRB ignition. These panels and all supply bottles were mounted atop the tunnel test section, except for the cooling N_2 which came from a trailer parked outside the tunnel building. In the control room, an extensive console was used to monitor and control these gas systems.

3. TEST SITE

The selection of the 19-OTS model has a significant impact on wind tunnel selection. The size of this model combined with the need to keep blockage at or below 0.5% requires a tunnel test section of 120 sq. ft. The model P_c levels combined with the need to match P_c/P_{∞} requires a variable density facility able to provide $q_{test} = 0.5 \times q_{flight}$. For these constraints combined with the desired Mach range of Table 1, there are only two candidates:

| <u>NAME</u> | SIZE | MACH RANGE |
|----------------------|-------------|------------|
| NASA Ames UPWT 11x11 | 121 sq. ft. | 0.5 - 1.4 |
| USAF AEDC 16T | 256 sq. ft. | 0.6 - 1.6 |

Both operate in continuous, as opposed to blowdown, mode. The capabilities of these candidates are compared to the requirements (using the Ref. 31 flight profiles) in Fig. 7. Either facility could meet the primary test needs. There are secondary technical items which favor AEDC 16T: (1) propulsion testing is commonplace there so that provisions for propellant handling, exhaust gas scavenging, etc., are already available; and (2) the larger size minimizes any wall effects on the model. These items alone would not compel the selection of AEDC 16T. Rather, cost and schedule (availability) considerations could be the deciding factors. Final selection and scheduling is beyond the scope of this effort.

4. INSTRUMENTATION

The 19-OTS model was built for base heating studies, and has been provided with extensive instrumentation in the base region of each component. This instrumentation measures surface pressures, temperatures, and heat transfer. Only the pressure instrumentation would be of use for FA-17 needs. However, base pressure alone would not fully satisfy the goal of validating that the recommended plume simulation parameters adequately account for all of the important plume-induced aerodynamics. For this goal it would be necessary to measure pressures or forces on the wing, elevons, body flap, vertical tail, and nozzles. To thoroughly quantify the complex aerodynamics on these complex geometries via surface pressure measurements would require a very large number of taps. A simpler approach is to incorporate force balances

into these components. Such balances must withstand the most critical of either power-off or power-on steady loads, and measure the power-on loads with precision adequate to satisfy the validation goal. Also, because metal balances would not damp out to steady state in the short duration of plume simulation (without providing mechanical dampers which would be complex beyond practicality of this test), special data reduction techniques will be needed. The design of balances to meet these criteria was undertaken. To date the wing balance and elevon flexures have been completed, as described below.

Loads were taken from earlier wind tunnel test programs. To establish the loads it was necessary to define the desired range of elevon deflection angles as these deflections cause significant effects on both wing and elevon loads. The flight values of deflection angles and angle of attack are not precisely known because in flight they will be controlled so as to minimize total wing loads. Estimated elevon angles are shown in Fig. 8; anticipated excursions about this nominal schedule are \pm 3-4°. The FA-17 wing and elevon balances were designed for this envelope of elevon deflections.

<u>4.1 Wing Balance</u> - The wing balance is intended to measure normal force and its location. For the FA-17 test it would be important to precisely measure the difference in plume on and plume off normal force; this difference was estimated to generally be no more than 10% of the likely plume off design level.

For wing balance design loads, data from Test IA80 were used. That test covered the range M = 0.9 \rightarrow 1.4 and α = -4° \rightarrow +4°, both with and without plume simulation. These data showed that normal force at the nominal flight value of $\alpha = 2^{\circ}$ would be no larger than about 22.5 lb., but this value would increase 4-6 lb. for each increase in α of 1°. Thus a balance designed to accommodate α = 4° would be operating at half or less of maximum capacity at the most important condition ($\alpha = -2^{\circ}$), with correspondingly reduced accuracy, especially considering the need to quantify plume-on to plume-off differences. This type of problem frequently arises, and can be handled by several techniques: different capacity balances for differing load ranges, lowering tunnel dynamic pressure to maintain constant force levels as nondimensional force coefficients increase, or limiting the test matrix. For this program it was decided that providing several balances would be too expensive, and that the change in Reynolds number accompanying a change in tunnel dynamic pressure would be unacceptable. Instead, it was decided to design the wing balances for $\alpha = -2^{\circ}$ and limit testing with this wing balance to $\alpha < -2^{\circ}$, while planning to test at $\alpha > -2^{\circ}$ with other instrumentation (elevon balances, base pressures, etc.). Thus, design wing loads were F_N = 22.5 lb., $dF_N/d\alpha$ = 6 lb./deg.

Wing center of pressure was relatively constant, generally being within \pm 0.25 in. of a point 3.0 in. forward of the elevon hinge line and 4.7 in. outboard of the wing root, Fig. 9. Wing mass properties were obtained by approximating the wing defined on RI Drawing SS-H01620, 4/12/76, by 41 trapezoidal prisms. These mass properties and loads were used to design a wing balance which could meet both static and dynamic conditions. Maximum stress at the gages of 10,000 psi was the design criteria. Location of this balance was severely constrained by the 19-OTS model fuselage design which was utilized for valving, metering, and combusting O_2 and H_2 . The only practical approach was to locate the balance in the volume originally used for wing attachment. A single point mass was used to represent the wing, and the balance was analyzed as a simple cantilever. The resulting design is sketched in Fig. 10. A prototype balance was built, gaged, and calibrated at MSFC. An aluminum wing approximating the 19-OTS wing was also built. The combined prototype balance

RM 024-1

Fig. 9 Wing Properties and Loads

<u>_</u>.

Fig. 10 Wing Balance

and simulated wing were tested for dynamic response, by hanging a weight at the estimated c.p. and then suddenly removing it. Response was satisfactory. Thus, the wing balance design capabilities have been demonstrated.

A deflection analysis of this balance indicates an angular deflection less than 0.1°. Such motion would mean about 0.015 in. tip deflection.

<u>4.2 Elevon Flexures</u> - The elevon flexures are intended to measure hinge moments. As with the wing balance, it would be important to precisely measure the difference in plume-on and plume-off hinge moments; these differences were estimated to be as much as 30% of maximum expected plume-off levels.

For elevon flexure design loads, data were used from Tests IA93 and IA135 as developed in Ref. 32. Inspection of these data did not clearly indicate which conditions might be critical. The main reason was that high confidence could not be placed in the elevon c.p. locations. To define the design loads, an envelope of loading cases was developed for all conditions of M = 0.9 - 1.25, $\alpha = -4^{\circ} \rightarrow 0^{\circ}$ at Schedule 6 deflection angles (Fig. 8) for each elevon: inboard and outboard. The hinge moments in these envelopes were taken from Test IA93 data, increased by 30% to account for expected differences in plume-on to plumeoff. The longitudinal c.p. locations were taken from Ref. 32. From inspection of these envelopes, three extreme cases were selected for each elevon. To estimate the lateral c.p. location, the Test IA135 data were integrated for the same conditions. The resulting locations were close to the respective c.g. locations. These selected cases are shown in Fig. 11.

Fig. 11 Elevon Properties and Loads

RM 024-1

Elevon mass properties were obtained as for the wing by approximating the elevons defined on RI Drawing SS-H01620, 4/12/76, by trapezoidal prisms. These mass properties and loads were used to design elevon flexures which could meet both static and dynamic conditions. It was desired to have each flexure be full span for the respective elevon to obviate any gap sealing problem, while achieving approximately 10,000 psi stress in the flexure to ensure adequate strain gage output. It was found that thickness of .030 -.032 in. were satisfactory for the static load situation. A dynamic analysis was then performed for a limited number of candidate designs for the Fig. 11 loading cases using the NASTRAN code. The dynamic analysis used a 2 msec ramp function (based on Ref. 24), and a structural damping coefficient of 1% of critical. The response characteristics were acceptable and the resulting flexure designs are sketched in Fig. 12.

<u>4.3 Other Instrumentation</u> - The 19-OTS model has several surface pressure ports which might be of some interest to the FA17.test, plus instrumentation to monitor the plume simulation equipment. Sixteen thermocouples are provided to monitor the temperature of the piezoelectric pressure transducers, Valcor valve cavity, charge tube gases, and SRB propellants, Table 4.

Piezoelectric pressure transducers are connected to the 33 surface pressure ports used for plume-on test data plus the 7 plume simulation monitoring ports. These transducers are mounted inside the model. Each transducer is compensated for acceleration and has a heat shield to minimize temperature and radiation effects. These piezoelectric transducers operate in a differential mode as opposed to an absolute pressure mode, and thus require a reference (plume-off, steady-state) pressure. For the 33 model surface pressure ports there are 17 reference surface pressure ports, which are connected by 0.095 in. i.d. tubing to a single, conventional stain-gage diaphragm pressure transducer through a scanning valve, located outside the wind tunnel. The two transducers monitoring SRB P_c are referenced to the pre-fire pressure of the ethylene-oxygen ignition gas mixture. For the other five monitoring transducers, the pre-fire reference pressures are so small relative to operational plume-on pressures that they may be neglected. The pressure transducers are summarized in Table 5, and their locations are sketched in Fig. 13.

5. TEST OPERATIONS

There are a variety of operations associated with this test whose needs sometimes conflict: safety in handling the various potentially hazardous materials used in plume simulation; quality of data especially in precise synchronization of the five exhausts and in well-calibrated instrumentation, and productivity in conducting the program with a minimum amount of test site occupancy. The ability to achieve the first two items has been demonstrated on each previous test using the 19-OTS model, but high productivity has not been shown. Operational details of the IH-39 test are presented in Ref. 33.

Pending final negotiations with a suitable wind tunnel, it is expected that equipment for this test will be supplied as follows. NASA-MSFC (either directly or through a contractor) will furnish the required number of piezoelectric pressure transducers with power supplies, thermocouples, and all wiring within the model. The wind tunnel will furnish scanning valves and transducers for the reference static pressures, an angle of attack indicator, and wiring from the model sting to the control room.

<u>5.1 Test Conditions</u> - Values of the various test parameters have been selected to cover a limited parametric investigation of the flight regime critical to plume simulation for power-on aerodynamic considerations. The transonic Mach number range for ascent along a nominal KSC ascent flight profile was selected, Table 6. The 19-OTS model is limited in SSME P_c to approximately one-half

THE TRANSPORT

of flight values, so to maintain P_C/P_{co} in test equal to the flight ratio, tunnel pressures were selected to be one-half of flight, Table 7. Values of angle of attack were selected to cover the expected flight range, but use of the wing balance must be limited, as discussed above, Section 4.1. To encompass the desired range of Mach number and angle of attack, while keeping the total program to a practical level, elevon deflection angles were generally limited to nominal values. Both SSME and SRB P_C were absolutely limited to nominal values. The total program is summarized in Table 7.

<u>5.2 Procedures</u> - There are several categories of procedures involved: instrumentation calibration, plume simulation equipment activities, data acquisition, normal run sequence, and abort/malfunction sequence. The latest integration of these functional procedures into a comprehensive sequence of steps is shown in the Appendix, Test IH-39 Checklist.

The piezoelectric pressure transducers will need to be calibrated at a series of discrete operating temperatures before installation in the model, to define the change of millivolt output with pressure, at each specified temperature. Low range transducers used for model surface pressure measurement should be calibrated at 75°F, 100°F, and 125°F. High range transducers used to monitor the propulsion simulation equipment should be calibrated at 100°F and 200°F. The electronic output of these piezoelectric transducers vanish under a continuous pressure, so it is necessary to use a device which applies a step pressure load and use the resulting instantaneous output values in the calibration. The conventional strain-gage pressure transducer used for plume-off steady-state reference pressures can be calibrated for room temperature operation. The wing and elevon balances will need to be calibrated before installation on the model. Additionally, frequent checks should be made during the test to verify that the primary calibration has not shifted for any reason. Special jigs/fixtures will need to be provided to facilitate these check calibrations.

To preclude damage from exposure to the elevated temperature of the continuous tunnel airstream, the piezoelectric transducers should be cooled to approximately 80°F and the SRB propellant and Valcor valve cavity to approximately 100°F, using GN_2 as coolant. Cooling lines for the piezoelectric transducers are routed to the SRB shrouds, the ET base cavity, the orbiter base, and the OMS pods. Cooling to these areas should be used while the tunnel is operating except when the test data are being recorded during model firing.

and a second statement and a source from the second statements and the second statements and the second second

Activities related to the plume simulation equipment begin with loading solid propellant into the SRB's. Pyrotechnic igniters for SRB's and SSME are installed. Completion of the pre-run checklist will verify readiness of model fuel and control systems, model configuration, and instrumentation. Then the tunnel may be closed and pumped down with the model at $\alpha = 0^{\circ}$ and GN₂ model instrumentation cooling initiated. Start the tunnel and obtain desired conditions; during this time, pressurize the autovalve charge tubes, and make any needed timing ajustments to the firing sequence control panel. If the charge tube gas temperatures vary significantly during this period, the charge tube pressures must be adjusted so that the fixed-geometry venturis will maintain the desired O/F = 6.0. Adjust model angle of attack as required. Verify that fuel, control, and recording systems are correctly adjusted and operating. When affirmative, cease cooling to the model and charge the SRB's with ethylene and oxygen. Operate the firing button. The firing sequence control panel will be used to control the SSME and SRB flows. The steady plume-on SSME flow will be limited to about 55 msec maximum to preclude deleterious nozzle heating. (This setting will produce a total SSME flow time of approximately 65 msec.). The steady plume-on SRB flow time will nominally be 100 msec for a nominal propellant thickness of 0.050 in. Due to the time required to reach steady plume-on conditions, the SRB flow will always be initiated before the SSME flow. All of these times are preset into the control panel, so operating the firing button activates each item at the proper time, including recording data. After the firing, resume model cooling, shut off recording equipment as appropriate, and set the model to $\alpha = 0^{\circ}$ for tunnel shutdown.

In the event of an aborted run or a malfunction in the plume simulation equipment, detailed procedures of the Appendix should be followed.

Data acquisition will be performed at five time periods:

| 1. | Just before | closing the tunnel | (ambient | pre-fire | call) |
|----|-------------|--------------------|----------|------------|-------|
| 2. | Just before | firing the motors | (tunnel | pre-fire d | call) |

- 3. During the motor firing plume on
- 4. Just after firing the motors
- 5. Just after opening the tunnel

Four of these periods are for plume-off conditions, and all channels will be recorded. For the plume-on condition, only the wing balance, elevon balances,

(tunnel post-fire call)

(ambient post-fire call)

base surface pressures and plume simulation monitoring ports (measured by piezoelectric transducers), plus events, will be recorded. The plume-off data will be recorded on digital encoding equipment, and the plume-on data onto an analog type system as a function of time. Table 8 summarizes the data acquisition process.

There are some photographic procedures involved. Installation photographs of each test setup are required. Photographs of the model assembly, components, instrumentation, etc., will be taken upon request of the responsible test engineer. Close-up photographs of the model instrumentation are required. High speed Schlieren movies are required for each run. The primary interest is the flow field generated by the model plumes and boundary layer separation induced by the model plumes.

5.3 Data Reduction and Presentation - Data from the wing and elevon balances will need special handling because these devices will not reach steady state operation during the time of plume simulation. Instead, their output data history will be a lightly-damped sinusoidal function, Fig. 14. The elevon balance is expected to require approximately 400 msec for oscillations to damp to about 5%, and approximately 600 msec to damp to about 1%, while plume simulation will be limited to about 55 msec. However, the balance dynamics are predicted to cover several cycles during plume simulation. A suitable approximation to the steady state value that would result if the plume simulation could be maintained for a long duration can be obtained from:

$$E_{\text{steady state}_{i}} = \frac{1}{2} \begin{bmatrix} 1_{2}(E_{\max} + E_{\max}) + E_{\min} \end{bmatrix}$$
(1)

where E is the individual balance output term. Per the methods of Ref. 34 for damping equal to 1% of critical, the result given by Equation 1 differs

Fig. 14 Balance Data Output

33

RM 024-1

from the exact solution by only about 0.02%. To minimize random experimental effects, the several values obtained at different *i*'s would be averaged for either the entire plume duration or for a time interval to be decided for each run by the test engineer after inspection of the Visicorder output.

Data from the model pressure instrumentation recorded as functions of time will be reduced to a single value (per parameter), as averaged over a specified time interval. This interval will be decided for each run by the test engineer after inspection of the Visicorder output. Operations for the pressures are detailed below.

The 7 propulsion simulation operating pressures and the 33 model surface pressures recorded as functions of time on analog tape are to be reduced using Equation 2:

$$P(t) = \left(\frac{\Delta E(t)}{GAIN}\right) \times \left(\frac{1}{S}\right) + P_R$$

where \Deltage to by the recording system at time, t; GAIN = net gain of the electronic system between the sensor and recording system;

- S = transducer sensitivity;
- P_R = steady state plume-off reference pressure.

The steady state plume-off reference pressure, P_R , is to be reduced using standard test site methods and presented in engineering units. Table 5 listed the reference pressure to be used with each piezoelectric transducer. The piezoelectric transducer sensitivity to temperature, S, used in Equation 2 will be determined by the transducer temperature. The temperature of the high range transducers monitoring propulsion simulation operation will be assumed identical to the tunnel freestream total temperature. Calibration sensitivities will be available at 100°F and 200°F. The temperature of the low range transducers measuring base pressures will be determined by surrounding thermocouples. A transducer/thermocouple correlation was given in Table 5. Calibration sensitivity for Equation 2, assume a linear variation between calibration temperatures.

There will be a variety of different types of electronic circuitry used to link the model instrumentation (piezoelectric transducers) to the analog tape recording system. To obtain a true response from each model sensor, the output voltage signals must be corrected to account for the different time constant of each sensor electronic circuit. Voltage output signals are to be corrected using Equation 3:

34

(2)

Contraction of the second s

RM024-1

$$\Delta E_{c}(t_{n}) = \Delta E(t_{n})\left(1 + \frac{\Delta t}{\tau}\right) + \Delta E_{c}(t_{n-1})\left[1 - e^{\left(-\frac{t_{n}-1}{\tau}\right)}\right]$$
(3)

where ΔE_{C} = corrected voltage;

ال مدين ال التي المالة المالة المحادث المالية

- ΔE = actual voltage output at time, t;
 - t = time at which the voltage is being corrected;
 - n = the number of time intervals from 0 to t;
 - $\Delta t = t/n = time interval at which voltages are recorded$ $(<math>\Delta t = 0.4 \text{ msec}$);
 - τ = circuit time constant.

From Equation 3, the corrected voltage at any time, t_n , is a function of the voltage output at that time, t_n , and the corrected voltage at the previous data point, t_{n-1} .

The presentation of reduced data shall be in three categories: header data, raw dynamic data, and reduced data. Header data shall be listed with the reduced dynamic data for each run and shall consist of tunnel operating conditions evaluated just before model firing, model configuration data, and facility data. Raw dynamic data will be primarily be Visicorder traces but may also include tabulated data. Reduced data will include tabulated steady state data plus both tabulated and plotted dynamic data. Table 9 summarizes the data presentation. It is desired to be able to tabulate any of the dynamic data vs. time at any point during the test as required.

The availability of data should be as follows. Visicorder data should be provided immediately after the run. Digital encoded data should be provided for immediate playback in the control room. Selected analog tape channels shall be played back on Visicorders immediately after the run. Data on the analog tape should be reduced and provided in tabulated form 24 hours after the run. All header data should be listed with tabulated data 24 hours after the run. Plotted data should be provided one week after the run. There need not be a data tape for DATAMAN for this test. Two complete copies of the data will be required: one for the test engineer and one for NASA-MSFC. One extra copy of the summarized data will also be required for the test engineer.

6. CONCLUDING REMARKS

Test FA17 would most favorably be conducted with a modified 19-OTS model in the AEDC 16T facility, but could probably meet program goals if performed in the 11 x 11 leg of NASA-Ames UPWT. Final test site selection and scheduling is beyond the scope of this effort.

To achieve program goals the 19-OTS model should be modified to include at least wing and elevon balances, and it may be desired to consider body flap, vertical tail, and/or SSME nozzle balances. That is, use of the extant base pressure instrumentation alone is not likely to provide adequate verification of the candidate plume simulation/correlation parameters and application techniques. Use of the 19-OTS model with its short-duration firing principles will require competent (and preferably experienced) staff because of the associated complexities. However, this model has been successfully used for several years so that no conceptual difficulties are envisioned. A suitable wing balance design was devised and a prototype built and successfully demonstrated. Elevon balances were designed in a similar fashion. No other balances have yet been investigated in any detail.

The FA17 model would not exactly match that of IA119. To provide for direct comparison, it would be desireable to add a limited set of runs to IA119 with a modified model. This modification would involve increasing the ET length by one diameter, and replacing the scale truss ET-to-Orbiter attachment with a large solid strut. It is anticipated that only a limited test matrix matching Table 7 would be required.
