# STUDY OF METALLIC STRUCTURAL DESIGN CONCEPTS FOR AN ARROW WING SUPERSONIC CRUISE CONFIGURATION

M. J. Turner and D. L. Grande Boeing Commercial Airplane Company

### SUMMARY

The principal objectives of the present study were to assess the relative merits of various metallic structural concepts and materials suitable for an advanced supersonic aircraft cruising at Mach 2.7, to select the structural approaches best suited for the Mach 2.7 environment, and to provide construction details and structural mass estimates based on in-depth structural design studies of representative wing and fuselage structures. During the first part of the study, an arrow-wing configuration was analyzed in considerable detail for compliance with criteria derived from the National SST program. An advanced technology afterburning turbojet engine concept developed under contract NAS1-11938 was used for propulsion.

A study of the internal structural arrangement was conducted based on the arrangement developed in a previous study of an arrow-wing supersonic cruise aircraft (NASA SCAT-15F). A series of structural variations were evaluated. The wing structure that was selected consisted of a multispar internal structure with aluminum brazed titanium sandwich panels for the wing surfaces, except for a machined skin on the lower surface of the main wing box. The fuselage was of skin stringer construction. Titanium was used throughout.

A single basic finite element model of the structure was developed for aeroelastic loads, stress, and flutter analyses containing approximately 2000 nodes, 4200 elements, and 8500 active degrees of freedom. Analyses were performed by an integrated structural analysis and design system interfaced with loads and flutter analysis systems. The elements in the wing covers were resized using an automated resizing module in the integrated system, with convergence, measured in terms of total mass change, occurring in three cycles. Nine flutter analyses were conducted to evaluate a series of stiffness changes to remedy a flutter deficiency in the strength design. Stiffness changes were based on engineering judgment and experience from the National SST program.

The resulting configuration, designated the 969-512B, meets most of the specified study requirements, having a maximum taxi gross mass of 340 200 kg (750 000 lbm), and a payload of 22 200 kg (49 000 lbm) representing 234 passengers in tourist accommodations, and a cruise Mach number of 2.7. The structure, stability and control characteristics, and systems meet the appropriate requirements of Federal Aviation Regulations, Part 25, Airworthiness Standards: Transport Category Aircraft, and the Tentative Airworthiness Requirements for Supersonic Transports.

It is concluded that a major advantage of the integrated flutter analysis and design system is the reduction in resources and cycle time required to perform analyses. This improved efficiency permits stiffness requirements to be imposed earlier in the design cycle. Also, the study contributes to structural analysis and design methodology and provides a detailed mathematical model of the baseline airplane that can be used to evaluate design improvements and advances in technology for supersonic cruise aircraft. Recommendations for further development of integrated design tools and applications methodology are discussed.

### **INTRODUCTION**

This document presents a general description of a study conducted by the Boeing Commercial Airplane Company as a part of the NASA Supersonic Cruise Aircraft Research program. The principal objectives of the study were to assess the relative merits of various concepts and materials suitable for an advanced supersonic aircraft cruising at Mach 2.7, to select the structural approaches best suited for the Mach 2.7 environment, and to provide construction details and structural mass estimates based on in-depth structural design studies of representative wing and fuselage structures. A brief description of the study has been presented previously in reference 1.

The airplane configuration on which the structural analysis was conducted is an arrow-wing concept representative of a 1975 technology level. A Mach 2.7 arrow wing configuration was selected for these baseline studies because previous investigations have shown it to be one of the most promising aerodynamic configurations for supersonic cruise. It is derived from a configuration presented by NASA (see ref. 2), and is similar to the Model 969-336C that was studied during the National SST program (ref. 3). Since arrow wing aircraft tend to be large and flexible, aeroelasticity is a major design consideration, and realistic aeroelastic considerations based on analysis of finite-element structural models and sophisticated aerodynamic loading analysis are required even in a preliminary design study of such a vehicle. The amount of interaction between the various technical disciplines in aeroelastic problems requires the use of computer-aided design methods to improve and expedite the aeroelastic and structural resizing cycle (ref. 4).

A detailed multidisciplinary analysis of the configuration was conducted, and further modifications and refinements to the airframe were introduced. This effort focused on those aspects of the configuration that are likely to impose significant constraints on structural design. Engine locations were dictated largely by performance requirements. Also pitching moment characteristics related to stability and control were given careful consideration in establishing horizontal tail size.

Basic objectives of the evaluation of the metallic structure were to select materials and structural concepts that were consistent with the requirements of an aircraft designed to cruise at Mach 2.7 and based on a 1975 level of technology. In assessing the various structural concepts and materials, such factors as mass, ease of fabrication, sealing of fuel tanks, maintenance and servicing, material and fabrication costs, and fail safety were considered.

The analytical design studies were conducted to evaluate the importance of factors such as: variations of structural concepts, including sandwich panels, stiffened thin sandwich panels, skin-stringer construction, and variations in frame, rib, and spar construction; variations in landing gear and engine location and the effect of variations in engine support beam stiffness; effects of temperature on material allowables and temperature gradients on stresses; flutter; static aeroelastic effects; control systems interactions with the loads; and volume and insulation requirements for fuel storage. Particular emphasis was put on flutter, aeroelasticity, and practical design considerations such as fail safety

and fastener requirements. In addition to the usefulness of the results obtained for the specific configuration, these studies provided a unique opportunity to appraise the computer-aided design methods that have been developed by the contractor during the past few years, and to bring into sharper focus those problems and technology areas requiring structural evaluation.

The following sections of this report present an abbreviated account of the configuration definition study, followed by a detailed exposition of the structural analysis and design. This latter account discusses the concept selection process and the selected concepts, followed by an account of the analysis and design process. In addition to a description of the analytical methods for loads, stress, and flutter, the iterative design process is described, leading to the final member sizes that satisfy strength and flutter criteria.

Recommendations are presented for necessary improvements in prediction of aerodynamic pressure distributions, advanced titanium alloys, and improved structural concepts.

### **CONFIGURATION DEFINITION**

The airplane configuration on which the structural analysis was conducted is an arrow wing concept representative of a 1975 technology level. It was derived from a configuration presented by NASA (see ref. 2) and designated as model 969-510. This configuration is similar to the model 969-336C studied during the National SST Program (ref. 3) except for modifications to the wing leading edge sweep angle to provide additional wing chord and box depth in the outboard wing, and an outward shift of the engines to provide for a larger inboard flap to improve low speed lift. In addition to the above changes, the canard and "demand leading edge flap" systems which were present in the earlier configuration have been removed.

A detailed, multidisciplinary analysis of the configuration was conducted, focusing on those aspects of configuration that are likely to impose significant constraints on structural design. For example, engine locations were given considerable attention, and were largely dictated by performance considerations, with potential implications concerning wing flutter. Also pitching moment characteristics related to stability and control have been given sufficient attention to establish horizontal tail size.

### ENGINE DEFINITION

The engine selected for this study is an advanced technology afterburning turbojet engine designated ATAT-1 developed under Contract NAS1-11938. This engine was based on the GE4/J6G afterburning turbojet, with modifications to geometry, mass, performance, and noise derived from data for more advanced technology designs. The total installed engine pod mass of 7570 kg (16 700 lbm) is representative of advanced technology variable cycle engines currently being studied under contract to NASA-Langley Research Center. To minimize pod weight, the engine is operated at the maximum afterburning temperature of 1644 K (2960° R) at takeoff.

The performance of the ATAT-1 is based on the GE4/J6G engine, the most advanced afterburning turbojet defined in the course of the U.S. National SST program. The installed performance was calculated accounting for all intake drag and recovery losses, environmental control system, secondary air system losses, and bleed and power extraction losses associated with the pod.

Prior work on engine/airframe integration for large supersonic airplanes indicates that a minimum drag installation is achieved when pod inlets are located behind the line of maximum wing thickness and the maximum pod area is close to the wing trailing edge. Lateral pod location is determined by spacing required to avoid mutual pod inlet interference and does not have a significant effect on cruise drag.

### 969-512B CONFIGURATION

The configuration used in the structural study, designated model 969-512B and incorporating the refinements resulting from the configuration review, is shown in figure 1. Geometric data and other characteristics are listed in table 1. The following modifications were made in defining the configuration for the structural study:

TABLE 1.—CONFIGURATION CHARACTERISTICS, MODEL 969-512B

| Geometry        | -              |         | Wing                        | Wing vert.<br>stabilizer | Vertical<br>stabilizer | Horizontal stabilizer                   |

- 1. Reduction of wing tip leading edge sweep angle by 0.080 rad (4.6 deg) to increase wing tip lift capability and improve pitching moment characteristics
- 2. Alteration of planform and increase in area of horizontal stabilizer to increase effectiveness and satisfy nose-down control requirements
- 3. Replacement of all-movable vertical tail by a larger surface with fixed fin and segmented rudder to satisfy engine failure criteria.
- 4. Alteration of wing-to-fuselage location to reposition airplane center of gravity with zero fuel mass within acceptable limits
- 5. Increase of wing thickness over the wheel well to accommodate the landing gear without an out-of-contour fairing on the upper surface
- 6. 0.026 rad (1.5 deg) nose-down twist of wing tip to optimize cruise trim drag
- 7. Alteration of fuel tank arrangement to locate fuel in the aft body and deeper wing sections to reduce fuel heating during cruise

A group mass and balance statement for model 969-512B is presented in table 2.

### STABILITY AND CONTROL

### LONGITUDINAL CONTROL

The horizontal tail sizing for the 969-512B is based on updated low-speed stability and control characteristics. The minimum tail area that meets center-of-gravity range requirements is  $50.44~\text{m}^2$  ( $543~\text{ft}^2$ ). A study was undertaken to determine the airplane mass sensitivity due to variations in horizontal stabilizer size. Although a smaller stabilizer satisfies control power requirements, a larger stabilizer results in a smaller operating empty mass and permits a c.g. range extending farther aft, thereby improving the airplane loadability. Consequently, a  $55.74~\text{m}^2$  ( $600~\text{ft}^2$ ) horizontal stabilizer was retained for the 969-512B configuration.

### LONGITUDINAL STABILITY

To meet minimum safe operational criteria throughout the flight envelope, longitudinal and lateral-directional flight-critical augmentation systems were incorporated in the design. The longitudinal augmentation system, shown in figure 2, produces a pitch rate feedback signal that is used to generate increased aerodynamic stiffness and damping. A second-order structural filter is used to prevent coupling between airplane dynamics and structural modes.

Wind tunnel data for flaps-down arrow wing configurations exhibit an unstable pitch break although the magnitude is dependent on the leading edge flap configuration, leading edge radius, basic wing planform, and trailing edge flap configuration. An alpha limiter system is used to prohibit angles of attack greater than that corresponding to  $C_{L_{\mbox{\scriptsize MAX\,DEM}}}.$ 

TABLE 2.—GROUP MASS AND BALANCE STATEMENT, MODEL 969-512B

| Group                             | Mass<br>(kg) | Arm<br>(m) | Mass<br>(Ibm) | Arm<br>(in.) |

A conceptual block diagram of the selected alpha limiter system is shown in figure 3. This system will not affect airplane characteristics until the alpha limit is being approached. At this time it will modify the apparent airplane pitching moment by commanding nose-down elevator if the pilot has not already initiated recovery. A more detailed discussion of the alpha limiter system is published in reference 2.

### LATERAL-DIRECTIONAL STABILITY AND CONTROL

The area of the wing-mounted vertical surfaces was selected to provide neutral stability at the cruise condition. This was achieved by maintaining the same ratio between the vertical surface area and the gross wing area as on the Langley wind tunnel model. The centerline vertical surface has the same geometry as the 1971 U.S. SST and is sized for engine-out control.

At M=2.7,  $_{1}1$  g level flight, the yawing moments from an outboard engine seizure and inboard engine inlet unstart were balanced with rudder deflection and sideslip. The aerodynamic moments due to this failure mode were assumed to be the same as those for the 1971 U. S. SST (see ref. 2), adjusted for the new engine locations. The incremental change in thrust level due to this failure was also assumed to be the same as that for the 1971 U.S. SST.

At low speed the yawing moment from an outboard engine failure was balanced by rudder alone. The centerline vertical surface was sized to statically balance the engine-out moment at  $V_1 + 7.5 \, \text{m/s} \, (+15 \, \text{kn})$ . The centerline vertical surface yawing moment coefficients due to sideslip and rudder deflection were based on 1971 U.S. SST data.

The high-speed lateral controls for the 969-512B configuration consist of an inboard flaperon, an inboard and outboard plain spoiler, and an outboard inverted spoiler-slot-deflector. The estimated rolling moment contributions of the individual control surfaces are presented in table 3. These estimates are based on 1971 U.S. SST wind tunnel data where possible.

TABLE 3.-969-512B ESTIMATED LATERAL CONTROL POWER

$$\left(C_{\ell} = \frac{\text{rolling moment}}{\text{qSb}}\right)$$

The design of the lateral control system considered two types of engine failure: (1) an outboard engine seizure in combination with an inlet unstart and total flameout of the adjacent inboard engine; (2) an inlet unstart and total engine flameout of both engines on the same side. The engine seizure case was considered only at 1 g level flight because of the low probability of its occurrence. Satisfactory control was available, since the greatest roll control requirement occurred at the instant of engine failure, before any sideslip angle had developed.

The double unstart, having a relatively higher probability of occurrence, was considered at all load factors up to 2.0 g. In this case the airplane exhibits large dihedral effects and a decrease in directional stability. This results in an unacceptable engine failure case where insufficient control exists to counter the steady state condition, much less control the peak overshoot condition. The large control requirements are primarily due to the high dihedral effect exhibited by the configuration at the angle of attack required for 2.0 g flight.

Three approaches were considered to control the 2.0 g double unstart case:

- Increase directional stability
- Increase roll control power
- Control engine failure with an automatic unstart system

Increasing directional stability required an increase in vertical tail size resulting in unacceptable increases in drag and weight. An increase in lateral control required a significant increase in lateral control surface area, exceeding the available space on the wing. Consequently it was decided to introduce an automatic unstart system. The automatic unstart system will sense the presence of an outboard engine inlet unstart in combination with a lateral acceleration. When this occurs it initiates an unstart on the opposite engine inlet, thereby reducing the yawing and rolling moments caused by engine failure. The unstart procedure is terminated when the inlet is stabilized in the unstart mode.

A flight-critical augmentation system is used to meet minimum safe operational criteria. Figure 4 shows a functional diagram of the lateral-directional augmentation system mentioned earlier. In this system yaw rate and lateral acceleration are fed back to the rudder for dutch roll damping and sideslip control following engine failure, respectively. Yaw rate to aileron feedback is used to reduce the divergence rate of the spiral mode and roll rate to aileron is used to improve the roll time constant. Structural mode filters are used in all feedback loops to prevent coupling between airplane dynamics and the structural modes.

### FUEL TANK ARRANGEMENTS

The fuel tank arrangement selected for the 969-512B configuration is shown in figure 5. The temperature of the fuel in the tanks must be kept well below the boiling

temperature to prevent cavitation at the boost pumps. At supersonic cruise altitudes the average temperature of the fuel must remain below 344 K (160° F) for unpressurized tanks.

Fuel temperature for the basic tank arrangement used on the 1968 version of the arrow wing was analyzed during the AST Task III system study (Contract NAS1-11938) for typical flight profiles. These studies showed that the rear main tanks, tanks 2 and 3 in figure 5, were especially vulnerable to aerodynamic heating. The rear main fuel tanks together with the auxiliary tanks which feed them during supersonic cruise should have tank wall thermal conductances less than 14.2 W/m<sup>2</sup> K (2.5 Btu/ft<sup>2</sup>hr<sup>0</sup>R). The forward main tanks are less vulnerable to heating requiring tank wall thermal conductances less than 38.4 W/m<sup>2</sup> K (6.77 Btu/ft<sup>2</sup>hr<sup>0</sup>R).

In addition to the fuel temperature problem, the fuel tank boundaries were moved inboard and an auxiliary tank was added to the aft fuselage to position the c.g. within the airplane c.g. limits.

The total tank capacities are more than adequate to permit a mission starting at a maximum taxi mass of 340 194 kg (750 000 lbm) for any desired payload.

### STRUCTURAL DESCRIPTION

The objective of the structural evaluation was to select structural concepts for the 969-512B configuration consistent with the requirements of a Mach 2.7 supersonic transport and a 1975 program go-ahead. The structural definition of the 969-512B was arrived at by considering materials and concepts for a 1975 design freeze. The concepts and materials were reviewed and selections made for primary structural applications based on Mach 2.7 performance requirements. The components of the airplane that were chosen for structural evaluation are those having the largest potential impact on the mass of the airplane. These are the wing skin panels, wing internal structure, and the fuselage shell. A baseline for comparison was established for each of these components from the previous study of the 969-336C airplane. Alternate structural concepts were designed for each of these major components and compared with the baseline design. The alternate structural concepts were assessed for mass, manufacturing complexity, stiffness, fatigue, thermal conductance and material cost, and qualitatively evaluated for maintainability and fail safety. This evaluation provided the basis for specific structural concept recommendations for the 969-512B configuration.

The selected materials and concepts were integrated into the structural arrangement for detail analysis and design. The basic airframe internal arrangement is derived from the 969-336C. Variations in this internal arrangement such as multirib construction and spar and post were considered but none showed significant advantages over the baseline multispar arrangement with a small number of ribs. A similar arrangement was employed on the National SST.

The following paragraphs describe the basic structural arrangement, materials, concepts, and trade studies of alternate structural concepts. The concept trade studies consisted of evaluating mass, manufacturing complexity, maintainability, fatigue, fail safety, and material cost. Also, the mass difference was evaluated for variations in wing spar spacing, a multirib arrangement with sheet-stiffener surfaces, and a wide spar spacing with intermediate posts to support the surfaces. Each of these studies led to a selection of the most efficient concepts and arrangements for use on the arrow wing aircraft.

As shown in figure 6 the wing is of multispar construction with a small number of ribs. The spar spacing is 88.90 cm (35.00 in.). The ribs are positioned to distribute the engine libads into the wing box, close out the outboard side of the wheel well, back up the outboard fin, and close out the wing tip. The engines are installed with front mounts attached to the rear spar of the wing, and beams to support the aft engine mounts are cantilevered off the rear spar. The wing spars aft of the wheel well form the main wing box, extending continuously across the fuselage. Spars forward of the wheel well are attached to fuselage frames that transmit bending and shear loads across the fuselage. The wing leading edge flaps function as high-lift devices for low-speed flight; they are supported from the front spar. The region immediately behind the rear spar, and bounded by an auxiliary trailing edge beam, is occupied by actuators, accessories, wires, and hydraulic lines. Apart from the portions of fixed surface adjacent to engine nacelles and the wing-mounted fin, the trailing edge region is occupied by flaps and ailerons.

The body structural arrangement, a portion of which is shown in figure 7, uses semimonocoque construction with frame spacing of 44.45 cm (17.5 in.), except in the forward areas. The lower lobe structure is continuous since the main landing gear is stowed in the wing rather than the body. Floor beams are transverse to the airplane centerline, except over the wing carry-through structure, where they are oriented longitudinally. The body has a double lobe cross section; the floor beams are located approximately at the body crease line dividing the two lobes.

The horizontal and vertical tail surfaces are of multispar construction supporting aluminum-brazed titanium honeycomb sandwich surfaces. The leading edges and the rudder and elevators are wedge-shaped surfaces, also made of aluminum-brazed titanium sandwich.

### MATERIALS EVALUATION AND SELECTION

Structural materials for the wing and fuselage were reviewed and selections were made based on the assumption that the airplane design was to be frozen in 1975, using materials that would be available at that time. Materials are divided into three main categories – metals, advanced composites/adhesive bonding, and fuel tank sealant/insulation. Materials for various applications were selected by screening the potential candidates, considering a combination of availability, environmental effects, production capability, cost, and projected status of specifications and allowables. The chart in figure 8 summarizes this selection process. In this chart the factors evaluated are marked with a "yes" or "no" indicating acceptance or rejection, adequacy or inadequacy. Factors which were not evaluated are noted by a dash. The following paragraphs describe the selected materials.

### **METALS**

Ti 6Al-4V has been modified and improved during the National SST program and the subsequent Department of Transportation (DOT) funded technology follow-on program. The improved Ti 6Al-4V beta-processed material possesses superior fracture and fatigue properties. These improved properties, however, are achieved at the expense of a 3% to 5% strength loss and 7% to 12% higher cost. Specifications for this improved Ti 6Al-4V have been written and are designated Advanced Supersonic Technology (AST) specifications. The AST Ti 6Al-4V material is recommended for high toughness and fatigue design applications, whereas conventional MIL specification materials are recommended for airframe components designed primarily by strength or stiffness.

PH15-7Mo (Th 1050 heat treat) steel is recommended for sheet and plate. 15-5 PH corrosion-resistant steel and Custom 455 corrosion resistant steel are recommended for forgings that are subject to high operating temperatures for hot structure. 300M low alloy steel is recommended for cooled structure such as landing gear.

### ADVANCED COMPOSITES/ADHESIVES

Development of advanced composites has been actively supported by government and industry funding for the past several years. However, only a very limited amount of the

available data was considered applicable to Mach 2.7 commercial SST technology. None of the high-modulus, high-strength composites were developed sufficiently to be considered ready for primary structural applications requiring a 50 000 hr life with thermal cycling.

### **FUEL TANK SEALANT**

Of 14 candidate materials screened the fluorosilicone DC-94-529 was the only fuel tank sealant developed sufficiently to be selected for use in the 1975 time period. It has been tested extensively under a contract with the Department of Transportation, with test specimens being exposed to three cyclic environments similar to the conditions experienced in flight. One test sequence duplicated a typical flight and another continuously imposed the most severe high temperature, i.e., 500 K, (440° F), and fuel vapor environment. A third test utilized a small sealed tank exposed to alternating cycles of environmental exposure and loading.

Unreliable adhesion to titanium and low strength and elongation after elevated temperature exposure are recognized deficiencies. There is no suitable injection or faying surface sealant for a Mach 2.7 SST.

### **FUEL TANK INSULATION**

Insulation materials and concepts were reviewed to provide data for assessment of the fuel temperature problem and for estimation of insulation mass requirements. Since it was concluded that a substantial reduction in insulation requirements could be achieved by reduction of thermal conductivity of structure with improved fabrication techniques, it was not considered worthwhile to make detailed insulation design studies based on 1975 requirements.

Insulation is needed for the system lines routed through the fuel tanks to prevent heat transfer to the fuel, and for the tank walls and structure to prevent premature fuel vaporization. The amount of insulation needed depends, of course, on the conductance of the fuel tank structure. Figure 9 shows the total tank conductance as a function of panel conductance. The materials considered for fuel tank insulation are listed in figure 10.

The most practical conduit insulation is a foamed elastomeric fluorosilicone which may be wrapped around the tubing; joints may be sealed with the fluorosilicone fuel tank sealant. Thermal conductivity of the  $320~{\rm kg/m^3}$  ( $20~{\rm lbm/ft^3}$ ) material was estimated to be  $0.043~{\rm W/m~K}$  ( $0.3~{\rm Btu-in/ft^2hr^0F}$ ). Further development of materials and methods can be expected to result in both the density and thermal conductivity being reduced by one-half.

The type and extent of insulation for tank structure will depend upon structural design. Sealed evacuated batts, consisting of titanium envelopes filled with dexiglass, may be used. They have a conductivity of  $0.0058~\rm W/m~\rm K~(0.04~\rm Btu-in/ft^2hr^0F)$  and a density of  $380~\rm to~770~\rm kg/m^3~(24~\rm to~48~\rm lbm/ft^3)$ . The batts may be tack welded in place or bonded with fuel tank sealant. This concept is in an advanced stage of development.

A flexible foam insulation may be used for areas that are irregular in contour or too small for batts to be advantageous. It could also be used to cover stiffeners and other extensions into the fuel. A density as low as  $270 \text{ kg/m}^3$  (17 lbm/ft³) is attainable with a conductivity of 0.043 W/m K (0.3 Btu-in/ft²hr° F). It can be attached to surfaces with fuel tank sealant.

### STRUCTURAL CONCEPTS

The objective of the structural evaluation was to select structural concepts consistent with the requirements of Mach 2.7 and a 1975 program go-ahead.

The design loads and environmental conditions were established from the 969-336C study to provide a consistent basis for comparing each of the structural concepts. Structural concepts were evaluated at three locations on the wing, shown in figure 11, and four locations along the body, shown in figure 12. These points were selected to represent a typical range of structural requirements for an arrow-wing configuration. The critical design loads for each of these locations are presented in reference 2.

The concepts evaluated are identified in table 4. The initial selection of candidate structural concepts was generally based on previous evaluation experience on the National SST program.

| Component        | Location       | Material | Concept                             |

TABLE 4.—STRUCTURAL CONCEPTS EVALUATED

The concept evaluation utilized a rating system which included mass, manufacturing complexity, stiffness, maintenance, fatigue, fail safety, thermal conductance, and material cost. No concept with a major deficiency in any one characteristic was evaluated, regardless of other favorable considerations. As seen in tables 5 through 8, a rating factor was selected for each characteristic from a range of 0 to 100 (very poor to very good) based on the concept's merit relative to a baseline which was arbitrarily

Carry through to another level

A superior candidate is established on basis of factors considered

given a rating of 50. The concepts were screened through several levels of evaluation. Each level of evaluation considered a different characteristic starting with the most important (mass) and continuing in a descending order of importance to the lowest (material cost). Starting with two or three candidates from the first screening level, the best were evaluated through sufficient levels to establish a superior candidate. The symbols identify those concepts selected to carry through to another level of evaluation. The superior candidate is noted by.

### WING SKIN PANEL CONCEPTS

The baseline wing skin panels on the 969-336C at design point 249 and the lower surface at point 269 utilized titanium "stresskin honeycomb" with welded edge members as shown in figure 13. Stresskin is a spotwelded honeycomb configuration which has constant skin gages and no edge member when purchased from the supplier. The addition of welded edge members, milling of face sheets, and contouring of the wing skin panels was required to complete a typical skin panel assembly. A face sheet of 0.152-cm (0.060-in.) titanium was the upper limit of manufacturing capability as evaluated by Boeing. Since the loads at point 431 and the upper surface at point 269 require face sheet thicknesses greater than 0.152 cm (0.060 in.), the corrugated core sandwich was selected as the baseline. Panel face sheets are machined to provide integral edge attachments. The panels are assembled by spot welding at the corrugation nodes. These panels are structurally efficient for loads oriented axially with the corrugation but are relatively inefficient for transverse loads.

Five alternate structural concepts were designed for the wing skin panels. Each candidate specimen was designed and sized to maintain a margin of safety from 0% to 5% utilizing the material selections recommended from the material screening evaluation, and design loads and environmental conditions identical to those for the baseline skin panel. Static, thermal, and fail safe requirements were incorporated into the design of each specimen.

Silver-brazed steel honeycomb was investigated because of its potential structural efficiency at high temperatures and high end loads. This configuration was sized for both points 269 and 431. It was not investigated at point 249 because the low loads produce a minimum gage sizing which is heavier than similar concepts of minimum gage titanium.

These panels utilize PH15-7Mo steel face sheets with  $0.635\,\mathrm{cm}$  (1/4 in.) cell  $88\,\mathrm{kg/m}^3$  (5.5 lbm/ft³) honeycomb core also of PH15-7Mo steel. The steel-brazed honeycomb has good biaxial capability for  $N_x$  and  $N_y$  loads but is still less efficient than brazed titanium honeycomb configurations because of its lower strength to mass ratio.

The structural efficiency of aluminum-brazed titanium sandwich throughout the range of arrow wing end loads justifies its development as a candidate. The configuration was sized for all three control point locations, 249, 269, and 431. The configuration utilizes Ti 6Al-4V Condition I for the face sheets and 0.635 cm (1/4 in.) cell 78.5 kg/m<sup>3</sup> (4.9 lbm/ft<sup>3</sup>) field core sandwich of Ti 3Al-2.5V. The aluminum-brazed titanium core

sandwich is structurally efficient in reacting combined  $N_x$ ,  $N_y$ , and  $N_{xy}$  loads. This is a superior candidate because of the efficiency of honeycomb sandwich in the load ranges involved and the high strength to mass ratio of the titanium.

The waffle skin panel arrangement, fully machined from Ti 6Al-4V plate, was considered because of good biaxial capability compared to a conventional sheet stiffener arrangement. The waffle panel arrangements are of average structural efficiency for tension applications and below average efficiency for compression applications.

Riveted sheet stiffener construction was investigated for points 269 and 431 because of its manufacturing simplicity and relatively good tension efficiency. The sheet stiffener arrangement utilizes machined zee sections riveted to a machined skin. The stiffeners and skin material are made of titanium. This arrangement achieves a manufacturing rating of 54, the best of any concept investigated.

The integrally machined and welded sheet stiffener arrangements were designed to improve the transverse buckling capability. The configurations were sized for points 269 and 431 and utilized Ti 6Al-4V Condition I. The skin panel plate has machined elevated ridges and the machined stiffener angles are then butt welded to the outstanding ridges. The material which would normally be used in the stiffener skin flange has been redistributed into the sheet to improve the panel buckling allowable. The machined and welded sheet stiffener arrangement is a superior candidate for tension application but is not as efficient as honeycomb for compression application in the load ranges involved at points 269 and 431.

As discussed earlier, a candidate speciman was designed in detail for each structural concept at the points identified in figure 11. The specimen in each case was 30.48 cm (12 in.) in span and half the spar spacing in width. The establishment of specimen configurations included as many edge member and joint details as possible. It should be recognized, however, that total weight of a major component can only be accurately obtained by a complete design and analysis of all joints and components involved. The concept coupon weight represents an indicator of the relative effectiveness of various concepts; however, these cannot be extrapolated to find total weight differences between concepts for major airframe components.

The critical design conditions, loads, and thermal environment are shown in reference 2. For lower surface concepts, 40% bending reversal was assumed to obtain compressive design loads. For biaxial tension and shear, the panel was checked for maximum principal tension and maximum shear stress. A 10% allowance is provided for the combined effects of area-out and section net area efficiency. This is consistent with design practice for wing panel sizing. Design details for the spanwise splices are in accordance with design practices for integral fuel tank panels. Stiffener-to-panel attachments were designed to provide load transfer capability for fail safe requirements. With the limited loads data available, the fatigue evaluation of the strength-sized panels was based on ground-air-ground (GAG) cycle stresses with fatigue reliability factors, fatigue detail ratings, and GAG damage ratios estimated from the National SST program.

The structural concepts considered at points 431 and 269 on the wing are evaluated in tables 4 and 5. As described earlier, each factor that is considered is listed in the order of priority in the left hand column. Each factor is considered in order, and only the concepts that meet a factor reasonably well are carried on into the subsequent evaluations. For example, only the concepts that are reasonably competitive from a mass standpoint are evaluated for manufacturing complexity, and only those that have a reasonable manufacturing complexity are evaluated for stiffness, etc.

As can be seen from the tables, the aluminum-brazed titanium honeycomb, figure 14, was selected for the upper surfaces at all points, and the lower surface at points 269. The integrally machined and welded sheet stiffener, figure 15, was selected for the lower surface at point 269 and 431. In the former case, the aluminum-brazed sandwich had a significant mass advantage in the upper surface, while in the latter case, the sandwich and the integrally machined and welded sheet stiffener are about equal in mass, with the latter having a significant advantage in manufacturing complexity.

Although stresskin was considered for a time on the SST program it was not considered for the 969-512B because of unacceptable fatigue risks resulting from the manufacturing process. Also, the problem of designing and manufacturing an acceptable edge attachment for stresskin panels has not been satisfactorily resolved.

### WING SPAR CONCEPTS

The baseline spar configuration at point 249 utilizes riveted sheet-stiffeners as shown in figure 16. At points 269 and 431 welded sine wave spars, as shown in figure 17, were utilized. The latter is a very efficient concept for both vertical shear and fuel crash loads when accessory attachments and cutouts are few in number.

Four alternate spar concepts were considered. The machined and welded sheet stiffener spar concept was conceived as a means of improving the structural efficiency by eliminating web-to-chord overlaps and stiffener-web overlaps. The configuration was sized for points 249, 269, and 431 utilizing Ti 6Al-4V Condition I. The web is pocket chem-milled with integral pads for joining chord members and stiffeners. The machined web stiffeners and spar chords are joined to the web by fusion welding. Because of the elimination of overlaps and efficient use of material, this configuration is the lightest sheet stiffener concept.

A machined extrusion spar was investigated because of the possibility that it would approach the structural efficiency of the machined and welded spar while minimizing cost by reducing welding requirements. The machined extruded spar was sized for points 249, 269, and 431 using Ti 6Al-4V. The titanium web stiffener extrusion requires 100% machining because of surface contamination and extrusion gage limitations. The maximum span per extruded web segment is approximately 53.3 cm (21 in.). Fusion butt welding would be utilized to join web segments. The mass of the rivet overlaps reduces the efficiency of this configuration.

The structural efficiency of both double edge and thin edge aluminum-brazed titanium honeycomb spar concepts was investigated. Both configurations utilized SS2-30 core with density of  $224~{\rm Kg/m^3}~(14.0~{\rm lbm/ft^3})$  at the periphery for bolt attachments. The thin edge configuration uses one welded chord attachment for minimum mass and one riveted to allow for buildup of tolerance. The double edge panel uses torque limited fasteners for spar chord installation.

The design and construction features of the silver-brazed steel honeycomb concept are similar to those described for aluminum-brazed titanium honeycomb. The skin and honeycomb core are of PH15-7Mo material. The manufacturing complexity rating is higher for steel construction than for titanium because the brazing cycle is more complex for steel.

Each of the spar configurations described above was analyzed for points 249, 269, and 431. Mass per unit spar length has been calculated for comparative purposes. At each of the locations considered the welded sine wave configuration is the lightest structural concept, followed by the sheet stiffener concepts, with the honeycomb concept the least efficient. Previous SST studies have established that hole and bracket reinforcements in the welded sine wave construction greatly reduce the mass efficiency and increase the complexity. This indicates that the number of holes provided for systems routing in various portions of the wing is an important consideration in the final choice of spar concept.

The evaluation of wing spar structural concepts is presented in table 7. As in the evaluation of the wing surfaces, the characteristics used in the evaluation are listed in the left-hand column in the order of priority, and the characteristics are evaluated sequentially. Only the concepts that are reasonably competitive in a given characteristic are included in the next evaluation.

The welded sine wave spar concept was selected as the superior candidate at points 269, 431, and 249 primarily because of the significant mass advantage over the other concepts.

### **FUSELAGE PANEL CONCEPTS**

The riveted sheet stiffener baseline concept and the 10 fuselage panel control points are shown in figure 18. Design conditions identical to those used for the baseline were used to size each of the alternate concepts at the 10 control points.

The use of aluminum-brazed titanium honeycomb skin panels for the body was investigated for the following reasons:

- Efficiency in carrying combined shear and compression is a requirement through most of the body end load range.
- A large portion of the body structure is critical for compression load conditions.
- The high degree of inherent stability of honeycomb skins allows a reduction in support structure to meet general instability requirements.

The aluminum-brazed titanium body skin design utilizes fabrication techniques similar to those required for the wing skins. The panels utilize integrally machined Ti 6Al-4V face sheets with SC4-20 titanium core. Dense core is used along the panel edge to resist bolt crushing loads. The outer skins are recessed for flush installation of circumferential splice straps only. Longitudinal splice straps are installed external to contour. The frame-to-panel attachments have been made by bolts which require densified core and skin pads locally at every frame. This requirement greatly complicates the fitup of core to face sheet. The superior stability of the honeycomb panels permitted a frame spacing of 88.9 cm (35 in.).

Integrally machined body skin panels have been investigated as a means of improving structural efficiency by tailoring of the cover material to the bending and shear requirements of the body. Stiffener spacing and intervening nodes have been sized and spaced to optimize compression and shear allowables. Integrally machined nodes for stiffener attachment eliminate the requirement for a flange to rivet the stiffener to the skin. Machined angle stiffeners have been welded to the face sheet node by fusion butt welding. Integral circumferential skin pads are utilized as part of body frame outer chords. A separate frame fail-safe chord is located inside of the skin stiffeners. All skin and frame components have been designed of Ti 6Al- 4V Condition I. The assembly of the monolithic panels by machining and welding represents a slightly more complex manufacturing procedure than the machining and riveting sequence utilized in sheet stiffener fabrication, as indicated by the manufacturing complexity rating in table 8.

The above three body structural concepts have been designed in detail for the baseline structural loads and environmental conditions at the 10 control point locations. The total mass of each panel specimen was calculated and reduced to an average mass per unit area for comparative purposes.

The evaluation of the fuselage structural concepts is presented in table 8. The factors on which the evaluation is based are listed in the left column. In each case the baseline sheet stiffener concept is evaluated in comparison with integrally machined skin stiffener and aluminum-brazed titanium honeycomb concepts. The procedure was the same as that used for the wing surfaces and wing spars.

The integrally machined concept was eliminated in the mass evaluation at all four evaluation points, except the crown at station 7874 (3100). Subsequent evaluation, with respect to manufacturing complexity, maintainability, and fatigue, established the superiority of the baseline skin stringer concept over the other two candidates. Consequently the baseline concept was selected for the entire fuselage.

# STRUCTURAL ANALYSIS AND DESIGN

This section provides a general overview of the detailed analyses and computational procedures that were used to establish an efficient distribution of structural material to satisfy strength and flutter criteria. The computerized system that was used in performing this work was organized around an interim version of the ATLAS Structural Analysis and Design System (ref. 5), interfaced with external programs for flutter analysis, and with the FLEXSTAB System for loads analysis, (ref. 6).

The major subtasks that make up the structural analysis and design process are identified in figure 19. This may be visualized as three interconnected discipline-oriented segments with the interconnection being provided by the ATLAS system. On the left of the figure is FLEXSTAB, used for prediction of steady aeroelastic loads which provide input to the strength design segment shown in the center of the figure. On the right is a group of operations associated with the flutter analysis and design to satisfy flutter criteria. The computer programs performing the various functions are shown in the upper portion of the boxes.

Basic data describing the aircraft were developed early in the program. This information, comprising aircraft geometry, structural arrangement, structural concepts, and structural materials, was then used to develop structural, aerodynamic, and mass models of the aircraft and other input data to initiate the analysis and design cycle.

#### THE INTEGRATED COMPUTER PROGRAM SYSTEM

# THE ATLAS SYSTEM

ATLAS is an integrated structural analysis and design system operational on the Control Data Corporation (CDC) 6600/CYBER computers. It is a modular system of computer codes, controlled by one executive module and with a common data base. The arrow wing analysis used a preliminary version of ATLAS. Hence, the system description that follows reports an evolving capability as it existed during the detailed analyses in the arrow wing study. The system's capabilities are broad in scope, supporting analyses in many different but related aeroelastic technologies. Execution of modules is controlled by the user by means of a technically oriented language. Input data are written in a problem-oriented language which provides versatile automatic data generating capabilities. Additionally, the various data preprocessors provide capabilities to reduce the amount of input data and flowtime required to define the structural problem. Data postprocessors allow selected data to be extracted, manipulated, and displayed to facilitate the evaluation of either input data or analysis results.

The ATLAS problem size limitations for stiffness and mass models are:

| Number of stiffness nodes    | 4 095  |
|------------------------------|--------|
| Number of stiffness elements | 32 767 |
| Number of loadcases          | 4 095  |
| Number of mass nodes         | 4 095  |
| Number of mass elements      | 32 767 |
| Number of mass conditions    | 200    |

Problems generally become critical for bulk storage or hardware reliability before these limitations are reached. For substructured stiffness and mass models there is no practical limit to the total problem size.

There are two basic types of modules in the ATLAS system: executive modules and computational modules. There are two executive modules, ATLAS (0,0) and Control. ATLAS (0,0) monitors the job execution. Control, which is generated by the user, performs such functions as selecting the sequence of computations, selecting analysis results to be displayed, and handling execution. In general, the Control module is generated from the control deck at execution time by the precompilers and compilers.

Computational modules are grouped into three types according to their function:

- Preprocessors read, decode, generate, and interrogate the input data or load data for a restarted job.
- Processors perform technical, analytical computations in the following disciplines:
  - Stiffness
  - Mass
  - Design
  - Linear matrix algebra
- Postprocessors extract and display input data or analysis results and save data for a later restart of the job.

Table 9 provides a summary of the capabilities of the ATLAS 2.2 system used during Arrow Wing Task II. The table is divided into three sections representing the Executive, Technical, and Pre- and Postprocessor modules.. The structure of Version 2.2 of the ATLAS System, which was used in the present study, is depicted schematically in figure 20.

TABLE 9.—A SUMMARY OF ATLAS 2.2 CAPABILITIES

| Module                 | Function   |
|------------------------|--|
| ATLAS (0,0)<br>Control | Initializes loading of module overlays, and closes system data files.  Defines the sequence of execution of modules.               |
| Aerodynamics           | Generates aerodynamic influence coefficients using three-dimensional linearized potential flow theory for general planar surfaces. |
| Design                 | Calculates margins of safety, and resizes the structure using a fully-stressed approach.   |
| Airloads               | Generates steady-state loads using AIC's from "AERODYNAMICS," mass matrices from "MASS," and flexibility matrix from "STIFFNESS."  |
| Loads                  | Prepares finite element static and thermal loads.  |
| Mass                   | Generates finite element mass matrices for primary and secondary structure, fuel, and payload.                                     |
| Stiffness              | Generates the finite element stiffness and stress matrices.  |
| Stress                 | Calculates the finite element stresses.  |
| Interpolation          | Establishes mode shape interpolation functions to be used by the airload generators.   |
| Vibration              | Calculates frequencies and mode shapes of a structure undergoing free, undamped vibrations.  |
| Preprocessor           | Reads the ATLAS Problem Deck, and loads the restart tape.  |
| Plot                   | Prepares SC4020, Gerber and Calcomp plot data.   |
| Report                 | Prepares printed reports of results generated by technical and utility modules.  |
| Output                 | Saves all problem data on a checkpoint file to enable subsequent problem restart.  |

#### FLEXSTAB SYSTEM

FLEXSTAB (ref. 6) is a system of programs developed by Boeing under contract NAS2-5006, to NASA-Ames Research Center It was designed to predict the stability characteristics of flexible airplanes based on the geometry, mass distribution, and flexibility of the airframe, using linear aerodynamic and structural theories. Although not principally designed as a loads analysis tool, FLEXSTAB generates pressure distributions in the process of performing a stability analysis, hence its use for loads analysis was a fairly simple task.

In preparation for the arrow wing contract a contractor development effort was directed at producing a version of FLEXSTAB that would produce design loads. The changes and additions made to FLEXSTAB during this time are shown in table 10. These changes were subsequently incorporated in the NASA version of FLEXSTAB 1.2.

TABLE 10.—BOEING PROGRAM TO IMPROVE EFFICIENCY AND RELIABILITY OF AEROELASTIC LOADS ANALYSIS

|   | Resson for a        | modification        |
|---|---------------------|---------------------|
| Addition of cycling capability for balanced maneuvers or unit solutions   | Improved efficiency | Improved capability |
| For unit solutions on $\alpha, \beta, q, \dot{\theta}, \dot{\phi}, \dot{\phi}, \delta_{E}, \delta_{R}, \delta_{A}, V_{TAS}, THRUST$   | •                   |                     |
| ALTITUDE and ATTITUDE   |                     |                     |
| For balanced maneuvers on:  | •                   |                     |
| n, q, $	heta$ , V $_{TAS}$ , U $_{de}$ , THRUST and ALTITUDE  |                     |                     |
| Added capability to generate rigid and flexible solutions in one computer run   | •                   |                     |
| Capability to select the degrees of freedom retained at the structural nodes  | •                   | •                   |
| Addition of the static gust solution based on the revised gust load formula   |                     | •                   |
| Addition of the capability to superimpose an externally generated pressure distribution on that computed by SD&SS** (nacelles, for example)   |                     | •                   |
| Added capability to generate in SD&SS the airloads and the inertia loads at the nodes separately  |                     | •                   |
| Added capability to specify load factor rather than pitch rate for balanced maneuvers   | •                   | •                   |
| Added capability to put user-specified matrices on the SD&SS output tape  | 1                   | •                   |
| Print out the equivalent airspeed and $C_{N_{\alpha}}$ in SD&SS   |                     | •                   |
| Develop interfaces: ATLAS - FLEXSTAB and FLEXSTAB -ATLAS  | •                   |                     |
| *Develop a program (VAMAT) providing the capability to generate net shear, moment, and torsion along wing, body, and horizontal tail in user-specified cross sections (using SD&SS tape output) |                     | •                   |
| *Develop a program (VMTSCM) providing the capability to scan through the loads and select critical loads  | •                   | •                   |
| *Develop a plotting program providing plots of sheer, moment, and torsion along wing, body, and horizontal tail   | •                   | ; <b>•</b>          |

<sup>\*</sup>These programs are not part of the FLEXSTAB program

<sup>\*\*</sup>Stability derivatives and static stability

The modifications to FLEXSTAB were carried out with two major purposes in mind – improvement in program efficiency and improved analytical capability – and table 10 identifies in which of these categories the various changes fall.

# FLUTTER MODULES

As indicated in figure 19, the flutter modules were also linked to the ATLAS system through a tape interface. Modal data, flexibility matrices, and mass matrices were transmitted from ATLAS to the flutter modules. RHO III, (ref. 7) was used to calculate unsteady aerodynamic loadings caused by motions of lifting surfaces based on the subsonic kernel function approach, utilizing the modal data supplied by ATLAS. These loadings were then used to calculate generalized aerodynamic airforces for use in subsonic flutter analysis. Similar airload calculations for supersonic flutter analysis were obtained from the Mach Box program (ref. 8). Generalized aerodynamic force matrices, together with generalized mass and stiffness matrices from ATLAS, were incorporated in the flutter equations and solved to define the flutter stability envelope by utilization of a V-g solution program based on the QR algorithm.

#### ANALYTICAL MODELS

#### STRUCTURAL MODEL

One finite element model of the structure was developed as the source of basic structural data for aeroelastic loads, stress, vibration, and flutter analyses. Consistency of geometric data was found to be particularly critical. Geometry of an individual component was generally defined in a convenient local reference frame. Hence, particular care had to be taken in defining coordinate transformations between these local reference systems and the global system that was used in defining the assembled model of the complete structure.

Close coordination between stress, flutter, and loads specialists was required to provide a single basic model from which special-purpose models could be derived to satisfy the requirements of each individual discipline. This interdisciplinary coordination is particularly important in the design of large supersonic aircraft that tend to be slender and very flexible, in which aeroelasticity is a major design consideration. Dynamic loadings associated with flutter often exhibit distributions that are vastly different from strength-critical loadings. Hence, requirements exist for detailed representation of structural characteristics in different regions of the aircraft to satisfy requirements for stress analysis, strength design, flutter analysis, and stiffness design. Prior experience on the National SST program provided useful background for modeling the arrow wing structure. Initial structural sizing to start the aeroelastic cycle was derived from the 969-336C design study, with appropriate adjustments to reflect the increase in maximum taxi gross mass to 340 194 kg (750 000 lbm). Since program constraints permitted only a single cycle of aeroelastic loads analysis, it was considered necessary to develop an initial sizing to match strength requirements reasonably well. Automated resize capability had not been provided in the ATLAS system when the initial sizing had to be done. Hence, this initial sizing was performed manually. Availability of automated resize capability will make it possible to employ a crude estimate of the initial sizing with considerable savings of time and effort on future jobs of this kind. A detailed description of the model and an account of model development and checkout are presented in reference 2.

The major portions of the structural model used in this study are shown in figure 21. The finite element model contains approximately 2000 nodes, 4200 elements, and 8500 active degrees of freedom. For dynamic analyses, a much smaller number of degrees of freedom are retained (225 for symmetric conditions and 260 for antisymmetric conditions). The loads analysis used a reduced model having 164 retained nodes and 192 degrees of freedom. The complexity of the model results from (1) the use of one model for stress, loads, and flutter analyses, and (2) the detail requirements for meaningful flutter analysis. For the wing, these requirements include structural modeling of the engine beams (allowing complete c.g. motion of the engines), leading and trailing edge controls, wing secondary structure, landing gear and wheelwell cutouts, major access doors, and wing-mounted fins as well as wing primary structure. For the rest of the aircraft, they include a detailed body idealization for wing attachment and a less sophisticated model of the remaining fuselage and the empennage.

# STRUCTURAL MODEL VERIFICATION

The structural model was generated and initial checks made over a period of about five months. During this period a maximum of three people worked on the model. About 17 man-weeks of effort were required to define and size the elements in the body. About 18 man-weeks of effort were involved in formulating the wing model, distributed equally between model definition and sizing. Four additional months were required to accomplish the following tasks: connect the wing and fuselage models, verify the accuracy of design data, check local modeling details, conduct a preliminary vibration analysis to review mode shapes and frequencies, make a preliminary flutter check, and revise portions of the wing structure to relieve a severe flutter deficiency before strength sizing.

The preliminary vibration analysis showed that there was a local resonance involving the main landing gear, which was supported in the stowed position on shallow beams extending across the top of the wheel well region. This resulted in a low-frequency, high-amplitude resonance of this local area, illustrated in figure 22. Several changes were made to suppress the objectionable mode by stiffening the landing gear uplock restraint. These included the addition of a full-depth rib on the inboard side of the wheel well, addition of lower surface honeycomb skin panels extending from the added rib to the side-of-the-body rib, and an increase in depth of the uplock beam.

Provision was also required to restrain the mathematical model at the center of gravity in order to calculate the flexibility matrix for use in the airloads analysis. This restraint was provided by adding special nodes and massless structural elements to prevent rigid body motions, both symmetrical and antisymmetrical. The added structure is statically determinate; its sole purpose is to transfer the support reactions to frames and body shell. It does not contribute to the mass or stiffness of the model; hence it does not affect the loads or flutter analysis.

The initial stress analysis, while done primarily for model verification, also afforded an early opportunity to check the operation of the ATLAS program when executing a

problem of this size. The arrow wing model is about 40% larger than the largest previously executed model and its stiffness matrix has a relatively large "half-band width."

The length of time required for model generation and validation was a result of the small size of the study team, the limited experience using ATLAS on a model of this size and geometric complexity, and lack of a "body" geometry package in the program. While experience gained from this study and programming improvements will decrease both the effort and time required to generate and validate a complex structural model, it is evident that model generation should begin as soon as possible in a design study to obtain maximum benefit from an automated design system.

# MASS MODEL

Different sets of retained freedoms describing structural deformation were required for aeroelastic loads analysis and for flutter analysis since the numbers and distributions of retained structural freedoms were different. Hence, it was necessary to develop two different sets of mass panels. To "lump" the masses at the retained nodes an "automated cookie cutter" technique (ref. 9) was used. For this process the location of the retained node is selected and the boundaries of the space that contributes mass to this node define a vertical prism ("cookie"). Figure 23 shows the retained nodes and panels used for modeling the flutter mass matrix. An external boundary as shown in the figure is required by the "PLOT GRID" ATLAS program.

# **AERODYNAMIC MODEL**

A basis for the aerodynamic analysis is provided by the loft contours that define the envelope of the airframe. This loft is used to produce the geometrical description of the surfaces of the airplane, and the associated slopes for use in the steady state loads analyses, as described later. These panels are illustrated in figure 24.

#### STRUCTURAL DESIGN LOADS

The selection of loads conditions for analysis was based on the requirements of the Federal Aviation Regulations, Part 25, and the Tentative Airworthiness Standards for Supersonic Transports (TAS). Loads analysis experience on the National SST program and on a previous study, performed by the contractor, of the 969-336C configuration was used as the basis for selecting design conditions. Where appropriate, recourse was made to the extensive analyses performed for the National SST design in the selection of design parameters.

# STRUCTURAL DESIGN AIRSPEEDS

The maximum operating speed and Mach number,  $V_{MO}$  and  $M_{MO}$ , are established to include all normal climb, cruise and descent conditions. The speeds chosen for the arrow wing were those determined for the National SST.

The design cruising speed,  $V_C$ , is equal to  $V_{MO}$ . Supersonic cruise Mach number is  $M_C = 2.7$ . The selected design cruising speeds exceed the requirements of FAR 25.

The design dive speed and Mach number,  $V_{\rm O}$  and  $M_{\rm O}$ , are the same as those used on the National SST, which provide an adequate speed margin between the cruise and dive placards.

The design maneuvering speed, VA, is based on the following equation:

$$V_A = V_{MIN DEM} \sqrt{2.5}$$

where  $V_{MIN\ DEM}$  is the minimum demonstrated speed with flaps retracted or a lesser speed based on a rational selection of  $C_{L_{MAX}}$  for structural design.

The design speed for maximum gust intensity,  $V_B$ , is established in the subsonic regime in accordance with FAR 25 and TAS. The  $V_B$  concept is not used for supersonic flight where slowdown or gust avoidance may not be operationally feasible.

The design flap speed,  $V_F$ , is derived in compliance with FAR 25. The design flap speed for each position is sufficiently greater than the operating speed recommended for the corresponding stage of flight to allow for probable variations in airspeeds and for transition from one flap position to another. The structural design airspeeds for the arrow wing are shown in figure 25.

# **DESIGN GROSS MASSES**

Pertinent gross masses are presented in table 11.

# **ENGINE THRUST**

The maximum installed thrust values for the ATAT-1 engine are presented in table 12.

# MANEUVER AND GUST CRITERIA

Flight loads for symmetrical balanced maneuvers are established within the maneuvering envelope in accordance with FAR 25. Except as limited by maximum design lift coefficients, the design limit load factors are as shown in table 13.

The airplane is assumed to be in equilibrium with zero pitching acceleration. The effects of pitching velocity are accounted for in the analysis. The airplane is analyzed for maneuvers at all points on or within the maneuver envelope for both maximum and minimum gross masses at the appropriate altitude.

The following maneuver time histories are also considered:

 Maximum Stabilizer Displacement - The airplane is assumed to be flying in a steady level flight attitude at speeds from V<sub>A</sub> to V<sub>D</sub> and the pitch control is suddenly deflected in an up or down direction at the maximum rate available to a deflection consistent with pilot effort.

TABLE 11.-DESIGN GROSS MASS

| Complision.              | Mass      |               |  |  |

| 2.9      | 18 287 | (60 000) | 102 490                     | (23 040)       |  |

TABLE 13.-LIMIT LOAD FACTORS

| Condition                       | Positive limit<br>load factor | Negative limit<br>load factor |
|---------------------------------|-------------------------------|-------------------------------|
| All speeds up to V <sub>C</sub> | 2.5                           | -1.0                          |
| At V <sub>D</sub>               | 2.5                           | 0.0                           |
| Flaps down condition            | 2.0                           | 0.0                           |

2. Checked Maneuvers – The airplane is assumed to be subjected to checked maneuvers for balanced conditions at any load factor within the design maneuver envelope and at all speeds between  $V_A$  and  $V_D$ . The elevators are checked back to a position such that the airplane pitching accelerations meet or exceed the FAR requirements.

A maneuver envelope for sea level altitude at the maximum flight mass is shown in figure 26.

Loads due to yawing maneuvers are established in compliance with FAR 25. The following time histories are considered:

- 1. From a condition of steady level flight at zero sideslip, displace the rudder control to the maximum position as limited by stops, boost capability, or pedal force.
- 2. With the rudder control displaced as in (1), allow the airplane to yaw to a maximum sideslip angle.
- 3. With the airplane yawed to the sideslip angle consistent with (2), return the rudder abruptly to neutral.
- 4. With the airplane yawed to the static sideslip angle consistent with the control displacement in (1), return the rudder control abruptly to the maximum value in the opposite direction.

Loads due to both vertical and lateral gust are computed at all speeds and altitudes on and within the flight envelope. Use is made of the revised gust load formula (ref. 10) in computing airplane load factors due to gusts. The design airspeed for maximum gust intensity,  $V_{\text{B}}$ , is not considered at supersonic speeds.

# LANDING, TAXI, AND GROUND HANDLING LOADS CRITERIA

Design landing impact loads were determined for the National SST using a dynamic analysis which included the significant elastic modes of the airframe, rigid body degrees of freedom, and a representation of the energy absorption characteristics of the landing gear shock strut and tires. Landing impact loads for the 969-512B configuration were obtained by applying the load factors obtained for the National SST to the mass distribution of the 969-512B. Aerodynamic forces acting during landing impact were neglected.

The air and ground handling loads are computed in compliance with the requirements of FAR 25. The taxi loads are computed on the assumption that the airplane experiences a 2 g acceleration at the center of gravity while taxiing. In each of these conditions, the external loads are placed in equilibrium with the linear and angular inertia loads in a rational manner. Ground handling loads are summarized in table 14.

The definition of geometry and forces for the ground load conditions is shown in figure 27.

# **AERODYNAMIC LOADS ANALYSIS**

The linearized potential flow method developed by Woodward is utilized in FLEXSTAB to generate aerodynamic influence coefficients for aeroelastic loads analysis. This system has the capability of treating a wide variety of configurations, and it may be applied at subsonic and supersonic speeds.

Accurate analytical techniques are required for the prediction of steady and unsteady aerodynamic load distributions, including the effects of structural deformation on large flexible aircraft. Accurate load prediction becomes particularly acute when critical structural or control design conditions occur in the transonic speed range.

Experience in design of the SST prototype identified a number of problem areas associated with aeroelastic analysis, the principal one being the need to develop a practical means of incorporating wind tunnel pressure data in the analysis to account for effects of separated flow and formation of strong leading edge vortices on this type of configuration.

The wing structural weight which resulted from the structural analysis for the delta wing of reference 11 was based on loads which were adjusted to reflect wind tunnel test results. The adjustments led to significant reductions in the loads relative to linear potential flow theory. The technique used in applying wind tunnel data to the loads analysis was based on two major assumptions:

- 1. Panel pressure coefficient slopes used to calculate incremental aeroelastic loads can be adjusted by a single factor per panel.
- 2. The location of the upper surface vortex is not affected by wing deformation.

Wind tunnel tests described in reference 12 of a flat and twisted wing of the same section and planform, and test-theory comparisons for this wing, have shown that these assumptions probably are not valid, since the vortex streaming aft over the wing alters the pressure distribution as a function of wing twist.

For the arrow wing loads analysis, only theoretical solutions were obtained involving the assumptions inherent in the linearized potential flow theory – thin wings, slender bodies, small angle of attack, small control surface deflections, and attached flow. Work is continuing to develop a means of incorporating wind tunnel data in the loads analysis, but such a method is not yet available.

# STRUCTURAL LOAD CONDITIONS

A structural model with 164 retained nodes and 192 degrees of freedom was selected from the complete structural mathematical model. Analysis conditions were selected on and within the maneuver envelope to cover the complete range of Mach numbers, design speeds, and load factors. Maximum flight mass at the appropriate altitude, and maximum zero fuel mass plus reserve fuel, were considered for all maneuver conditions. In addition, the minimum flight mass, which occurs in the ferry flight configuration, was considered for the gust conditions.

The following conditions were analyzed:

- 1. Symmetric, balanced maneuvers at maximum flight mass
- 2. Symmetric, balanced maneuvers at maximum zero fuel mass plus reserve fuel
- 3. Design vertical gusts at maximum flight mass
- 4. Design vertical gusts at the ferry flight mass

- 5. Checked and unchecked elevator maneuvers as specified in FAR 25.331(c)
- 6. Design lateral gusts at the maximum flight mass
- 7. Rudder maneuvers as in FAR 25.351(a)
- 8. Landing impact
- 9. Taxi
- 10. Ground handling as specified in FAR 25.471 through 25.509

Loads were calculated for a total of 154 flight conditions. The critical design conditions selected for use in the resizing are shown in table 15. Ultimate shear and bending moment on the forward body due to landing impact are presented in figures 28 and 29. The forward body is the only portion of the structure for which landing impact is the critical condition.

# **JIG SHAPE**

The jig shape represents the stress-free condition for the aircraft structure and corresponds to a state of zero applied loads. The analysis of design loads is based on the camber slopes for this jig shape. On the other hand, the performance of the configuration is optimized for a shape corresponding to a particular flight condition, normally a mid-cruise condition. Before calculating design loads, therefore, the jig shape must be computed from the shape defined for use in the performance calculations.

This was accomplished in FLEXSTAB by first trimming the airplane for the mid-cruise design condition, with the airplane treated as a rigid body. The resulting loads were then applied to the flexible airplane and the increments of camber and displacement due to this loading were subtracted from those defined for the design condition to yield the jig shape. The wing and body vertical displacements from the mid-cruise design condition to the jig shape are shown in figure 30.

#### THERMAL ANALYSES

Supersonic aircraft are subjected to heating effects from several external and internal sources. Structural thermal analysis is required to determine resulting temperature gradients which produce thermal stresses, and to establish temperature limits for material selection. Internal heat sinks provided by the structure and the fuel must be considered in the analysis in order to predict temperature and stress distributions. These are then used in the design and sizing of the structural elements, in the selection of suitable structural materials, and in determining insulation requirements for fuel tanks.

The thermal analysis initially requires the establishment of criteria, a mission profile, a fuel management plan, and external and internal environments to predict heating rates to the various regions of the aircraft. The next phase is the determination of the thermal response of the particular structural cross section yielding the required temperature distributions, gradients, and stresses.

The criteria and methods used in the present analysis are identical to those employed on the National SST program. In determining the structural temperatures, no factors of safety were applied. However, a factor of safety of 1.25 was applied on thermal strains to account for uncertainties.

The major sources of external heating for a commercial supersonic transport are aerodynamic and solar heating. Both were considered in the present analysis. The analysis methods and results are described in the following paragraphs.

#### **AERODYNAMIC HEATING**

Based on studies of several alternate procedures conducted on the National SST program, Eckert's reference temperature method was selected for determining heat transfer coefficients for this study. The Reynolds analogy and the Blasius skin friction relationship were used for laminar flow regions; a modified Reynolds analogy, the

Prandtl-Schlichting-Wieghardt skin friction relation, and Rubesin correction factor (ref. 13) were used for turbulent flow regions. Flat plate approximations were used in calculating heat transfer coefficients for the large external surfaces having small curvature.

#### SOLAR ABSORPTANCE AND SURFACE EMITTANCE

The effects of solar absorptance and surface emittance on the equilibrium wall temperature are shown in figure 31. For this study the titanium solar absorptance was assumed to be  $\alpha_{SOL}=0.7$ , and the surface emittance was assumed to be  $\epsilon=0.2$ . It was further assumed that the lower surfaces of the aircraft received 10% of the solar energy reflected from the earth (albedo).

# TRANSIENT THERMAL ANALYSIS

The externally generated heat flows into the aircraft through the skin surfaces and adjoining structural members mostly by conduction and radiation. There is a certain time lag in the structural temperature response due to thermal resistance, resulting in temperature gradients which produce thermal stresses. A thermal analyzer computer program was used in generating the thermal gradient and the temperature time histories required for the selection and sizing of various structural members. The program is based on a finite difference solution of the heat flow equation using a three-dimensional nodal network. Effects of conduction, convection, radiation, external and internal heat sources, and property variations with time, temperature, and direction are included.

For transient thermal analyses structural members, such as a wing spar and upper and lower panel combination, are divided into a suitable number of elements, represented by lumped masses at the centroids. The thermal model is then represented by a passive electrical network for analysis. This network of capacitors, resistors and radiators, in conjunction with sources, sinks, and the aerodynamic heating boundary conditions are used to calculate the thermal response.

The thermal stresses in the structural members were calculated using a stress subroutine that solves the following equation:

$$\sigma_{j} = \alpha_{j} E_{j} \Delta T_{j} - E_{j} \frac{\sum_{i=1}^{n} \alpha_{i} E_{i} A_{i} \Delta T_{i}}{\sum_{i=1}^{n} A_{i} E_{i}}$$

This equation predicts the thermal stress in each of n uniaxial elements. The n elements are assumed to be of equal length at a reference temperature as in a stiffened panel. When subjected to temperature differentials from the reference temperature, the members are constrained against rotation but allowed to translate to a common length at which the total axial load of the n members is zero.

The thermal analysis of the arrow wing SST configuration was conducted for selected locations shown in figure 32. These locations and structural arrangements are listed in table 16.

TABLE 16.—THERMAL ANALYSIS CONDITIONS

| Configuration                  | Point | Case | Description   | Insulation         |
|--------------------------------|-------|------|---|--------------------|
| Fuel tank no. 1<br>(Spar area) | 249   | 1    | Tank height = 1.10 m (43.3 in.) Upper panel does not touch fuel | None               |
|                                |       | 2    | Tank height = 0.89 m (35.0 in.) Upper panel touches fuel        | None               |

|                                |       | 2    | Spar aft of point 431   | None               |
| Wing panel dry bay area        | 431   | 1    | Fwd of point 431  | None               |
|                                |       | 2    | Aft of point 431  | None               |
| Body stringers                 | 5     | 1    | Lower crown   | None               |
|                                | 6     | 2    | Upper crown   | None               |

The aerodynamic heating rates were calculated using a 6190 km (3340 nmi) mission profile, as shown in figure 33, for the 1962 U.S. standard atmosphere. Since the flow along the wing and the body is mostly turbulent, turbulent heat transfer rates were used in the analysis. Solar heating and radiation to outer space was included in the calculation of the transient skin temperatures. The thermal conductance of the 25.4 mm (1 in.) deep honeycomb panel was assumed to be 34 W/m $^2$ K(6.0 Btu/ft $^2$  hr  $^0$ R). For the denser honeycomb core, at the joint with the spar, a value of 216 W/m $^2$ K (38.0 Btu/ft $^2$  hr  $^0$ R) was used.

To determine the effect of fuel on tank structures, the fuel management scheme shown in figure 34 was used in the transient analysis. This fuel management is consistent with the flight performance of the 969-512B. The thermal conductance between the structure and the fuel was assumed to be 170  $\,\mathrm{W/m^2K}$  (30.0  $\,\mathrm{Btu/ft^2}$   $\,\mathrm{hr^0R}$ ) It was further assumed that the panel and the spars of tank no. 1 were not internally insulated. Insulation with a thermal conductivity of 0.058  $\,\mathrm{W/m}$  K (0.4  $\,\mathrm{Btu\text{-in/ft^2hr^0R}}$ ) was used only for the tank no. 2 area which contained integrally stiffened lower panels.

The initial temperature before the aircraft flight was assumed as 288.8 K (60° F). Typical temperature time histories for a representative wing section, figure 35, are shown in figure 36. Thermal stresses are shown in figure 37. For complete results of the thermal analysis see reference 2.

#### **FUEL TEMPERATURE ANALYSIS**

The environmental control system for the SST relies heavily on the fuel as a heat sink to cool the passenger cabin and certain equipment. Therefore, control of the fuel temperature is a critical factor in the design of the environmental control system and the engine fuel system. The fuel temperatures for the 969-512B missions were calculated using a thermal analyzer program developed during the National SST program.

#### MISSION DESCRIPTION

The mission profile that was used for fuel temperature analysis consists of 106 minutes of Mach 2.7 cruise flight on a standard day. Significant points on the profile are listed in table 17.

| Condition        | Time from start of taxi. | Mach no.     | Altitude |         |  |  |
|------------------|--------------------------|--------------|----------|---------|--|--|

| Touchdown        | 167.08                   | 0.22         | 0        | (0      |  |  |

TABLE 17.-MISSION PROFILE

The fuel temperature analysis considers single trips as well as two consecutive legs of a New York-Paris round trip flight using the most adverse combinations of fuel usage and bulk fuel temperature. The initial fuel temperature in the tanks is assumed to be 306 K (90° F) as discussed in reference 2. Bulk fuel temperatures greater than 306 K(90° F) were estimated to occur less than 2.5% of the time. Prior to the second leg of the flight, all auxiliary tanks were refilled with 306 K(90° F) fuel. The main tanks, containing the hot reserve fuel left from the first leg of the flight, were also refilled with 306 K (90° F) bulk fuel, resulting in a somewhat higher initial temperature. Subsequently during climbout the main tank temperature decreases as cooler fuel is pumped in from the auxiliary tanks.

It was assumed that the fuel usage during the first leg of the flight was normal for the flight profile and that the airplane landed with normal reserves aboard. The fuel usage during the second leg of the flight was assumed to increase uniformly throughout the flight to reflect the use of the trip fuel allowance. This combination provides a worst-case situation in that the greater amount of hot fuel left from the first leg of the flight results in a higher initial fuel temperature in the main tanks for the beginning of the second leg. Also, the use of the reserve fuel during the second flight results in larger temperature increases in the main tanks by the end of the cruise segment.

#### TEMPERATURE LIMITS

The critical fuel temperature occurs at the end of the cruise segment at an altitude of 20 600 m (67 500 ft). At this altitude the boiling temperature of maximum volatility kerosene is 353 K (175° F). Allowing a margin of 8 K (15° F) to account for pressure uncertainties, temperature stratification of the fuel in the tanks, and pump cavitation, a bulk temperature of 344 K (160° F) is established as the maximum allowable temperature of fuel remaining in any tank.

An engine/airframe interface fuel temperature limit of 394 K (250° F) is established assuming engine electronics will be cooled with another coolant, and that a burner nozzle fuel temperature limit of 436 K (325° F) is reasonable.

#### **FUEL SYSTEM**

An important factor influencing fuel temperature is the amount of wetted area in each fuel tank as a function of quantity of fuel in the tank. The wing and body surface coordinates and fuel tank boundaries were analyzed to determine both fuel volume and hot surface area of the fuel tanks including corrections for unusable fuel volume.

The fuel tanks on the 969-512B shown in figure 5 are primarily aluminum-brazed titanium honeycomb sandwich panels except for the rear fuselage auxiliary tank, 14A, which was riveted sheet stiffener construction, and the lower surface of the main wing box which has integrally stiffened skin stiffener construction. The thermal conductance of the aluminum-brazed titanium honeycomb sandwich was estimated to be 34 W/m<sup>2</sup>K (6 Btu/ft<sup>2</sup> hr °F). A previous analytical study estimated that the effect of additional heat paths due to the panel edge members, access holes, and fasteners increased the net average fuel tank conductance to 62.4 W/m<sup>2</sup>K (11 Btu/ft<sup>2</sup>hr°F). This relationship is illustrated in figure 38. The conductance of the skin stiffener areas in tank 14A and the aft wing is estimated to be 3400 W/m<sup>2</sup>K (600 Btu/ft<sup>2</sup> hr °F).

#### **FUEL TEMPERATURE**

The maximum temperature of the fuel in the main tanks at the end of a second supersonic cruise mission is shown as a function of fuel tank conductance in figure 39. For the purposes of this trade study, the conductances of all main and auxiliary tanks were considered equal. As indicated, tank conductances of about 22.7 W/m²K (4 Btu/ft² hr °F) are required to keep the rear main tank fuel temperature below the 344 K (160° F) maximum, and conductances of about 34 W/m²K (6 Btu/ft² hr °F) would be required for the forward main tanks. All auxiliary tanks except the rear fuselage auxiliary tank 14A are emptied early in the flight before much fuel heating can occur. Since the brazed aluminum honeycomb structure used in auxiliary tank walls provides reasonable insulation, it was determined that the fuel temperatures would be maintained below the 344 K (160° F)) maximum and that no insulation was required for these auxiliary tanks. Based upon the above study the tank conductances shown in table 18 were established as requirements and used in subsequent analysis. To attain this level of tank conductance additional insulation will be required in main tanks 1, 2, 3, and 4 and in auxiliary tank 14A.

TABLE 18.-FUEL TANK CONDUCTANCE

| Tanks                 | Tank conductance,<br>W/m <sup>2</sup> K (Btu/hr ft <sup>2</sup> |
|-----------------------|---|
| Forward mains 1 and 4 | 28.3 ( 5)   |
| Rear mains 2 and 3    | 17.0 (3)  |
| Auxiliary 1A and 2A   | 62.4 (11)   |
| Auxiliary 2A and 3A   | 62.4 (11)   |
| Auxiliary 5A and 6A   | 62.4 (11)   |
| Auxiliary 14A         | 62.4 (11)   |
| Ballast               | 62.4 (11)   |

It should be noted, however, that significant improvements have been achieved in low-conductivity brazed core design and in diffusion-bonded sandwich panel manufacturing techniques subsequent to completion of this study. These improvements will result in net fuel tank conductances about 50% lower than those used in the fuel temperature analysis reported herein, and should virtually eliminate the need for adding extra fuel tank insulation.

The problem of excessive fuel temperatures is largely associated with flights which combine adverse thermal conditions such as high onloaded fuel temperatures and/or consecutive trips with hot reserve and/or ballast fuel remaining from the earlier trip combined with trips which used fuel reserves in an adverse manner. Table 19 shows the fuel temperatures at the end of cruise or start of descent (whichever is higher) in the main fuel tanks, at the engine/airframe interface, and at the fuel nozzles for a series of conditions using the tank conductances listed above. On a first trip with onloaded fuel at 289 K ( $60^{\circ}$  F), trip condition 1, excessive fuel temperatures do not occur. When the onloaded fuel temperature is increased to 305 K ( $90^{\circ}$  F) the end-of-mission fuel temperatures increase significantly but are still satisfactory. On a second consecutive trip with 305 K ( $90^{\circ}$  F)) onloaded fuel, the main tank temperatures increase to above 344 K ( $160^{\circ}$  F). If the second trip uses trip fuel reserve, the forward fuel tank temperature rises to over 347 K ( $165^{\circ}$  F). In all cases the engine/airframe interface fuel temperature remains less than 394 K ( $250^{\circ}$  F), and the engine nozzle temperature remains less than 436 K ( $325^{\circ}$  F) maximum.

The temperatures in table 18 were determined for the 969-512B airplane, which had a mission duration of 2.8 hours. A longer duration at supersonic cruise will tend to aggravate the fuel temperature problem. However, increased mission range does not affect fuel temperature as adversely as might be expected, because the amount of onloaded fuel would have to be increased, which also increases the available fuel heat sink. Previous studies of the 969-336C airplane indicated that the fuel temperature rise with increasing range was a function of tank conductance, and for the conductances recommended herein the rate of increase would be about 0.0045 K/km (0.015° F/nmi).

# TABLE 19.-FUEL TEMPERATURES FOR VARIOUS TRIP CONDITIONS

| Trip condition   | On loaded         | Maximum temperatures at end<br>of cruise or start of descent<br>(whichever is higher), K (°F) |                              |                                  |                  |  |  |
|--|-------------------|---|------------------------------|----------------------------------|------------------|--|--|
| Trip condition   | fuel temp, K (°F) | Forward<br>main tanks<br>1 or 4   | Rear<br>main tanks<br>2 or 3 | Engine/<br>airframe<br>interface | Burner<br>nozzle |  |  |
| 1. Normal, first trip  | 289 (60)          | 324 (130.3)   | 328 (129.9)                  | 376 (217.4)                      | 414 (285)        |  |  |
| Higher on-loaded fuel temp, first trip   | 306 (90)          | 340 (153.0)   | 340 (153.3)                  | 388 (238.6)                      | 425 (306)        |  |  |
| <ol> <li>Same as 2, except second trip;<br/>reserve plus ballast fuel discharged<br/>to main tanks after first trip</li> </ol> | 306 (90)          | 345 (159.8)   | 345 (161.1)                  | 392 (246.4)                      | 430 (315)        |  |  |

| 5. Same as 4, except with<br>earlier discharge of rear auxiliary<br>tank 14A at 3.03 kg/sec<br>(400 lbm/min) per main tank     | 306 (90)          | 345 (160.2)   | 344 (157.5)                  | 392 (246.0)                      | 425 (307)        |  |  |
| 6. Same as 5, except discharge of tank 14A at 6.06 kg/sec (800 lbm/min) per main tank  | 306 (90)          | 344 (158.2)   | 342 (156.0)                  | 391 (244.0)                      | 426 (308)        |  |  |

<sup>\*</sup>Conductances per table 18

Two possible alternatives to additional tank insulation were investigated to reduce fuel temperature. The first of these was to compartment the main tanks so that the inboard portions of all main tanks would have a capacity of 13 600 kg (30 000 lbm) fuel each, and the outboard portion would be converted into additional auxiliary tanks. The results of this concept are shown in figure 40. This compartmenting scheme would reduce final fuel temperature about 4.4 K (8° F), but would introduce the additional weight of bulkheads, pumps, gages, etc. required for the additional auxiliary fuel tanks.

Another possibility is to start discharging the fuel from the rear fuselage auxiliary tank (14A) prior to the end of cruise. This is effective only when tank 14A has sufficient insulation to keep the fuel cool. The results of this concept are shown in table 18, conditions 5 and 6. In both cases the transfer from tank 14A started 15 minutes before the end of cruise. For condition 5 the transfer rate was 3.03 kg/sec (400 lbm/min) per main tank, and for condition 6 the rate was 6.06 kg/sec (800 lbm/min) per main tank. As can be seen, this results in tank fuel temperature reductions of 3.05 K (5.5° F) and 4.16 K (7.5° F) respectively. The penalty for early discharge of tank 14A is that the c.g. moves forward during supersonic cruise, which would require moving the forward c.g. limit, and would result in increased trim drag with the associated performance penalty. The magnitude of this performance penalty has not been established, nor has the increase in forward c.g. limit been identified.

#### STRESS ANALYSIS AND STRENGTH SIZING

The stress analysis and resizing of the structural members is the culmination of structural design for strength. These analyses involve a number of activities relating to the preparation of external loads in a form to be applied to the airframe to produce internal loads, preparation of many sets of data necessary to properly utilize allowable stresses and recognize practical design limitations on the structural members, and checking of the data and programs to assure proper operation and accurate results. This last item, checkout of data and programs, is perhaps the most critical requirement for producing analyses of the type described herein. Experience on analyses of large finite element models has shown that flow time and manpower requirements for this checking function are often underestimated.

The following paragraphs describe these activities as carried out on the arrow wing, followed by the description of the stress analysis and results of resizing.

The initial effort consisted of a thorough checkout of the mathematical model to verify correctness of initial data and transfer to the computer. This checkout took the form of checking listings and plots of the many input parameters, locations of members and nodes, classification of members, etc. Following this, sample vibration analyses, deflection, and stress analyses were conducted, and equilibrium and reactions were checked.

The wing was divided into a number of regions, illustrated in figure 41, based on commonality of skin panel construction, spar web construction, spar spacing, and fuel tankage. These regions were defined to expedite the analysis of effects of high structural temperatures and associated thermally induced stresses for each load

condition. Allowable stresses were established for these structural elements by reducing the room temperature allowables by an amount equal to 1.25 times the calculated thermal stresses. The 1.25 factor on the thermal stresses is consistent with the requirements on the National SST program. In cases where thermal stresses relieved the mechanical stresses induced by the airloads, the thermal stresses were conservatively neglected.

A number of subsets of structural members were defined for convenience in specifying design data necessary for stress analysis and resizing. The types of information specified in this manner are: properties of elements used to convert internal loads into stresses, definition of upper and lower bounds on areas or skin gages to limit the redesign for practical reasons, and specification of elements that are not to be resized for special reasons. A number of these subsets are depicted in figures 42 and 43. Figure 44 summarizes the lower bound data for surface panels and spars.

The analytical model represents the right half of the airplane. Deflections were calculated for the symmetric and antisymmetric load components for a given load condition with appropriate boundary conditions applied in the plane of symmetry to specify either symmetric or antisymmetric elastic behavior with respect to this plane. These deflections were then superposed to form the deflections for the design conditions. For unsymmetric conditions, deflections are determined for both sides of the airplane. These superposed deflections then form the basis for the stress analysis of the selected design conditions.

The strength design requires evaluation of: (1) stresses due to the various load conditions, (2) the relation between imposed and allowable stresses, i.e., margins of safety, and (3) structural member size changes necessary to obtain the desired values of the margins of safety.

The stability interaction equation used for evaluation of margins of safety in biaxial compression and shear in the honeycomb sandwich wing covers is:

$$R = \left[ \frac{R_{X}}{1 - R_{XY}^{2}} \right]^{4} + \frac{R_{y}}{1 - R_{Xy}^{4}}$$

where  $R_x$ ,  $R_y$ ,  $R_{xy}$  are the ratios of actual to allowable inplane load for axial and shear loads. For strength-critical loading conditions, a modified Hill's yield criterion was used. The influence of temperature on elastic moduli and allowable stresses was included in the analysis.

Structural elements that were not restrained by minimum gage requirements were resized to obtain new member sizes. Automated resizing of the fuselage elements was not attempted because of the problem posed by buckled skins and the smaller structural weight savings expected in the fuselage. Elements in the fuselage were resized by hand and the resizing process for these elements converged in two cycles. Since lumped areas used in model beam elements in the fuselage are composed in part of effective skin areas and these are influenced by buckling, body pressurization, and thermal stresses, iterative procedures were employed in resizing these elements. Effects of body

pressurization and thermal stresses on effective areas were included in the analysis. Stringer spacing, fastener sizes, and stringer geometry were also defined to establish compression allowables. The relevant design parameters, effective areas, and allowables were adjusted in successive analysis cycles until overall consistency was achieved, with the margins of safety near zero. Figure 45 presents typical material properties as a function of temperature, and figure 46 presents typical compression allowables for various temperatures.

Elements in the wing covers were resized using the ATLAS automated resizing module, with convergence, as measured by total mass change, occurring in three cycles. The resizing module uses the interaction equation given above, and an iterative solution technique. Margins of safety were calculated considering stability, allowable stress level, and fail safety for multiple load cases. Elements were grouped in sets as indicated previously in figures 42 and 43 to allow imposition of common constraints, such as panel minimum face sheet thickness, spar web minimum gage, spar chord minimum areas, and mechanical properties and instability allowables with appropriate thermal stress decrements. Constraints between element types, such as maintaining cap areas of at least one-quarter of the area of the larger adjacent panels for fail safety, were manually determined after a given cycle and imposed as lower bound data in the next resizing cycle.

The stress analysis was run for eleven symmetrical and four unsymmetrical flight conditions, and three symmetrical and two unsymmetrical ground load conditions. Resizing of the body and the wing carry-through structure was completed manually following the first cycle of stress analysis. Subsequent resizing of body structure was confined to the region containing wing carry-through structure.

Typical initial wing panel gages and those resulting from successive cycles of automated resizing are presented in figure 47. For each upper and lower surface panel, three gages are shown. Reading from top to bottom, the first set of values are the upper/lower surface panel gages derived manually from the SCAT-15F as the initial sizes. The second and third sets of gages were obtained from successive cycles of automated resizing.

For lower surface panels of integrally stiffened skin construction, the initial value is the area per inch of skin plus stiffener, while the second value, in parentheses, is the skin gage. For upper and lower surface panels of honeycomb sandwich construction, the single value shown is the sum of the inner and outer face sheet gages.

In the wing region having integrally stiffened lower surface panels, where skin gages are shown in parentheses, it should be noted that the initial sizing of the upper surface panels was larger than required because of the effect of the improved chordwise compressive load allowables of the honeycomb panels relative to that of the corrugated core sandwich on which the initial sizing was based.

The total theoretical masses of the wing box, spars, and panels were evaluated at the end of each successive cycle of stress analysis and resize. The criterion for convergence of the design was based on the total wing box mass. Figure 48 presents the normalized mass of the wing box and illustrates that at the end of the third cycle the mass had essentially converged to a constant value.

# FLUTTER ANALYSIS AND RESIZING

Initial sizing of the arrow wing structure was based on design loads from the early design study of the 969-336C configuration, reported in reference 3, suitably modified to account for the increased gross mass in the present study. However, it was anticipated that a significant increase in structural stiffness, beyond the level provided by the strength design, would be required to satisfy flutter prevention criteria. Since program cost constraints limited aeroelastic loads analysis to one cycle, it was considered necessary to conduct a preliminary flutter analysis with initial sizing and to make some adjustments in stiffness prior to the loads analysis, in order to obtain a set of design loads that would be reasonably consistent with the final design.

# FLUTTER ANALYSIS PROCEDURE

Flutter results were obtained in a single computer run including the generation of stiffness and mass matrices, vibration mode analysis, generation of unsteady air forces for all lifting surfaces, and solution of the flutter equations. A generalized coordinate approach was used in formulating the flutter equations, with a truncated set of airplane vibration modes, together with the relevant rigid airplane degrees of freedom for symmetric and antisymmetric cases. Subsonic kernel-function and supersonic Mach box versions of unsteady lifting surface theory were used to calculate generalized air forces on the wing. The Q-R algorithm was used to solve the complex eigenvalue flutter problem. Constant altitude classical V-g flutter solutions were cross plotted to match the Mach number of the unsteady air forces, and this result was confirmed by an automated flutter solution routine based on the Nyquist criterion. A supplementary study of energy balance at neutral stability was made to provide insight into the flutter mechanism, and to assist in defining changes to increase the flutter speed.

The stiffness modifications which were made in meeting flutter criteria were based on engineering judgment. These judgments were aided by interpretation of the energy balance at the onset of flutter, which identified the vibration modes important to the flutter mechanism. Plots of frequency vs airspeed showed which of these modes required stiffening, and inspection for high strain regions, in those mode shapes, indicated the areas where increased stiffness was required.

#### PRELIMINARY FLUTTER ANALYSIS AND STIFFNESS RESIZE

The preliminary flutter analysis was confined to the symmetric high gross mass condition and to a high subsonic Mach number, M=0.9, based on the flutter results for the National SST program. The same analytical detail and procedures were employed in this preliminary study as in the final analysis. Airplane plunge and pitch and the first 18 symmetric airplane vibration modes were used as generalized coordinates in setting up the flutter equations. Results of the preliminary flutter analyses and the effects of the preliminary stiffness resize are summarized in figure 49 and table 20.

# TABLE 20.-PRELIMINARY SYMMETRIC WING FLUTTER RESULTS

| M = 0.9 - | High | Gross | Mass | Condition |
|-----------|------|-------|------|-----------|
|-----------|------|-------|------|-----------|

| Wing structure  | Flutter<br>speed,<br>m/s (kn) EAS       | Frequency,<br>Hz |
|---|---|------------------|
| Bare wing flutter speed (no nacelles and fin)   | 212 (413)                               | 5.7              |
| Initial structural design 1.05 MN/m<br>(6-kips/in.) engine beams                                | 93 (181.0 <sup>a</sup> )<br>143 (278.0) | 2.18<br>3.58     |
| Initial design with stiffened tip and aileron<br>1.58 MN/m (9-kips/in.) engine beams            | 112 (217.0)<br>216 (420.0)              | 2.29<br>3.67     |
| Initial design with stiffened tip and aileron 4.72 MN/m <sup>-</sup> (27-kips/in.) engine beams | 224 (436.0)<br>224 (435.0)              | 1.90<br>3.72     |

<sup>a</sup>6100 m (20,000-ft) solution; Mach number not matched. Clearance speed (1.2 V<sub>D</sub>); 259 m/s (504 kn) EAS

The flutter speed with initial sizing of the structural model was 93 m/s (181 kn) EAS at a frequency of 1.9 Hz, which was 166 m/s (323 kn) EAS below the design requirement at M=0.9. An appraisal of the flutter mode showed large amplitude nacelle motion as well as large energy inputs from excessive wing tip distortion and windup of the low-speed aileron relative to the inboard location of its actuators. These flexibilities were also very apparent in the flexibility influence coefficients and the vibration mode shapes.

As a result of the initial assessment of flexibilities and preliminary vibration analysis, it was decided to stiffen structure in three areas before initiating the FLEXSTAB aeroelastic loads analysis:

- 1. In the wing tip outboard of the wing-mounted fin, spars and covers of the main box and secondary structure behind the rear spar were doubled.
- 2. The low-speed aileron covers were quadrupled in thickness to minimize windup relative to the inboard location of the actuators.
- 3. The strength-designed nacelle support beams were stiffened by a factor of 1.5 to 1580 kN/m (9000 lb/in.), defined at the rear mount location with the beam cantilevered at the wing rear spar.

Little improvement in flutter speed of the critical low-frequency mode was obtained with this preliminary stiffness resize; it rose to  $112 \, \text{m/s} \, (217 \, \text{kn})$  EAS, still 148 m/s (287 kn) EAS below the M=0.9 requirement. However, the flutter speed of the less critical overtone flutter mode did rise appropriately with the stiffened wing tip, as can be seen for this condition in table 20.

Experience on the National SST program indicated that the critical low-frequency flutter mode could not be controlled without further stiffening of the engine beams, which are cantilevered off the wing rear spar. This was further confirmed by large amplitude motions of the outboard nacelle in the calculated critical flutter mode of the arrow wing configuration. Since the trailing edge structure of the wing is attached to the nacelles and engine support beams, the wing deformations that are induced by large nacelle motions produce significant changes in the oscillatory wing airloads that have a destabilizing effect on the wing flutter mode. This was confirmed by wind tunnel tests on the National SST program. Vibratory displacements associated with the fifth airplane vibration mode were found to be an essential ingredient of the wing flutter motion. The shape of this particular mode is displayed in figure 50 for two different values of engine beam stiffness to illustrate the decoupling of the outboard nacelle resonance that occurs with increased engine beam stiffness. This decoupling effect is mainly responsible for the improved flutter speed with stiff engine beams.

# FINAL FLUTTER ANALYSIS AND STIFFNESS REDESIGN

Following the automated resize of wing primary structure and prior to the final flutter analysis, some changes were made to the strength-designed structural model. These included locks on the low-speed aileron and outboard flaperon during high-speed flight, wing tip and low-speed aileron stiffening that had been adopted prior to the loads analysis, and engine beam stiffening to 4.5 times the strength design value. With these stiffness increments the effect of strength resizing was a slight decrease in flutter speed to 0.817 of the speed requirement at M=0.9, compared with a flutter speed ratio of 0.865 prior to the strength resize (with the same stiffness increments, apart from the control locks). No reduction in gages or member sizes, below the values specified for strength, were allowed in defining further structural changes to meet flutter criteria. These changes are listed in table 21.

Six additional design modifications, based on engineering judgment, were analyzed in attempting to improve the wing flutter speed. This analytical work was first confined to the symmetric, high gross mass condition at M=0.9. It was finally concluded that further efforts to increase the flutter speed of the critical 1.9 Hz wing flutter mode, via structural changes based on engineering judgment, would produce an unrealistically high mass penalty. Hence it was proposed that the subsonic dive placard be reduced by 26 m/s (50 kn) EAS to achieve flutter clearance. The reduced placard would impose a range decrease of 46 km (25 nmi) with fixed fuel loading, or an increase of 588 kg (1297 lbm) in fuel loading for constant range.

The structure with the final stiffness design modifications was then analysed for symmetric flutter at low gross mass and for antisymmetric flutter at both high and low gross masses and M=0.9. This confirmed that the symmetric, high gross mass condition was critical. Flutter analyses were then conducted for that condition at other Mach numbers. The resulting flutter boundary for the 969-512B configuration with titanium structure (1975 technology) appears in figure 51.

<sup>&</sup>lt;sup>a</sup>Initial design with preliminary stiffness

The stiffness design modifications to provide flutter clearance are summarized in figure 52. The penalty associated with the stiffness redesign is equivalent to 4637 kg (10 223 lbm), per aircraft including the 1339 kg (2953 lbm) equivalent of a 1.3 drag count increase for thickening the wing tip.

# **MASS ANALYSIS**

The mass statement for Model 969-336C (see ref. 2) was revised early in the study to account for advances in subsystem design and in structures and materials technology that have occurred since the earlier study was made. This revision, data from the National SST program, and data from the AST study (Contract NAS1-19938) were then used to develop a preliminary mass and balance statement for the 969-512B configuration, and detailed mass distributions were defined for calculation of the mass matrices required for aeroelastic loads and flutter analyses.. The mass distribution and the mass matrix were revised as the design evolved, reflecting iterative design changes to satisfy strength and flutter criteria. A mass and balance statement for the final

bFinal stiffness

configuration was prepared to provide a basis for assessment of the performance impact of the structural changes. This final mass statement and the preliminary mass statement from Task I are displayed together in table 22.

#### WING AND CONTENTS

Masses of wing structure and contents were introduced into the mass model in a number of ways. The theoretical masses of spars, ribs, and cover element skins were automatically calculated from the material density and volume required to satisfy the structural requirements. To these were added the masses of nonoptimum structure, consisting of padups, fasteners, fittings, etc., to arrive at total structural mass. The theoretical-to-actual mass increment was input as a percentage of the cover material, spar, rib, and beam masses. The derivation and a more detailed explanation of the theoretical-to-actual factor is discussed in later paragraphs.

Surface panel skins, honeycomb core and braze, and main landing gear doors were entered in the program as plate mass elements and distributed over the appropriate area. Some of the miscellaneous items in the wing box, such as fairing, fuel system provisions, aerodynamic fences, and jacking provisions were treated as rods, plates, or point masses, based on shape similarity.

Mass distributions for wing contents and secondary structure were determined from Model 969-336C data. Masses of leading and trailing edge structure and wing contents were defined for the mass panels shown in figures 53 and 54. Input data for these items were generated manually. Inertia data for the mass panels were generated automatically within the ATLAS analysis module.

#### CORRECTION OF MASS ANALYSIS

In conjunction with a later study, reported in references 14 and 15 and dealing with the application of advanced composite materials to the arrow wing structure, a detailed review of the structural mass analysis of the titanium arrow wing structure has been accomplished. In the course of this review some errors have been found. Principally these consisted of omission of spar and rib web stiffeners, inclusion of core and braze contributions in the integrally stiffened portion of the lower wing surface, and failure to fully account for spanwise edge padup masses in deriving theoretical-to-actual factors for wing surface panels. Detailed descriptions of these errors and revision of the mass analysis are presented in sections 5 and 9 of reference 14. In order to provide an adequate basis for derivation of theoretical-to-actual factors for composite wing panels it was found necessary to develop panel designs using both titanium and composite materials and including edge attachment details for five representative locations on the arrow wing. Design data for the five titanium panels from the later study were used in developing the theoretical-to-actual factors that were employed in correcting the mass analysis of the titanium structure.

Correction of the errors noted above has increased the mass of the titanium wing structure listed in table 22 by 930 kg (2050 lbm). The corrected value is 44 370 kg (97 810 lbm).

<sup>\*</sup>See text subsection: Correction of mass analysis

# **BODY AND CONTENTS**

The body structure and contents are plotted as a one-dimensional running load in figure 55. The concentrated masses of galleys and contents at the galley doors are identified, as well as the buildup of mass at the front spar. This plot does not include the wing-body intersection, passengers or cargo masses.

The wing-body intersection and carrythrough structure inboard of buttock line 55 are included in the mass model as part of the body. The passenger and cargo mass is shown as a one-dimensional load distribution in figure 56, for a full payload condition. Since the body structure was sized manually, as noted earlier, the mass input data for the body were also generated manually.

#### EMPENNAGE AND WING-MOUNTED FIN

The mass distributions of the wing-mounted vertical fin, the body-mounted vertical tail, and the horizontal tail were all represented as sets of concentrated masses in the mass model for aeroelastic loads analysis. For flutter analysis the body-mounted vertical tail and horizontal tail were represented as rigid inertias with mass, center of gravity, and three-axis moments of inertia. The wing-mounted vertical fin was represented as a set of concentrated masses, as in the aeroelastic loads analysis.

#### **FUEL**

The fuel tank arrangement and tank capacities for the model 969-512B are shown in figure 5. A balance diagram with c.g. limits and fuel management for the maximum gross mass condition is shown in figure 57. The fuel distribution by tank was calculated for each of the 27 design conditions, consistent with the c.g. limits and fuel management sequence. These fuel quantities were translated into percentages of tank capacities and distributed into consistent mass panels. The body fuel was treated as a set of point masses in the aerodynamic loads analysis and as a point mass and moment of inertia data in the flutter analysis.

# WING BOX MASS ESTIMATION METHOD

The finite element analysis of the wing primary structure produced the masses of the theoretically designed structural elements. The mass of the nonoptimum structure was added to convert from theoretical to total structural mass, as shown in figure 58. Figure 59 gives an example of nonoptimum structural items in a honeycomb wing surface panel. These consist of: skin padups along the panel edges and access doors, basic honeycomb core, dense core along the panel edges, braze material, and miscellaneous items, such as access doors, fuel system provisions, fairings, etc.

The theoretical-to-actual structural factors used in the arrow wing program were derived from design details from the National SST program. The masses of the basic skin panels were compared with the calculated masses for the released structural drawings to arrive at the factors as shown in figure 60. Two sets of curves are shown, one for the Model 2707-300 prototype airplane (PT) and the other for the 2707-300

production airplane prototype point design (PPD). The lower theoretical-to-actual factor for the PPD airplane was used for Model 969-512B. The PT airplane was defined in greater detail, thus helping to substantiate the slope of the curve. These curves show that the factor is relatively high for the lighter skin gages, primarily due to fastener provisions and padups at the panel edges. The correction factor for the lower surface is larger than for the upper surface because of more numerous cutouts. As can be seen on figure 60, outboard wing section 17 does not plot consistently with the remainder of the wing sections, due to additional wing tip cover material that was required to disperse concentrated loads from both leading edge and trailing edge flaps. The Model 969-512B has a similar outboard wing tip section, but these higher factors were not considered appropriate, since the basic skin gages in this area were doubled to help alleviate flutter.

A review of the honeycomb core masses on the National SST program showed that approximately 25% must be added to the upper surface and 30% to the lower surface basic core mass to account for the dense core around the panel edges and access holes. Similar percentages must be added to the basic braze mass to accommodate the dense core at the panel edges. A study similar to that for the surface panels was made to determine the theoretical-to-actual factors of the spars and ribs on the National SST program wing. It was found that the average mass increment for all spars was 15% of the theoretical structural mass and 18% for all ribs.

Figure 61 gives a summary of the method of estimating the total structural mass of the wing box starting with the theoretical structural mass generated by ATLAS.

# MASS CHANGES RESULTING FROM REDESIGN FOR STRENGTH

Table 23 shows three wing masses: (1) the Task I wing mass estimate, 42 710 kg (94 160 lbm); (2) a re-estimate with preliminary stiffness, 46 180 kg (101 820 lbm); and (3) a structurally resized wing with preliminary stiffness, 41 870 kg (92 310 lbm).

The Task I wing mass in column (1) of table 22 was based on 969-336C masses with revisions added for changing material from stresskin to aluminum brazed titanium honeycomb, for changing the wing planform and flap configuration, increasing the gross mass from 288 030 kg (635 000 lbm) to 340 190 kg (750 000 lbm), and other miscellaneous design changes.

Column (2) is a revised estimate of Model 969-512B wing mass based on the ATLAS resized structural box, modified for preliminary stiffness increases. These increases consist of doubling the outboard wing tip spars and covers, quadrupling the outboard aileron cover material, and stiffening the engine beams.

The breakdown of the 3475 kg (7660 lbm) increment between columns (1) and (2) is as follows:

| Outboard aileron stiffness increase     | + 381 kg  | (+ 840 lbm)                      |
|---|-----------|----------------------------------|
| Outboard wing tip stiffness increase    | +1416 kg  | (+3122 lbm)                      |
| Increase associated with initial sizing | +1677 kg  | (+3698 lbm)                      |
|   | +3474  kg | $\overline{(+7660 \text{ lbm})}$ |

Column (3) is the mass of the wing as resized by ATLAS inboard of the wing-mounted fin, while retaining the sizing for stiffness in the outboard aileron and wing tip region.

The distribution of the 4314 kg (9510 lbm) reduction is as follows:

| Reduction of cover material | $-2227~\mathrm{kg}$ | (-4910 lbm)  |
|-----------------------------|---------------------|--------------|
| Reduction of spar material  | −1159 kg            | (+2556 lbm)  |
| Reduction of rib material   | - 937 kg            | (-2066  lbm) |
| Increase of beam material   | + 10 kg             | (+ 22 lbm)   |
|                             | -4313 kg            | (-9510 lbm)  |

# ADDITIONAL MASS REQUIRED TO SATISFY FLUTTER CRITERIA

Nine wing flutter analyses were conducted at M=0.9 with various stiffness combinations in order to satisfy flutter criteria. These structural configurations are identified in table 21, and the corresponding comparisons in wing structural mass are summarized in table 24.

Several revisions were also made to the wing-mounted vertical fins to satisfy the flutter requirements. These modifications included increased skin gages, spars, and ribs, as well as the addition of an intermediate horizontal rib. However, there was a decrease in the sizing of the base rib. The mass of the Task II wing-mounted fin with initial sizing was 1290 kg (2850 lbm). Stiffness design modifications added another 213 kg (470 lbm) for a total of 1503 kg (3320 lbm) per airplane.

#### FINAL GROUP MASS STATEMENT

Table 21 shows the Model 969-512B group mass statements for Task I and Task II and the mass increments.

The 726 kg (1600 lbm) increase in wing mass is the net change resulting from the ten cycles of analysis necessary for strength design and flutter prevention. This mass includes 822 kg (1812 lbm) reduction due to structural resizing for strength, and 1548 kg (3412 lbm) increase for the final modifications to satisfy flutter criteria.

The 316 kg (850 lbm) wing-mounted vertical tail mass increase includes 172 kg (380 lbm) for strength design and 213 kg (470 lbm) for the final stiffness modification for flutter.

As described earlier, a study was conducted to determine the fuel temperature rise during supersonic cruise on the Model 969-512B. This study indicated a minimum requirement of 694 kg (1530 lbm) of fuel tank insulation is required to keep the fuel temperature below the 344 K (160° F) limit. This is 327 kg (720 lbm) over the 367 kg (810 lbm) allowance in the initial mass estimate.

## EFFECTS OF REDESIGN ON AIRPLANE PERFORMANCE

The mission performance of the arrow wing 969-512B configuration with the ATAT-1 engine was updated to reflect the changes in mass, drag, and climb placard which were necessary to satisfy strength, flutter, and thermal requirements. The total range decrement was 250 km (135 nmi), itemized in table 25.

TABLE 25.-STRUCTURAL DESIGN IMPACT ON MISSION RANGE

| Change                  | Equivalent<br>mass, kg (lbm) | Range<br>km (nmi) |  |  |
|-------------------------|------------------------------|-------------------|--|--|
| ОЕМ                     | +1438 (+3170)                | -109 (-59)        |  |  |
| C <sub>D</sub> +0.00013 | +1275 (+2811)                | -96 (-52)         |  |  |
| Placard                 | +588 (+1287)                 | -44 (-24)         |  |  |
| Total                   | +3301 (+7278)                | -250 (-135)       |  |  |

The changes in range due to increased OEAS and drag were obtained from trades previously established and shown in figure 62. The placard change from the original climb speed of 180 m/s (350 kn) to 154 m/s (300 kn) to provide for adequate flutter margin, illustrated in figure 63 by the dotted line, gave a range decrement of 46 km (25 nmi), primarily due to reduced subsonic rate of climb at the reduced placard speed.

The updated performance is compared with the original 969-512B in table 26. The takeoff and approach data are unaltered by the changes.

## RECOMMENDATIONS

Experience gained from this study has identified a number of problem areas where further work on automated design tools and basic technology is needed. These needs are discussed in the following paragraphs.

## FURTHER APPLICATIONS OF THE ARROW WING MODEL

The mathematical model of the arrow wing configuration is a valuable resource that can be used in further studies to evaluate the effect of configuration changes and technology advances on supersonic cruise aircraft and to continue the development of procedures for structural design optimization.

As noted in the description of the flutter analysis, a number of trial-and-error attempts were required to arrive at the modifications for the flutter requirements. These structural variations were based on experience and judgment from the National SST program. The development of formal optimization techniques would not only improve the cycle time required to come up with such structural modifications, but would undoubtedly result in additional weight savings.

A study of finite element modeling criteria would be a valuable contribution to integrated analysis and design methodology. Essential structural details that have important effects on wing flutter speeds of supersonic cruise configurations were identified by analysis and wind tunnel model tests on the National SST program, and these details have been accounted for in this study. However, it has not been possible, within budget and schedule constraints, to determine how rapidly the flutter prediction deteriorates as the finite element model is simplified by decreasing the number of nodes, decreasing the number of structural elements, and thus increasing the size of individual finite elements. Such a study would be valuable for generating preliminary design modeling criteria that relate the fineness of the structural grid to the required quality of mass and aeroelastic predictions.

Design refinements were limited to variations instructural sizing with fixed concepts and materials and a fixed structural arrangement. Because of the mass penalties associated with flutter on the arrow wing configuration, the possibility that significant mass savings could be achieved by variations in structural arrangement should be explored. The ATLAS System provides an appropriate tool for conducting such a study on the arrow wing model. Consideration should be given, at least, to variations in rib spacing, spar spacing, and spar direction. A meaningful study would cover the entire aeroelastic cycle, including loads analysis, resizing for strength and flutter, and final mass analysis.

# RESEARCH ON PREDICTION OF AERODYNAMIC PRESSURE DISTRIBUTIONS

For typical high aspect ratio configurations at subsonic speeds, methods of incorporating experimental data into the aeroelastic solution for static loads are well developed and

have been substantiated by flight tests. However, for typical low aspect ratio configurations where lifting surface aeroelastic solutions are required, no satisfactory methods of incorporating rigid experimental data into the solution have been developed. Similar uncertainties exist in the prediction of unsteady aerodynamic loads for prediction of flutter characteristics at transonic speeds and/or high angles of attack.

Limited work on these problems has been performed and is described in references 12 and 16. Research should be continued at high priority to develop theoretical and empirical methods for prediction of pressure distributions on complete vehicles, including effects of structural deformations and control displacements, with particular emphasis on the transonic regime.

#### ADVANCED TITANIUM ALLOYS

There is a definite possibility that new and more efficient titanium alloys will be available within the next five year period with some development effort. Two alloys currently under development, Ti-17 (Ti-5Al-2Sn-2Zr-4Mo-4Cr) and Ti-10V-2Fe-3Al, have the potential of providing 25% higher allowable stresses with the equivalent fracture toughness of Ti-6Al-4V, condition I. The use of these alloys as upper and lower surface cover material for the strength-designed portion of the wing is expected to produce significant weight reductions. In addition, the improvement in allowables would also apply to the strength-sized spar and rib chords. The associated improvement in structural mass of spar and rib chord areas is estimated to be about 650 kg (1400 lbm). The degree to which this mass reduction would be compromised by stiffness requirements related to flutter criteria is uncertain at this time.

During the quality control inspection of titanium extrusions, the tensile modulus of elasticity, E, is routinely checked. Boeing's experience shows that E for extrusions is significantly higher than for sheet and plate material, with the mean value being approximately  $120.6~\rm GN/m^2~(17.5\times10^6~\rm lb/in^2)$ . Maximum values as high as  $137.9~\rm GN/m^2~(20\times10^6~\rm lb/in^2)$  have been observed. The development and selective use of high modulus titanium in areas requiring extra material for stiffness would reduce the mass increment for added material by about 15%. The higher tensile modulus of elasticity of the spar and rib chords would allow a reduction in the lower surface chord areas when the fail-safe minimums are critical.

Utilization of an advanced titanium alloy as primary structural material is one approach that may be used to achieve significant reductions in structural mass of a supersonic cruise aircraft. Development work on new titanium alloys, and testing to provide data on material properties for the design, should be continued.

## **FABRICATION TECHNIQUES**

Aerodynamic heating has a significant impact on the design of the environmental control system that is used to cool the occupied areas of the airplane as well as the equipment and systems. Fuel is the primary heat sink used to remove heat from the environmental control system. Any improvement in insulating properties of the structure reduces the amount of extra insulation, retains the thermal capacity of the fuel to absorb heat from inside the airplane, and reduces the required capability of the

environmental control system. While titanium itself is a relatively poor conductor of heat, the presence of aluminum braze material in the wing cover panels provides a low resistance path through the sandwich, and increases the effect of aerodynamic heating on fuel temperature.

Boeing has developed a core configuration for use with aluminum-brazed titanium sandwich that eliminates the bridging effect of the aluminum braze alloy, and greatly reduces thermal conductivity. A new process is also being developed that uses diffusion bonding for sandwich panels instead of brazing and shows significant cost savings for manufacturing. The concepts have been demonstrated on laboratory samples, and additional development work is required to scale the process and designs up to full size hardware. It is recommended that sufficient funding be put into these developments to determine the ranges of panel sizes and loads for which the new process and concepts are efficient.

## CONCLUDING REMARKS

An in-depth structural design study of an arrow wing supersonic cruise aircraft has been completed utilizing structural materials and concepts that are representative of the 1975 level of technology. The study requirements specified a gross takeoff mass of 340 000 kg (750 000 lbm), a payload of 22 200 kg (49 000 lbm), and a design range of 7800 km (4200 nmi).

The final configuration resulted from trade studies considering propulsion integration, wing-to-fuselage location, and horizontal tail shape and size. Wing twist and camber were optimized to give a maximum lift-to-drag ratio of about 8.6. An advancedtechnology afterburning turbojet engine model developed in a previous Boeing study (Contract NAS1-11938) was selected for aircraft propulsion. Although this engine definition was considered satisfactory for the structural study, its performance parameters were not well enough defined to determine the absolute range of the aircraft, A conventional structural arrangement was optimized with respect to fuselage frame spacing and wing spar spacing to provide a near-minimum-mass structure. Sandwich panels with titanium face sheets aluminum brazed to a titanium honeycomb core are used throughout the upper wing surface. The forward, lightly loaded, portion of the wing lower surface and both surfaces of the stiffness-designed wing tip are also aluminum-brazed titanium honeycomb panels. The aft portion of the wing lower surface, which has large tensile loads, is an integrally machined and welded sheet stiffener construction in the wing outboard of the fuselage and an integrally machined waffle construction under the fuselage where large biaxial loads occur. Wing internal structure (spars and ribs) consists of stiffened sheet webs in the heavily loaded aft portion and sine wave webs in the forward portion. Fuselage structure is conventional sheet-stringer construction.

The ATLAS System, an advanced computerized analysis and design system, was used as the primary tool for the detailed structural analysis and design phase of the arrow wing study. Sizing of structural members for strength was accomplished by a combination of manual and automated methods, based on the fully stressed design principle. Deficiencies in wing flutter speed were corrected by an iterative improvement procedure based on prior experience on the National SST program and engineering judgment. The study provides a baseline aircraft design for assessment of current technology and for use in future studies of aerostructural trades, and application of advanced technology such as composite structural materials and active controls.

This design study using a large, complex mathematical model provided an opportunity to appraise the effect of the use of an advanced computerized structural design system on design methods.

The following conclusions have been drawn:

1. An integrated design system should be used in the preliminary design phase of a large supersonic aircraft development progam to reduce manpower and design cycle time and to provide sufficient modeling detail for aeroelastic analysis.

- 2. Static aeroelastic effects and flutter should be considered as early as possible in the design process so that stiffness-constrained members are identified and not unnecessarily resized for strength.
- Generation and validation of a complex finite element model is a major item in the structural analysis effort, and the use of automated modeling methods and sophisticated graphics capability is desirable to decrease both manpower expenditure and flow time for this task.
- 4. Automated resizing for strength is an important factor in reducing design cycle time because the finite element model can be generated more quickly by using unrefined initial estimates of member sizes, and automated resizing during subsequent design cycles is much faster than manual methods.
- 5. Main fuel tanks should be located in the deeper portions of the wing to reduce the fuel temperatue rise due to aerodynamic heating.
- 6. Since the mass addition necessary to prevent flutter may be an appreciable fraction of the payload mass, efficient, automated structural optimization for flutter is desirable in computerized design systems.
