## Abstract

In this paper we investigated the effects of sphericity on the radiation reflected from a planet with a homogeneous, conservative scattering atmosphere of optical thicknesses of 0.25 and 1.0. We considered a Henyey-Greenstein phase function with asymmetry factors of 0.5 and 0.7. Significant differences were found when these results were compared with the plane-parallel calculations. Also large violations of the reciprocity theorem, which is only true for planeparallel calculations, were noted. Results are presented for the radiance versus height distributions as a function of planetary phase angle. These results will be useful to researchers in the field of remote sensing and planetary spectroscopy.

## Introduction

In a recent paper by Adams and Kattawar (1977), hereafter referred to as part I, detailed comparisons were made between the plane-parallel approximation (PP) and the more realistic spherical shell atmosphere (SSA) calculation for a homogeneous, conservative, Rayleigh scattering atmosphere. In this paper large deviations between the PP and SSA cases were noted for certain angles of incidence and emergence. Also gross violations of reciprocity were found for certain angles using the SSA. It is the purpose of this paper to make similar comparisons for an atmosphere which has varying degrees of asymmetry in its phase function. To this end we have chosen to use the Henyey-Greenstein phase function (HG), namely

$$
\begin{equation*}
P(\xi)=\frac{1-g^{2}}{4 \pi\left(1-2 g \xi+g^{2}\right)^{3 / 2}} \tag{1}
\end{equation*}
$$

where $\xi$ is the cosine of the scattering angle $(\cos \theta)$ and $g$ is the asymmetry factor given by

$$
\begin{equation*}
\langle\xi\rangle=g=\int_{-1}^{1} \int_{0}^{2 \pi} \xi P(\xi) d \phi d \xi \tag{2}
\end{equation*}
$$

It should be noted that $P(\xi)$ is normalized to unity when integrated over $4 \pi$ steradians.

## Sampling the Phase Function

Let $\phi(\psi)$ be a uniform density function defined by

$$
\phi(\psi)= \begin{cases}1 & 0 \leq \psi \leq 1  \tag{3}\\ 0 & \text { otherwise }\end{cases}
$$

also let $Q(\psi)$ be the distribution function of $\xi$ defined by

$$
\begin{equation*}
Q(\psi)=\int_{-1}^{\psi} P^{\prime}(\xi) d \xi \tag{4}
\end{equation*}
$$

where

$$
\begin{equation*}
P^{\prime}(\xi)=\frac{1-g^{2}}{2\left(1-2 g \xi+g^{2}\right)^{3 / 2}} \tag{5}
\end{equation*}
$$

and

$$
\begin{equation*}
\int_{-1}^{1} P^{\prime}(\xi) d \xi=1 \tag{6}
\end{equation*}
$$

Now it is clear that there exists an $R$ and $\psi$ such that

$$
\begin{equation*}
\int_{0}^{R} \phi(y) d y=Q(\psi)=R \tag{7}
\end{equation*}
$$

since both density functions are normalized to unity. Now obtaining $Q(\psi)$ from eqs. (4) and (5) and solving for $\psi$ in terms of $R$ we get

$$
\begin{equation*}
\psi=\frac{1+g^{2}-\left[(g(2 R-1)+1) /\left(1-g^{2}\right)\right]^{-2}}{2 g} \tag{8}
\end{equation*}
$$

It should be noted that $\psi=-1$ when $R=0$ and $\psi=1$ when $R=1$ and $R$ is a random
number between zero and unity. In Fig. 1 we show how well the distribution of the variable $\psi$, obtained by sampling using eqn. (8), agrees with the theoretical density function for the cases where $g=0.5$ and 0.7 .

## Calculational Results

For these calculations we have maintained the same model as was used in part I. In this study we only vary the asymmetry parameter $g$ and we will consider two values, namely $g=0.5$ and 0.7 . It should be noted that in the case of Rayleigh scattering which was used in part I that $\langle\xi\rangle=0$ but this does not correspond to the case of $g=0$ for the $H G$ phase function which is isotropic scattering. In Figs. 2a-2d we present results for the reflected radiance versus nadir angle for the cases where $\theta_{0}=0^{\circ} ; \tau=0.25$ and $1.0 ; g=0.5$ and 0.7 . All nomenclature is the same as that used in part I of this series. The first thing to be noted is that the radiance for the SSA case is always greater than or equal to the PP case for all nadir angles less than the one for which ISSA reaches a maximum. This result is independent of the $g$ parameter and is also true for Rayleigh scattering. To aid in interpreting the results for this and other figures we have constructed Tables 1 and 2 giving $I_{S S}^{P P}, I_{S S}^{S S A}, I_{S S}^{S S A} / I_{T S}^{S S A}$ and $I_{S S}^{P P} / I_{T S}^{P P}$ for $g=0.5$ and 0.7 respectively. If these tables are compared with the corresponding table in part I we note that multiple scattering is much more di: inant for the cases where $g=0.5$ and 0.7 than it is for Rayleigh scattering. The exceptions being at extreme nadir angles for $\tau=0.25$. We also note that the greater the asymmetry factor the greater the effect of multiple scattering particularly for nadir angles greater than $70^{\circ}$. Differences between the PP and SSA of $20 \%$ are still prevelant at $\tau=0.25$ in the region where the SSA radiance peaks and diminish considerably as the optical depth increases to 1.0. The
matrix operator (MO) calculations are presented so that one could gain some insight into the statistical fluctuations in the results by comparing with the backward plane-parallel calculation (PP). In figs. 3a-d the solar incident angle is $70.47^{\circ}$. To better understand the behavior depicted in this figure one should refer to Tables 1 and 2. Comparing similar cases for $\mathrm{g}=$ 0.5 and 0.7 we again see that slightly more multiple scattering exists for $\mathrm{g}=0.7$ than for $\mathrm{g}=0.5$. This difference is much more pronounced when $\mathrm{g}=$ 0.7 is compared to the similar case for Rayleigh scattering in part I, Table 1. Also note that for $\tau=0.25$ and for angles greater than $80^{\circ}$ there is relatively more SS for the SSA than for the PP case while at all other angles they are comparable. Closer analysis of the data yields a very important result. We see that only when differences appear in the SS do we get differences in TS. It thus appears that differences in SS are a necessary condition for differences in TS. In Figs. 4a, 4b, 5a, 5b the solar zenith angle is increased further to $84.20^{\circ}$ for $g=0.5$ and 0.7 respectively. If we again refer to Tables 1 and 2 we first note the fact that $I_{S S}^{P P}<I_{S S} S S A$ for all nadir angles up to $85^{\circ}$. This accounts for the fact that ITP < IS TS is comparable between the PP and SSA. There is also an extremely important result worth noting in this data and that is the fact $I_{S S}^{S S A}$ for $\tau=0.25$ can be greater than $I_{S S}^{S S A}$ for $\tau=1.0$. This result can not occur for the PP case since $I_{S S}^{P P}$ is a monotonically increasing function of $\tau$ for fixed directions of incidence and emergence. This phenomenon is strictly due to curvature effects and more will be said about this when we present the radiance versus height distribution. Finally we observe again that as $g$ increases the ratio of SS/TS decreases.

In Figs. 6a-d we present the radiance versus height distribution for both SS and MS for a pair of reciprocal points $\left(\theta, \theta_{0} ; 0,60^{\circ}\right.$ ) and $\phi=0^{\circ}$ for $\tau=0.25$, 1.0 and $g=0.5,0.7$. These curves should be compared with Figs. 9 and 11 of part I for Rayleigh scattering. There are several noteworthy differences. First we observe that for Rayleigh scattering and $\tau=0.25$ the $S S$ contribution is always greater than the MS contribution. This is no longer true when we go to more asymmetric phase functions. In fact from $0-50 \mathrm{~km}$ the MS is comparable to the SS for $g=0.5$ and 0.7 . For the $\tau=1.0$ case the MS dominates everywhere over SS for $g=0.5$ and 0.7 whereas for Rayleigh scattering the MS exceeds the SS up to 88 km . Also the MS distribution is much broader for $\mathrm{g}=0.5$ and 0.7 than it is for Rayleigh scattering. This is due to fact that the forward peak in the phase function tends to inject the photons deeper into the atmosphere. Therefore if one looks at these results from a spectroscopist point of view then it becomes apparent that significantly different regions will be probed in an inhomogeneous atmosphere depending on the type of scattering taking place. In Fig. 7a we present the SS and MS versus height distribution for the cases where $\tau=0.25$ and $g=0.5$ for the following equal incident and emergent angles, $\theta=\theta_{0}=0^{\circ}$, $60^{\circ}, 83^{\circ}$ and $\phi=0^{\circ}$. These angles were chosen so that if one were viewing a planet from a spacecraft at a large distance then these angles would correspond to a point at the intensity equator on the mirror meridian at phase angles of $0^{\circ}, 120^{\circ}$, and $166^{\circ}$ respectively. We first see that as the phase angle increases the ratio of SS/TS increases; in fact these ratios are 55,65 , and $83 \%$ respectively. A most interesting feature in the SS show?d be noted for the case $\theta=\theta_{0}=83^{\circ}$ and that is the fact that it reaches : minimum at 65 km and actually increases as we progress further from the top of the atmosphere and then falls abruptly to zero below 48 km . This behavior is understandable when we consider
the fact that the distance of closest approach (DCA) along the line of sight of the detector is 51.8 km , therefore there can't be any $S S$ contributions below this level. Also for all levels above this altitude, $S S$ constributions are coming from both sides of the DCA. Now as we move from the DCA toward the subsolar point the transmission from the source to the scattering volume is increasing but the transmission from the scattering volume to the detector is decreasing at a faster rate. Another interesting feature is seen in the MS for this case. It is fairly uniform down to about 60 km and then rises in unison with the SS contribution and then falls precipitously below 50 km . This is in sharp contrast to the behavior of the MS contribution at the two smaller angles. For these cases the MS contribution is weakly monotonic decreasing from the top of the atmos. eere. In Fig. 7b corresponding cases are presented except now $\tau=1.0$. Now the optical thickness is large enough that the behavior exhibited by the $S S$ at $\theta=\theta_{0}=83^{\circ}$ for $\tau=0.25$ is no longer present. Now it should be clear that the $S S$ contribution for $\tau=0.25$ can indeed be greater than the $S S$ contribution for $\tau=1.0$; a result which was alluded to earlier in the sequel. We should again emphasize the fact that this phenomenon can only occur in the SSA calculation and is totally prohibited by the PP approximation. The ratios of $S S / T S$ for $\theta=\theta_{0}=0,60^{\circ}$, $83^{\circ}$ are 21,40 and $78 \%$ respectively, thus there is much more multiple scattering for $\tau=0.25$ than for $\tau=1.0$ at the smaller angles while at $\theta=\theta_{0}=83^{\circ}$ the difference is much smaller, $83 \%$ compared to $78 \%$. Thus it is clear that significantly different regions of the atmosphere are being probed as we view a planet over a wide range of phase angles.

In Table 3 we explore the violations of reciprocity for the SSA calculation, we first note that the SS results for the PP approximation satisfy reciprocity everywhere. Also the $T S$ results satisfy reciprocity to within a few percent. These results are presented to give one an idea of the statistical fluctuations
to be expected in the SS: calculation since the same number of histories were run for corresponding angles. We also note that $\mathrm{I}_{\mathrm{SS}}^{\mathrm{SSA}}\left(\mu, \mu_{0}, \phi\right) / \mathrm{I}_{\mathrm{SS}}^{\mathrm{SSA}}\left(\mu_{0}, \mu, \phi\right)$ is independent of phase: angle and deviations from the ratio of $\mu_{0} / 4$ are sirictly due to curvature effects (see Table 2 of part 1 for Rayleigh scattering results). It is also apparent that the addition of MS makes matters worse. Also increasing the asymmetry of the phase function increases the discrepancy. inis is physically what oise would expect sirice the greater the asymmetry the further removed a photon will be from its point of injection tefore emergence.

## Conclusions

We have examined the effects of sphericity on homogencous conservative scattering atmospheres of optical depths $\tau=0.25$ and 1.0 with scattering according to a Henyey-Greenstein phase function for two values of the asymmetry factor, namely 0.5 and 0.7 . Significant disagreement was found between the PP approximation and the more realistic SSA calculation. We also found that the degree of asymmetry strongly affects the radiance versus height distribution for multiple scattering. We have also shown that significantly different regions of the atmosphere are probed as one views a planet over a wide range of phase angles. These results will be useful for researchers in the fields of remote sensing and planetary spectroscopy. Violations of reciprocity also becomes more severe the more asymmetric the phase function.
