#### ABSTRACT

A 0.14-scale dynamically scaled model of the Space Shuttle orbiter wing was tested in the Langley Research Center 16-Foot Transonic Dynamics Wind Tunnel during September 1974 to determine flutter, buffet, and elevon buzz boundaries. Mach numbers between 0.3 and 1.1 were investigated. Rockwell Shuttle model 54-0 was utilized for this investigation. A description of the test procedure, hardware, and results of this test is presented herein.

#### INTRODUCTION

Flutter boundaries for the Space Shuttle orbiter configuration 140B wing were investigated. This investigation was conducted in the NASA Langley Research Center's 16-Foot Transonic Dynamics Wind Tunnel. The model was a 0.14 scale dynamically scaled right wing panel mounted on a rigid model of a segment of the right side of the orbiter fuselage. This investigation was called OS6. The model was designed and fabricated by Grumman Aerospace Corporation under Purchase Order Agreement M3W3XMU483002 with Rockwell International Corporation's Space Division. Grumman also performed pretest measurements and calibrations of the model, conducted the test, and analyzed the test results under this same purchase order. Much of the information presented in this report was derived from Reference 1, which is Grumman's final document of its work under this purchase order.

### NOMENCLATURE

#### CONFIGURATIONS INVESTIGATED

The wing-elevon model was a 0.140 geometric scale representation of 140B Space Shuttle Orbiter components. It was dynamically scaled; i.e., the reduced frequency ratio and mass density ratio were scaled to 1.0 to properly simulate stiffness and mass properties of the full scale structures. The model scale factors were established to assure that estimated flutter boundaries fall within the range of the LaRC 16-foot TDT. The model had a stressed skin design constructed of epoxy-resin (pre-preg) fiberglass plies layed up on cellular-cellulose acetate (CCA) foam backing; local areas such as root attachments and actuator back up structure were reinforced by steel sheet (.003" thick) to assure a smooth load transition at the metal-fiberglass interfaces. The model had a control surface (elevon) with actuator stiffnesses modeled by steel flexural pivots. Access panels at the control surface actuator locations facilitated changing the pivot flexures. Different flexures were tested to simulate nominal, 75% of nominal, and 50% of nominal actuator stiffnesses. Fuselage fairings adjacent to the wing were size scaled to simulate proper local flow characteristics as well as to place the surfaces outside the tunnel boundary layer; they were not dynamically scaled. fairings were constructed of fiberglass skin attached to aluminum frames. The model consisted of the following components:

- 1. One sidewall mount to tunnel mounting plate
- 2. One partial non-dynamic fuselage

- One wing assembly (including elevons)
- 4. One additional set elevons (inboard and outboard)
- 5. Nine elevon flexure sets:
  - (a) 3 Stiffness Level 1
  - (b) 3 Stiffness Level 2
  - (c) 3 Stiffness Level 3
- 6. One internal model shaker
- 7. One control surface deflect/release mechanism per elevon
- 8. Eight (8) strain gage circuits (4 bending, 4 torsion)
- 9. Two magnetic induction coil elevon position indicators
- 10. One accelerometer (wing tip)
- 11. Control panel for shaker and deflect/release mechanism

Note: .Items 6 through 10 and one (1) set of item 5 are included in Item 3.

Figure 1 shows a sketch of the model assembly and Figure 2 presents photographs of the model.

The following scaling parameters were used to simulate an altitude of 30,000 feet during the test:

| Mach Number                   | M                | *************             | $v_r/a_r$ ,   | 1.0                     |

Where:  $\mu_r^*$  = absolute viscosity coefficient ratio = ..90

gr = gravitational acceleration ratio = 1.9

 $a_r$  = sonic speed ratio = .52

Air speed is the aircraft flight speed; velocity is the speed associated with vibrations of the model. These quantities differ only when the reduced frequency ratio is not unity.

The following nomenclature was used to designate the model components:

| B <sub>26</sub>    | Body    | Similar to B <sub>26</sub> lines in area of wing. Only left-hand side duplicated outboard of B.L. 63 and with truncated forward fuselage section. |
|--------------------|---------|---|
| M <sub>7</sub>     | QMS Pod | Outboard portion, left-hand side only.  |
| M <sup>158</sup> ' | Wing    | Left-hand wing only similar to W <sub>116</sub> except modified to remove spanwise twist from airfoil section                                     |
| B45                | Elevons | Inboard and outboard left side only.  |

A complete description of model components and dimensional data is given in Table II. The model was referred to as configuration 1, 2, or 3 depending on which flexures were used for the elevon. Table III defines these configurations.

The model was equipped with its own internal shaker and control surface deflector/release mechanism; this device was remotely activated in the tunnel control room by a GAC supplied control box. The shakers were of the rotary unbalanced force type driven by a flexible cable shaft and designed to produce an approximately constant force output (1.5 to 2 lbs.) from 15 to 70 Hz. The model control surface deflector/release mechanism consists of a roller cam, mounted on a pivot arm attached to the aft face of the main surface rear spar, which contacts a pawl attached to the front face of the control surface front spar. To deflect and release, i.e., "pluck" the control surface, the pivot arm

was rotated via an attached cable until the roller cam contacted the pawl, forcing it aside. This action deflected the control surface until the cam overrode the pawl, releasing the control surface.

The model had the following instrumentation:

| Type of Measurement                            | Device Used                          |
|--|--------------------------------------|
| Uncalib. Wing Bending Moment                   | Four active arm strain gage circuits |
| Uncalib. Wing Torsion                          |                                      |
| Uncalib. Wing Bending Moment                   |                                      |
| Uncalib. Wing\Torsion                          | ₩                                    |
| Uncalib. Dynamic Elevon<br>Position (inboard)  | Magnet & coil assembly               |

Figure 3 diagrams the instrumentation setup.

#### TEST FACILITY DESCRIPTION

Major elements of the NASA Langley Transonic Dynamics Tunnel are an electric motor drive system, a cooling system, a gas-handling system, a tunnel control room and observation chamber, a transonic test section, and a model calibration laboratory.

Test section is 16 feet square and has a uniform flow region more than 10 feet in length. Throughout this region, Mach number deviation is less than  $\pm$  .005 for subsonic speeds and generally less than  $\pm$  .01 above Mach 1. Maximum Mach number is 1.20. Mach number, which depends on compression ratio across the fan, is controlled by varying the motor rpm or remotely varying the angle of pre-rotation located ahead of the fan.

Transonic flow is generated by three slots in both the ceiling and floor of the test section.

Drive system consists of a two-speed range wound-rotor induction motor directly connected to a fan which may be considered-as a single-stage compressor. Fan speed ranges are 24 to 235 rpm for operation in Freon-12 and 15 to 470 rpm for operation in air.

Motor speed is automatically controlled by a liquid rheostat and eddy current brake to better than  $\pm \frac{1}{2}$  percent. At the maximum rpm in each speed range, shaft output is 20,000 horsepower, continuous rating.

Cooling system consists of a two-row vertical tube cooler through . which water is circulated to maintain a stagnation temperature under  $150^{\circ}F$ .

#### TEST PROCEDURE

Various calibrations and measurements were performed on the model prior to the test to determine its dynamic properties. These are described below:

Flexibility influence coefficients were measured and compared to the scaled full scale coefficients.

Influence coefficients were measured as the deformation slopes (spanwise and chordwise) per unit load due to force loads singly applied to the models at prescribed locations. The slopes were measured with small mirrors attached parallel to a model surface at prescribed locations. The mirrors reflected a projected grid network onto a vertically oriented screen; any change in the angular position (slope) of a mirror due to a change in loading was detected and measured on the screen. For these measurements, the vertically oriented models were cantilevered from their respective root attachment fittings, which simulate fuselage flexibility, and the loads were applied with weight and pulley arrangements. Separate measurements of the model root attachment fitting flexibilities were made with the respective model detached; the influence coefficients (flexibilities) were the root attachment spring displacements per unit load at the point of load application. Again, the loads were applied with weights, but the linear displacements (Y and Z directions) were measured with a linear differential transformer. Resulting root flexibilities are presented in Table IV. Resulting influence coefficients are presented in Table VI.

Figure 5 shows the load points used to determine influence coefficients.

Model mass distribution was also scaled in addition to stiffness scaling for complete model dynamic simulation. To demonstrate compliance with the required model mass distribution, the following inertial properties of the model were measured:

- 1. weights of main surfaces and control surfaces
- 2. C.G. locations of the main and control surface structures
- moments of inertia of the main surfaces about their C.G. X, Y, and Z axes
- 4. hinge line inertias for the control surfaces
- 5. C.G. moments of inertia of complete models about the pitch (Y) axis for the wing and yaw (Z) axis for the fin

The center of gravity of each model component (main and control surfaces) were located by suspending the model alternately at several (at least two) pivot points, scribing the plumb lines from the pivot points on the model surface, and thereby determining the C.G. as the intersection of these lines. Model moments of inertia were measured with the aid of a low frequency vibration rig, which was essentially an oversized flexural pivot, or a bifilar pendulum, depending on the reference axis. When using the vibration rig, the model was cantilevered normal to one of the flexural pads and caused to oscillate freely about the flexural axis. The frequency of oscillation was measured with an accelerometer mounted on the moving flexural pad. The moment of inertia of the model and the tare inertia of the rig about its flexural axis is determined from the

following relationship:

$$I_{O} = K/(2\pi f)^{2},$$

where:

K was the measured rotational spring rate of the rig about its flexural axis (inch pounds/radian),

f was the measured frequency of oscillation (Hz), and

 ${\bf I}_{{\bf O}}$  was the calculated moment of inertia of the model plus the tare inertia of the rig about its flexural axis.

It was a simple matter to subtract the known tare inertia of the rig from the calculated inertia, Io and transfer the resultant model inertia about the flexural axis to the model's C.G. axis to obtain the model C.G. moment of inertia. The pitch axis moment of inertia was measured using a bifilar pendulum to measure oscillatory frequencies instead of the vibration rig because of model mounting constraints. These calculations were done on a panel by panel basis with panels as shown on Figure 4. Resulting calculations and measurements are given in Table V.

Measured model modes and frequencies were compared to calculated full-scale modes and frequencies (assuming correct model/full scale weight ratio). Ground vibration surveys were conducted on the model cantilevered from its fuselage root attachment springs. The model was instrumented with one fixed and one survey (movable) accelerometer (Endevco - Model 2264-150). Vibration excitation was provided by an electromechanical shaker with a lightweight movable element secured to the model (Miller Model-A6466). During the vibration survey, while

monitoring the response of the fixed reference accelerometer on an oscilloscope, a frequency sweep was made and the large amplitude resonant responses were noted for the first five modes of each model; then returning to the first noted resonant response and dwelling there, a survey of the structural response was made with the portable accelerometer moved to prescribed locations on the wing model for each successive mode. Generalized mass of the modes was determined experimentally by the procedure outlined in reference 2 and is presented in tables VII and VIII. Additional measurements were made during the test period using a hand held probe for data acquisition and a Goodman electromagnetic shaker for excitation. These measurements are documented in reference 1.

The model was proof-loaded to assure it possessed adequate strength to sustain the inertial and aerodynamic loads acting on it during the wind tunnel testing. The proof loads were based on a load estimate schedule prescribed by Rockwell International. The model test loadings were achieved by placing lead sheets on the model's surface to yield equivalent shear loads and bending moments at the roots.

The wing model was mounted in the Langley Research Center 16-foot
Transonic Dynamic Tunnel cantilevered off the east side wall with the
fuselage fairing and root attachment fitting. Within the model fuselage
fairing was a rigid framed support structure which also acted as a mounting butt for the model on its root attachment fitting; the structure was
bolted to the tunnel sidewall turntable; this turntable varied the model

angle of attack. The shaker flexible drive cable, control surface deflector/release cable, strain gage, control surface coil, accelerometer and force link wiring were rooted from the semi-span mount through to the control room via stainless steel tubing. Figure 1 presents a sketch of the model installation. Figure 3 presents photographs of the installation.

The general operating procedure was to make progressively higher constant total pressure sweeps through the Mach range from 0.6 to 1.2 until the ascent trajectory plus the required 32% margin of safety was investigated. Following this, testing continued at more extreme operating conditions until flutter was obtained or tunnel operating limits were reached. Pauses were made at several discrete Mach nos. during each sweep to stabilize tunnel conditions. At these points, the main model surfaces and control surfaces were excited, respectively, by the internally mounted rotary unbalanced shaker and control surface deflect/release mechanisms. During shaker excitation, the measured model amplitudes and frequencies were recorded and interpreted to assist in predicting the onset of flutter. After the shaker excitation, each control surface was deflected and released in an attempt to initiate "buzz." During the deflect/release operation, the control surface hinge moment was measured. in an attempt to predict the onset of "buzz." This procedure was done as follows:

1. The model was installed and visually inspected in the tunnel;

#### TEST PROCEDURE (Concluded)

- 2. Modal frequencies were checked with the aid of an electromechanical shaker and the model instrumentation;
- 3. The desired tunnel operating path was selected;
- 4. The wind-off data readouts were recorded;
- 5. The wind tunnel was started and the model was trimmed to zero lift during the first low q run;
- 6. Desired Mach number and dynamic pressure were obtained;
- 7. When flow conditions stabilized, the model shaker was operated at a constant sweep rate from 15-70  $\rm H_Z$ . At the conclusion of the sweep, a review of the data was made (plots of 1/modal amplitude and modal frequency vs. q were made and used to predict the onset of flutter);
- 8. If no flutter was observed during step 7, the control surfaces were "plucked" one at a time in an attempt to initiate control surface "buzz"; during this "plucking" operation, a record was made of the control surface hinge moment via the force link in the actuator cable of the plucker device;
- 9. If no flutter was observed during step 8, a higher Mach number and q on the same constant total pressure path was used to repeat steps 7 and 8;
- 10. Steps 4 through 9 were repeated for different values of constant total pressure (H) until the Orbiter ascent trajectory boundary was cleared and/or the flutter boundary defined in the transonic flight regime:
- 11. Steps 2 10 were repeated for each new control surface configuration.

Two high speed movie cameras and a T.V. monitor were used during the runs to record any dynamic instability. The movie cameras were located to provide both a side view and rear view of the model.

Table I summarizes the test program and tunnel conditions.

### DATA REDUCTION

Freestream data were measured and reduced using standard test facility techniques. Model data recorded were:

- 1. Oscillograph traces of the model strain gage circuits.
- 2. Oscillograph traces of tunnel parameters.
- 3. High speed movies.
- 4. Tabulated data.

Figures 6 through 16 present plots of the test results.

#### DÍSCUSSION OF RESULTS

Tests on the wing were made to investigate the effect of varying the stiffness of the outboard elevon actuator on the dynamic characteristics of the wing model. To achieve this goal, a series of three configurations were tested. Table III outlines a description of the various configurations tested and a summary of the frequencies measured on those configurations with the model installed in the tunnel. Due to the large amount of camber in the wing, a series of runs was made to establish minimum load conditions on the model. The model mount was designed so that small changes in the angle of attack of the fuselage, and thus the wing, could be made remotely. Table I, in addition to summarizing the maximum tunnel conditions, lists the angles of attack and elevon deflection angles required to minimize model loads.

Configuration No. 1 was made with nominal elevon actuator stiffness. Although runs 31 through 47 were made in this configuration, only runs 41 through 47 were made at sufficiently high dynamic pressure to clear the configuration. The other runs were mainly used to establish model trim conditions. No flutter or other dynamic instability was encountered within the tested region. A summary plot of test conditions may be found in Figure 6.

Runs 48 through 53 were made with the model in configuration 2.

During these runs flutter was not encountered; however, some low damping was noted during runs 51, 52, and 53. A plot of test conditions for configuration No. 2 may be found in Figure 7.

### DISCUSSION OF RESULTS (Concluded)

For configuration No. 3, the outboard elevon actuator stiffness was reduced below the level tested during configuration 2. Runs 54 through 57 were made in this configuration and flutter was encountered during run 57, which resulted in loss of the outboard elevon. The flutter frequency was recorded at 28 Hz indicating, along with visual observation, that the flutter mechanism involved the outboard elevon rotation and wing 1st bending modes. See Figure 8 for a plot of test conditions for configuration No. 3.

The following observations were made:

- 1. No flutter was detected on the wing model with nominal elevon actuator stiffness within the scaled trajectory.
- 2. Flutter was encountered with the wing model when the stiffness of the simulated outboard elevon actuator was significantly reduced.
