#### INTRODUCTION

The primary function of an aircraft's horizontal tailplane is to balance the pitching moment which arises when the lift force developed by the wing is not applied through the airplane's center of gravity. Control of the airplane in the vertical plane is accomplished by varying this balancing moment so that the wing seeks a new equilibrium lift. The size of the horizontal tail thus determines the allowable c.g. travel as well as the lift coefficient which can be generated at any time. One does not gain a higher degree of control capability, however, without accepting at the same time a performance decrement resulting from the higher drag of the larger surface.

Since the advent of the airplane, designers have pondered the problem of positioning and sizing the horizontal tail to achieve both good aircraft performance and acceptable longitudinal stability and control. Their problem is compounded by the passage of the wing through the air ahead of tail. This produces (1) a downward inclination or downwash in the air approaching the tail, and, if the tail is directly in the wing wake, (2) a lower velocity at the tail due to the wing drag force. If the tail is sized assuming the onset flow to be freestream but is instead immersed in the wing wake, it will be unable to generate the expected trim moment. Thus, to maintain control capability one must either locate the tail such that it never encounters such momentum deficiencies or else increase its size proportional to the kinetic energy deficiency actually encountered. The latter course entails a performance penalty. Because of the non-linear response of the tailplane to onset flow angle, it is important to know the local flow direction everywhere in the tail region as well as those areas where momentum deficiencies exist. One would like to predict the wake location and the velocity deficit in the region of the horizontal tail to facilitate the process of positioning and sizing.

As part of its program to provide technical support to the light aircraft industry and to aeronautical education in general, the National Aeronautics and Space Administration funded the present study at North Carolina State University. This work seeks to provide rigorous, easy-to-use methods (which now means computer programs) to predict the downwash and velocity profiles in the vicinity of the horizontal tailplane as well as detailed descriptions of the methods used, their historical antecedents, and some worked out examples. The study is thus analogous to previous studies (Ref. 1,2,3,4) which treat riding and handling qualities, aircraft performance, and wing and body lift and drag in a similar fashion.

As will become evident from the literature review, the procedures for estimating downwash angle and wake position are better-defined than those for estimating wake velocity profiles. The downwash calculation is usually approached by replacing the wing with a series of horseshoe vortices representing both the wing lift and the vorticity shed by the wing. The downwash is a result of the interaction of the flow due to these horseshoe vortices with the freestream flow. It is most intense in a curved plane emanating from the trailing edge of the wing. The locus of this plane is usually obtained by integrating the local downwash angle from the wing trailing edge to some downstream point of interest. More rigor may be added to this method by permitting the trailing vortices to deflect both spanwise and vertically so that their paths become streamlines. These streamlines then define the wake centerline position. This approach permits both upwash ahead of the wing and downwash behind to be calculated with a greater degree of accuracy than does the more conventional straight vortex method. The downwash computer program presented in this report employs the deflected vortex approach.

Since the purpose of the present work is to provide a rigorous yet relatively simple method for determining the <u>onset flow in the immediate neighbor-</u> <u>hood of the horizontal tail</u>, it is not necessary to continue the calculation beyond this region to the point where the trailing vortices rollup into the familiar vortical flow patterns observed far downstream of the aircraft. While the method employed herein can treat the inviscid flow aspects of this region satisfactorily, other simpler methods are entirely adequate for developing the essential features of this "far field" problem; further, the method used here to determine the viscous dissipation present about the wake centerline is valid only in regions of quasi-planar flow, certainly not in vortical flow regions. For this reason also, no attempt should be made to extend the calculation downstream beyond the region of the horizontal tail.

The perceptive reader will note that no mention is made in the ensuing pages of the obvious contributions of the fuselage, both viscous and inviscid to the character of the flow field downstream of the wing. While the downwash method used does include a treatment of the effects of fuselage interference on the wing lift distribution, it does not include the effect of diminishing fuselage size as one moves aft on the downwash field nor the effects of the rapidly growing boundary layer on the aft fuselage. These were regarded as small perturbations whose determination would be excessively difficult given presently available analytical tools; for this reason they are not included. The user must therefore consider this fact in applying the results to new design situations.

Another contribution which has been neglected in the computation is the modification in the wing's downwash field due to the upwash field of the horizontal tail. Since the upwash angles are inherently smaller than the downwash angles and since the tail lift is generally less than 1/5 the wing lift, this contribution has been neglected.

The method used herein is based on the lifting line representation of the wing; it is therefore applicable only to situations where the wing is of moderate-to-high aspect ratio, unswept, and relatively lightly loaded (the fuselage does not cover a very significant portion of the wing area). Situations where these conditions are not satisfied will usually demand a much more complex lifting surface treatment.

Another consequence of the lifting line representation is that the induced field in the immediate neighborhood of the wing is distorted by the concentration of the wing's bound vortices along a single line instead of being distributed over the whole surface. Thus the downwash and upwash angles in this region may be excessive while at greater distances they will be indistinguishable from those obtained from a lifting surface representation. Since, the region of interest in light aircraft is located more than 1.5 wing chords downstream of the wing's trailing edge, a lifting line representation should be quite adequate.

The variation in flow velocity as one moves vertically across the wing plane of symmetry is usually approximated by empirical relations derived from experimental data given the wing section drag coefficient and the distance behind the wing trailing edge. A more exact approach solves the two-dimensional boundary layer equations, using a finite difference technique, for the wake flow and then applies this solution along various streamlines displaced spanwise as given by the wake position procedure above. The result is a quasi-three-dimensional solution. The starting conditions for the integration are the viscous velocity profiles on both upper and lower wing surfaces. This approach is used here to determine the vertical variation in flow magnitude.

The work presented here begins with a two-part review of the pertinent literature dealing with the determination of (1) downwash angles and wake sheet location, and (2) velocity profiles in the wing wake. General theory and discussion of results sections are then presented for both the downwash (WASH) program and the velocity profile (WAKE) program. User instructions, program listings, and sample outputs of both programs are given in the appendices. ·

LITERATURE REVIEW

. .. .. ...

#### DOWNWASH AND WAKE POSITION

In order to estimate the lift and drag forces experienced by an aircraft's horizontal tail, it is imperative that the magnitude and direction of the local onset flow be known. The disturbance produced by the wing is the major contributer to non-uniform horizontal tail onset flows. Dwinnell (Ref. 5) points out that a wing generating a lifting force must have a pressure differential from the lower to the upper surface with the higher pressure on the lower surface. At the wing tips the air tends to flow laterally from the lower to the upper surface in an attempt to remove this differential. This lateral or spanwise flow is from wing tip to wing root on top and from wing root to wing tip on the bottom (see total velocity vectors in Figure 1). The air immediately aft of the wing trailing edge is given a swirling motion due to the

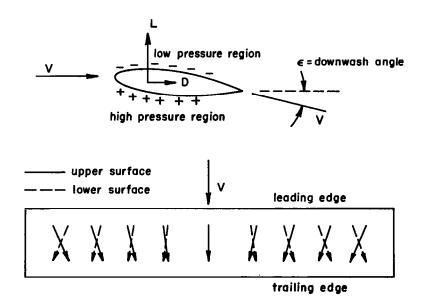

Figure 1. Side and planform views of flow over a wing (bound and trailing vortex patterns not shown in sketch).

shearing of the transverse velocity components on the upper and lower surfaces. These swirls or vortices, more predominant at the wing tips, are referred to as trailing vortices, and they tend to give the air behind the wing an average downward inclination, usually called downwash (see Figure 1 for definition of downwash angle). The spanwise variation of the downwash is a function of the wing planform shape.

The circulation theory developed in the late 1800's and early 1900's to account for lift in an inviscid fluid proved to be very useful in estimating downwash. In 1878 Lord Rayleigh showed that the swerving flight of a "cut" tennis ball could be explained best in general terms by comparing it to the case of a cylinder placed in an inviscid uniform stream. By imposing a circulatory flow upon the cylinder, the cylinder developed a force normal to the direction of the uniform stream (a lift force), directly proportional to the strength of the circulatory flow. In 1910 Joukowski showed that when a cylindrical body of arbitrary cross section moves with a velocity V in a fluid whose density is  $\rho$  and there is a circulation of magnitude  $\Gamma$  around it, a force normal to the velocity is produced equal to the product pVF per unit length of the cylinder. Joukowski made the assumption that the flow must leave the sharp trailing edge of airfoil-like bodies smoothly. Using this hypothesis, usually referred to as the Kutta-Joukowski condition because Kutta reached the same assumption independently somewhat earlier, the problem of lift became purely mathematical: one has only to determine the amount of circulation so that for zero vertex angle at the trailing edge, the velocity of the flow leaving the upper surface is equal to that leaving the lower surface. For finite vertex angles the trailing edge must be a stagnation point.

Although the work of Rayleigh and Joukowski was concerned with wings having infinite aspect ratios (no spanwise flow), the circulatory flow idea was extended to wings with large aspect ratios and little or no sweep by Prandtl in his now well-known Lifting-Line Theory. von Karman (Ref. 6) summarizes Prandtl's theory in the following way: (a) the wing is replaced by a lifting line perpendicular to the flight direction; (b) the lifting line is assumed to consist of a bound vortex with circulation variable in order to account for the fact that the lift may change along the span; (c) in accordance with the change in circulation along the span, free vortices are born and extend downstream; however, (d) the flow produced by the vortex system is considered as a small perturbation of the fundamental stream relative to the wing, and therefore (e) it is assumed that the free vortices approximately follow the original direction of the streamlines parallel and opposite to the flight direction: (f) the flow in the immediate neighborhood of a wing section is determined by the two-dimensional solution given by Kutta and Joukowski.

In the lifting line theory the wing surface is replaced by a line vortex of varying strength, called the bound vortex. A sheet of trailing vortices extends from the lifting line downstream to infinity: The perturbation in the flow field due to an infinitesimal segment of each vortex is found from the Biot-Savart Law (expressed here following Reference 7 in Vector notation).

$$\tilde{w} = \frac{\Gamma}{4\pi} \frac{d\bar{k} \times \bar{a}}{|\bar{a}|^3}$$
(1)

where

 $\bar{w}$  = induced velocity vector at a point in the flow field

 $\Gamma$  = strength of the vortex whose segment is being considered

 $d\bar{k}$  = vector having the direction and length of the infinitesimal vortex filament

a = the vector from the vortex filament to the point

the local value of  $\Gamma$  on the bound vortex is determined from

$$\Gamma(\gamma) = \frac{Vc C_{\ell}(\gamma)}{2}$$
(2)

where

 $C_{\ell}$  is the section lift coefficient of the wing  $V^{\ell}$  is the free stream velocity c is the wing chord

The strength of a particular trailing vortex is determined by the <u>change</u> in the  $\Gamma$  of the bound vortex which occurred as one moved outboard from the spanwise position where the previous trailing vortex was shed. All of the vorticity on the wing must eventually be shed downstream. The flow direction in the field downstream (or upstream for that matter) of the lifting line is then a sum of the contributions of all the trailing vortices, the bound vortex, and the free stream. The perturbation in the free stream velocity field resulting from these contributions is most intense in a sheet which for positive lift moves downward and to the rear from the lifting line. In the physical situation which this model represents this sheet is essentially the center of the wing wake. From equation (2) it is evident that the greater the wing lift the greater the vortex strength; thus it is reasonable to expect that the greater the wing lift the greater will be the downward deflection of the wake centerline as it moves aft.

Attention will now be directed to ways of evaluating the  $\Gamma$  distribution over the wing since it is essential for downwash calculations. Reference 8 notes that the main problem of lifting line theory is the determination of the spanwise distribution of air loads on wings from the fundamental equation of the theory. Its simpliest form relates the absolute and effective angles of attack,

$$\alpha_{a} = \alpha_{a} - \alpha_{i} \tag{3}$$

where

 $\alpha_{a}$  = absolute angle of attack

 $\alpha_{2}$  = effective angle of attack

 $\alpha_i$  = induced angle of attack.

The effective angle of attack may be expressed in terms of  $\Gamma$  by writing the section lift equation as

$$\rho V \Gamma = \rho V^2 c m_0 \alpha_0 / 2$$
 or  $\alpha_0 = \frac{2\Gamma}{m_0 V c}$ 

where ρ = density of air m\_ = section lift curve slope.

Now the induced angle of attack may be written as -  $\tan^{-1}(\frac{w}{V}) \& - w/V$  and since w can be expressed in terms of  $\Gamma$ , then the only unknown in the fundamental equation is  $\Gamma$ . Using the Biot-Savart Law the downwash velocity  $w_{y,y}$  at the point y on the bound vortex, induced by a vortex behind the wing at the point y may be written as

$$w_{y_{O}y} = \frac{d\Gamma}{4\pi} \frac{1}{y_{O} - y} .$$
 (4)

Replacing dF by (dF/dy)dy and noting that the downwash at y resulting from all the trailing vortices may be obtained by integrating w  $_{y_0}^{v_0}$  from - b/2 to b/2 (b is the wing span), then

$$w_{y_{o}} = + \frac{1}{4\pi} \int_{-b/2}^{b/2} \frac{d\Gamma/dy}{y_{o} - y} \, dy \, .$$
 (5)

The fundamental equation can now be written in the form

$$(\alpha_{a})_{y_{o}} = \left(\frac{2\Gamma}{m_{o}}V_{c}\right)_{y_{o}} + \frac{1}{4\pi V} \int_{-b/2}^{b/2} \frac{d\Gamma/dy}{y_{o} - y} dy$$
 (6)

where the subscript refers to the variable evaluated at the point  $y_0$ .

Probably the best known procedure for solving the fundamental equation is given by Glauert in Reference 9. The first step is to invoke the following substitutions:

$$y = b/2 \cos \theta \tag{7}$$

 $\Gamma = Vb \sum_{n=1}^{\infty} A_n \sin n\theta .$  (8)

The sine series rather than the cosine series is chosen for  $\Gamma$  because the boundary conditions of  $\Gamma = 0$  at both wing tips ( $\theta = 0$  and  $\theta = \pi$ ) are automatically satisfied for all values of A. The constants A are found by determining the values necessary to force the flow over the wing to be tangent to the mean camber surface. It can then be shown that the fundamental equation can be written as

$$\sum_{n=1}^{\infty} \left[A_n \sin n\theta(\mu n + \sin \theta)\right] = \frac{\mu}{2} \alpha_a \sin \theta$$
(9)

where  $\mu = m_{o}c/(4b)$ .

The above equation is valid for any spanwise station ( $\theta$  between 0 and  $\pi$ ), and in general  $\mu$  and  $\alpha$  will be functions of  $\theta$ . The problem has been reduced to one of determining the values of the coefficients A which will satisfy the above equation at every desired value of  $\theta$  along the span of the wing in question. If a 5 term series is desired for  $\Gamma$  then equation (9) must be applied at 5 spanwise stations yielding 5 equations in the 5 unknown A 's. Once the A 's have been obtained then Equation 8 will yield  $\Gamma$  for different spanwise positions.

As an alternative to solving Equation 9 at several spanwise stations, the computer programs given in Reference 4 are quite useful. Programs are presented to (1) calculate the lift, drag, and moment coefficients of conventional airfoils (two-dimensional) and (2) given the wing planform shape and airfoil characteristics for the root and tip sections, extend these twodimensional characteristics to three dimensions. By using a lifting line theory, the three-dimensional extension yields local lift, drag, and moment coefficient information at several spanwise stations along the wing span. The section lift coefficients may be used directly in Equation 2 to compute the strength of the bound vortex.

With the foregoing as background, attention will now turn to literature specifically treating the calculation of downwash. Two 1939 NACA Reports have become classics in the field: NACA TR-648 (Ref. 10) and NACA TR-651 (Ref. 7). The latter presents methods for predicting important wake parameters in terms of the distance behind the airfoil trailing edge and the profile drag coefficient for plain and flapped wings. The methods were based on a correlation of extensive experimental measurements of downwash angles and wake characteristics. Downwash was computed in the wing chord plane using the Biot-Savart equation

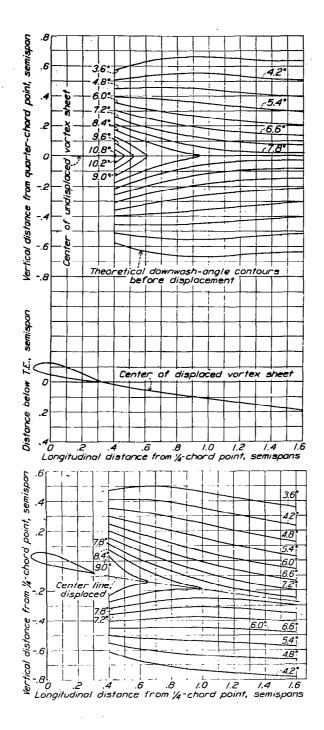

and

operating on a vortex system made up of a bound vortex at the wing quarterchord and a planar vortex sheet extending straight behind the guarter-chord line to infinity. It is pointed out that the wing wake coincides with the trailing vortex sheet because of their common origin at the trailing edge and their equal freedom to move in the induced velocity field behind the wing. The vertical displacement of the vortex sheet can therefore be approximated by integrating the downwash angle in the streamwise direction from the trailing edge to some specified distance downstream. Silverstein, Katzoff, and Bullivant used the idea of superposition to obtain maps of constant downwash angles behind the wing. First, using a planar vortex system, downwash angles were calculated at several points in the plane of symmetry to yield a contour map similar to that of Figure 2. This map was then distorted in the vertical plane to account for the vertical displacement of the vortex sheet. The distorted contour map is also shown in Figure 2. Using this procedure, which neglects spanwise curvature of the wake sheet as well as vortex roll-up effects, agreement with experimental data is good at distances typical of to the tail plane locations.

. . . . . .

In NACA TR-648 (Ref. 10) Silverstein and Katzoff prepared downwash charts to make the methods presented in TR-651 more readily useable in design activities. Included in the report are curves of the lift and drag of flapped airfoil sections and charts for finding the contribution of the different types of flaps to the total wing lift. The downwash charts are for elliptical wings and wings of taper ratios 0.1, 0.2, 0.3, and 0.5, with aspect ratios of 6, 9 and 12, having flaps covering 0, 40, 70 and 100 percent of the wing span. These charts may be used without a prior knowledge of the material in TR-651. Although written some 35 years ago, these reports are still the basis of current downwash predictions for light aircraft.

The interest in high speed flight led to some new downwash investigations in the late 40's and early 50's. In Reference 11 a study was made in the Langley 7- by 10-foot wind tunnel to determine downwash angles behind wings of various sweep angles and aspect ratios. Although the emphasis was on sweep effects, downwash characteristics were also measured for some unswept wings. The results are displayed graphically as curves of constant downwash angles. In 1954 an experimental investigation was conducted by Tolhurst (Ref. 12) to define the downwash field and vortex sheet shape behind a large-scale wingfuselage combination incorporating a 63° swept-back wing of aspect ratio 3.5. Data is presented for 9 vertical-transverse planes behind the wing for 3 angles of attack at a Reynolds number of 6.1 million. A comparison of these experimental results with theory showed that an acceptable approximation to the downwash distribution within the distance surveyed could be obtained if the vortex sheet were assumed to be flat and the spanwise vorticity distribution were assumed to be that of the wing. Rogers (Ref. 13) studied the application of two-dimensional vortex theory to the prediction of flow fields behind wings of wing-body combinations at subsonic and supersonic speeds. The wing trailing vortex was represented initially by line vortices distributed to approximate the spanwise distribution of circulation along the trailing edge of the exposed wing panels; however, a bound wing vortex was not included.

### Figure 2.

Ļ

Example of downwash calculation procedure (Ref. 7) in the plane of symmetry for a USA 45 airfoil at  $C_L = 1.175$ .

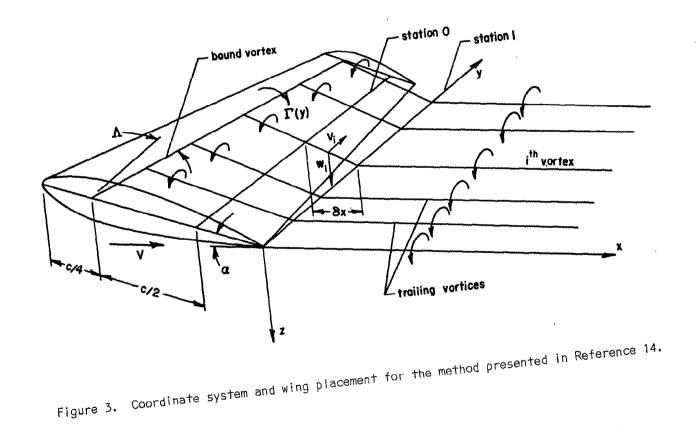

The afterbody was represented by corresponding image vortices within the body. Two-dimensional line-vortex theory was then used to compute the induced velocities at each vortex, and the resulting displacement of each vortex was calculated by means of a numerical stepwise integration procedure. The displacement of each vortex independently permits inclusion of both the roll-up phenomenon and the spanwise wake-sheet curvature. Rogers found that this method predicted vortex paths at high speeds with reasonable facility and accuracy.

In 1970 Butter and Hancock presented a method (Ref. 14) for calculating the shape of the trailing vortex system behind a swept wing at low speed. The authors were concerned about the two-dimensional approaches which omit the main wing bound vortex; they believed that when C<sub>1</sub> is large the wing circulation effects are significant. A method was therefore proposed which would include the effect of the main wing bound vorticity and the three-dimensional pattern of trailing vorticity. The wing is replaced by a single lifting-line bound vortex which represents the circulation distribution around the wing while the trailing sheet is approximated by a number of discrete line vortices. Starting with a nearly planar system (<u>i.e.</u>, bound vorticity on the wing and trailing vorticity streamwise as in Figure 3) and using a step-by-step process, working downstream aft of the wing trailing edge, the vertical and spanwise displacements of the trailing sheet are determined. To calculate the position of the ith vortex at station 1,  $\delta x$  behind the 3/4-chord line (station 0), the sidewash and downwash velocities, (v, and w,) due to all the other vortices are calculated at  $\delta x/2$ . The change in vertical and spanwise position ( $\delta z$  and  $\delta y$ ) for the ith vortex from station 0 to station 1 is then given by

$$\delta y = v_1 \delta x / V$$
 and  $\delta z = w_1 \delta x / V$  (10)

This procedure is used to obtain the new position of each vortex at station 1. Downstream of station 1 each vortex extends to infinity using the y and z coordinates at station 1. Once the locations are established at station 1, the remainder of the stations downstream may be analyzed in a similar manner. Butter and Hancock found that the principal factors governing the accuracy of the results are the downstream step-size and the number and position of the vortices chosen to represent the trailing vortex sheet. They note that if too many trailing vortices are taken numerical difficulties may arise; induced velocities calculated at a point between two such vortices will be given by the difference of two large velocities of opposite sign. When compared with experimental results, the downwash angles were found to be too large near the trailing edge due to the concentrated nature of the bound vortex; however, further downstream agreement was good.

In Reference 15 Labrujere presents a method for calculating the vortex location behind a thick lifting wing. The flow around a wing in uniform onset flow is determined with the aid of a source distribution on the surface of the

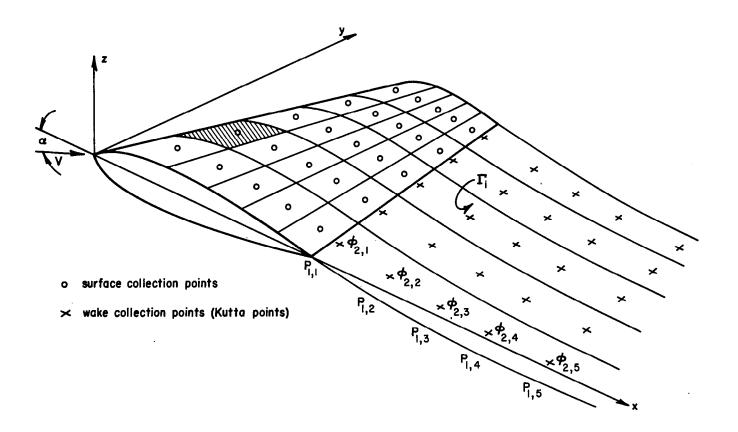

Figure 4. Representation of wing and wake by a source distribution on the wing surface and discrete vortices inside and behind the wing (Ref. 15).

16

í.

wing and a vortex distribution on its camber surface and wake. The wing and camber surface are divided into a number of strips whose edges are formed by lines y = constant and which are each subdivided in a number of quadrilateral panels. Along the periphery of each camber panel a line vortex is located (see Figure 4). The strengths of these "singularities" are determined by imposing the boundary condition of tangential flow to the wing surface at a number of surface points and the condition of tangential flow to the trailing vortex sheet at a number of "Kutta points" noted in Figure 4. Since the position of the vortex sheet and the strength of the singularities are related "non-linearly", an iterative procedure is required in order to determine the shape of the sheet as well as the singularity distributions for a given wing and at a given angle of attack. Although only a limited comparison with experimental results was made using this method, the agreement was good.

Comparing Labrujere's technique with that of the previous reference, there are three reasons why the Butter and Hancock method is preferred as the basis for further work: (1) Labrujere combines the problems of the flow over the wing and the flow in the wake, solving them simultaneously; for a large number of panels both on the wing and in the wake this requires both more computer storage and a longer execution time than is required for the two problems independently (necessary in the Butter and Hancock approach). (2) The iterative nature of Labrujere's method may necessitate several executions unless the initial estimate of the wake shape is accurate. (3) Although Butter and Hancock's method may be used iteratively to improve accuracy, they found that for step sizes of a quarter semispan and smaller, subsequent iteration did not significantly affect the position of the trailing vortices.

In the last few years the interest in trailing vortex sheets has turned to the far field problem. At large distances behind the wing, vortex roll-up has occurred, and the hazard of one aircraft flying into the vortex core of another aircraft has spurred interest in trying to analytically predict the shape and velocities of a rolled vortex pair as well as the dissipation of this vortex pair with time. References 16, 17, and 18 cover the topic very well and discuss the pertinent work which has been done to the present time.

-

#### WAKE VELOCITY PROFILE

While an inviscid theory is acceptable for predicting the location and inclination of the wing wake, the estimation of actual velocities requires a viscous analysis. The velocity deficit behind a wing is a function of the wing drag, a viscous phenomenon caused by the shear forces which the wing introduces in the fluid. The only really correct way to attack the problem is to solve the full, time-dependent Navier-Stokes equations of motion in three-dimensions over a substantial region. With present computers and computational techniques, computers will have to grow in storage size and speed by one or two orders of magnitude in order to obtain an accurate solution to the problem in the space of a few hours.

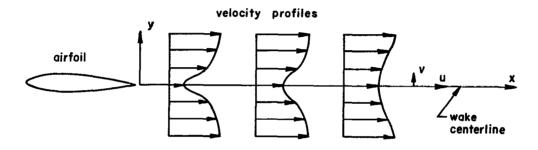

Boundary layer theory, which has been a valuable tool in solving for the viscous flow over airfoils and even bodies at zero or small angles of attack (Refs. 19 and 4), has also been applied to the flow in jets and wakes. Boundary layer theory consists of simplifying the Navier-Stokes equations so that they are applicable in the viscous flow near the surface of a body or in a wake. For the flow over a body the region where viscous effects are dominant is usually very thin compared to the body size. The equations are simplified by estimating the order of magnitude of each term and neglecting those which are small compared with the other terms. As might be expected, these simplified equations are much easier to solve, yet they retain the correct physical description of the flow in most cases. The conventional way of approaching the wake problem is to assume that the flow downstream of the trailing edge can be described by the boundary layer equations which are then solved by a momentum integral or finite-difference method. The remainder of this section will review some of the pertinent literature on the determination of wake velocity profiles.

Two-dimensional wakes were probably first investigated by H. Schlichting in his thesis presented to Goettingen University in 1930. In his general text, <u>Boundary Layer Theory</u> (Ref. 20), he notes that a wake is formed behind a solid body which is being dragged through a fluid at rest or behind a solid body which has been placed in a stream of fluid. The velocities in a wake are smaller than those in the main stream and the velocity losses in the wake amount to a momentum loss in the fluid due the body drag. The spread of the wake increases as the distance from the body is increased, and the differences between the velocity in the wake and that outside become smaller. A wake is a free turbulent flow (not confined by solid walls) and therefore of boundary layer nature. This means that (1) the region of space in which a solution is being sought does not extend far in the transverse direction, as compared with the main flow direction, and (2) the transverse gradients are large. The problem can therefore be studied using the two-dimensional, steady, boundary layer equations given below:

 $u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \frac{1}{\rho} \frac{\partial \tau}{\partial y} \qquad (x-momentum equation) \qquad (11)$ 

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0$$
 (continuity equation) (12)

where x and u are the coordinate and velocity along the wake centerline, y and v are the coordinate and velocity normal to the wake centerline,  $\rho$  is the density of the fluid, and  $\tau$  is the turbulent shearing stress (see Figure 5).

The pressure gradient term has been dropped from the x-momentum equation because, from a certain distance behind the body on downstream, the pressure remains essentially constant in the y-direction. This assumption is not necessarily true near the airfoil trailing edge. To integrate Equations 11 the turbulent shearing stress must be expressed in terms of the main flow parameters. One of the simpliest and most widely used wake flow models for  $\tau$  is that given by Prandtl in Equation 13.

$$\tau = \rho \varepsilon \frac{\partial u}{\partial y} = \rho c b (u_{max} - u_{min}) \frac{\partial u}{\partial y}$$
(13)

where b denotes the width of the wake, c is an empirical constant, and  $\varepsilon$  is the virtual kinematic viscosity or eddy viscosity, assumed constant over the whole wake width. Schlichting points out that experience has shown that for two-dimensional turbulent wakes, the wake width increases as  $\sqrt{x}$  while the centerline velocity decreases as  $1/\sqrt{x}$ .

As noted in Reference 20 Goertler and Reichardt investigated the twodimensional wake behind a circular cylinder. Goertler found that if he assumed:

- (1)  $u_1 = U u$  which at large distances from the body is small compared to U, the freestream velocity,
- (2) the drag on the cylinder is obtained by applying the momentum theorem far downstream so that

$$D = h\rho \int_{y=-\infty}^{y=+\infty} u_{1}(U - u_{1}) dy$$
 (14)

where D is the drag on the cylinder of height or length h, (3) that the second term of Equation 11 is small compared to the first,

then, by integrating the simplified version of Equation 11

$$\frac{u_1}{U} = \frac{1}{4\sqrt{\pi}} \frac{UC_D d}{\varepsilon_0} \frac{1/2}{(\frac{x}{C_D d})^{-1/2}} e^{(-\eta^2/4)}$$
(15)

where:

C<sub>D</sub> = cylinder drag coefficient

 $\varepsilon_{0}$  = constant eddy viscosity

d = cylinder diameter

x = distance downstream behind the cylinder

 $\eta$  = nondimensionalized y-coordinate =  $y \sqrt{\frac{U}{\epsilon_{x} x}}$ .

. . . .

Upon comparison with experimental measurements made by Schlichting, Goertler evaluated the constant in Equation 13 with the relation

$$\epsilon_{o} = (0.047)(2b_{1/2} u_{1_{max}})$$

where:

 $b_{1/2} = half the wake width halfway between u_1 and u_1 at some x-station min$ = the maximum value of  $u_1$  in the wake at that x-station. <sup>u</sup>1<sub>max</sub>

Using similar assumptions and a slightly different eddy viscosity model, Reichardt arrived at the following expression for u1:

$$\frac{u_1}{U} = \frac{\sqrt{10}}{18(.18)} \left(\frac{x}{C_D d}\right)^{-1/2} \left\{ 1 - (y/b)^{3/2} \right\}^2 .$$
(16)

`:

Schlichting (Ref. 20) notes that the two solutions for the wake velocity actually do not differ much one from the other.

While the above work was concerned with the wake of a circular cylinder, in 1939 Silverstein, Katzoff, and Bullivant (Ref. 7) generalized the available experimental results so that velocity profile and wake width information behind airfoils could be predicted in terms of the downstream distance and the profile drag coefficient. The profile drag of an airfoil may be approximately equated to the loss of momentum in the wake by the relation:

$$d_{O} = \rho \int_{-\infty}^{\infty} u(U - u) dy$$
 (17)

where  $d_0$  is the drag per unit span. At distances behind the wing comparable with tail-plane location, where the static pressure in the wake has reached that of freestream, experimental investigations have shown that Equation 17 may be approximated in coefficient form by the more elementary expression:

$$c_{d_0} = \frac{1}{c} \int_{-b/2}^{b/2} (1 - \frac{q}{q_0}) dy$$
 (18)

where,

c<sub>d</sub> = section profile drag coefficient

q/qo = ratio of dynamic pressure in the wake to that in the freestream b = wake width

c = winq chord.

The wake may be completely described by the width b, the loss of dynamic pressure at the wake center  $\Delta q$ , and the shape of the wake profile. As an aid in generalizing the results, the following nondimensional ratios were adopted:

$$n = \frac{\Delta q}{q_0} = (1 - q/q_0)$$

$$\zeta = \frac{1}{2} \left(\frac{\text{wake width}}{\text{wing chord}}\right) = \frac{b}{2c}$$

$$\xi = \frac{\text{distance behind trailing edge of wing}}{\text{wing chord}} = \frac{k}{c}.$$

Using Prandtl's proportionality relations

$$\varsigma \sim \xi^{1/2} c_{d}$$
 and  $\eta \sim \frac{c_{d}^{1/2}}{\epsilon_{F}^{1/2}}$  (19)

the available experimental data was used to find the proportionality constants which should be used in Equations 19. It was found that:

$$\zeta = 0.68 c_{d_o}^{1/2} (\xi + 0.15)^{1/2}$$
 (20)

$$\eta = \frac{2.42 c_d^{1/2}}{\xi + 0.3}$$
(21)

fit the data very well. The equation for n was found to vary with  $1/\xi$  rather than  $1/\xi^{1/2}$  as mentioned previously. The authors point out that discrepancy is probably associated with the high values of n near the trailing edge of the experimental data used for correlation; in Prandtl's formulation n was assumed small. For a complete wake description, the shape of the profile must also be defined. The profile shape was found to be closely approximated by either of the following empirical relations:

$$\frac{\eta'}{\eta} = \begin{bmatrix} 1 - (\frac{\zeta'}{\zeta}) \end{bmatrix}^{1.75 2}$$
(22)

or

$$\frac{\eta'}{\eta} = \cos^2(\frac{\pi\zeta'}{2\zeta})$$
(23)

where  $\eta'$  = relative loss in dynamic pressure  $\zeta'$  = distance from wake centerline ( $\zeta' < \zeta$ ).

The profiles given above are assumed symmetric about  $\zeta' = 0$  and for  $\xi$  values in the vicinity of the tail plane this is not a bad approximation even for unsymmetric airfoils.

In TR-648 (Ref. 10) Silverstein and Katzoff made the methods presented in TR-651 easily adaptable to design by preparing charts for determining the velocity profile at the horizontal tail. Over the years both TR's have been very valuable in predicting tail plane velocity profiles for light aircraft.

In 1947 an investigation of free turbulent mixing was presented by Liepmann and Laufer in Reference 21. The investigation examined the various ways turbulence had been modeled up to that time and discussed the physical significance of the models using experimental measurements of the mean velocity, the intensity and scale of turbulent fluctuations, and the turbulent shear in a two-dimensional mixing zone. The authors decided that the assumptions of constant mixing length and constant exchange coefficients (as in Equation 13) across the wake width were, strictly speaking, incorrect. Measurements of the field fluctuating velocities in a turbulent mixing zone show that both the mixing length and exchange coefficient vary across the mixing region, contrary to the assumptions made by Prandtl and others. They concluded that if only the mean-velocity distribution of a turbulent flow problem is desired, it usually can be obtained by dimensional considerations, assuming a reasonable curve (e.g., an error function in the case of a mixing region), and determining one constant from experiment. (This agrees with the methods already presented from References 20 and 7). Also, for an understanding of turbulent flow in general, a study of various mean-velocity distributions is of little use; the field of turbulent fluctuations must be studied in detail probably requiring a knowledge of the diffusion of turbulent energy. The constant exchange coefficient as presented in Equation 13 can therefore be used in a turbulence model with good success if only mean velocity profiles are desired; but for any deeper understanding of turbulence, the microstructure must be investigated more fully.

The subject of eddy viscosity models is treated to some extent in References 22 and 23. Elassar and Pardolfini, using a multilevel linear difference scheme examined four eddy viscosity models and evaluated the constants in these models by comparing calculated velocity profiles with experimental data in the similarity region. The thrust of the report is directed toward high-speed compressible flow, and all the models are more complex than Equation 13. In Reference 23 similarity solutions of the boundary layer equations in wakes with tailored pressure gradients were obtained. Experimental data was used to obtain a value for the constant eddy viscosity and the agreement between theory and experiment is described as good. While both of these reports are valuable in a general nature, it would be desirable to have viscosity constants evaluated using data obtained in the wake behind an airfoil. References 24 and 25 indicate that boundary layer solution procedures are being applied to high-speed turbulent mixing layers using more elaborate viscosity models than that given in Equation 13. These same techniques should be readily adaptable to low speed turbulent mixing and could be very useful if computer storage requirements and execution times are not excessive.

In order to improve upon the turbulent wake prediction methods, more experimental data are necessary for wake profiles at several stations behind an airfoil rather than at the tail-plane location only. References 26 and 27 are very helpful in this respect in that they present two-dimensional velocity profiles in the wakes of symmetrical Joukowski and Piercy airfoils respectively. An 11.8 percent thick Joukowski airfoil was tested at angles of attack of 0 and 6 degrees for a Reynolds number of 0.42 million. Velocity profiles were measured at stations of 0.0005, 0.0025, 0.01, 0.25, and 0.5 chord lengths behind the airfoil trailing edge. A similar investigation on the 12 percent thick Piercy airfoil, with wires on the leading edge to force transition, yielded velocity profiles at 0.0005, 0.0025, 0.01, 0.25, and 0.4 chord lengths. In addition to the profiles, the drag coefficient and other boundary layer information was also measured.

A recent report by Goradia and Lilley (Ref. 28) also present some experimental data for profile measurements behind a modified NACA 0015 airfoil at several angles of attack. The report describes a procedure developed by the authors to improve two-dimensional drag predictions for single and multielement airfoils by describing the airfoil wake using regions of similarity. Although correlations are given for only two or three airfoils and the computer program is not provided, the procedure seems to have improved the drag predictions given in CR-1843 (Ref. 29). Experimental data, taken in connection with this work is presented in both tabular and graphical form; however, the tabular data, particularly at stations near the airfoil trailing edge, indicate profiles which fail to return to freestream velocity at the upper and lower edge.

While the data given in the three references cited above are valuable, they were taken in the wake of symmetrical airfoils. More data is obviously needed, particularily for unsymmetric airfoils, but the lack of data is due in part to the high cost of wind tunnel testing and the difficulty of measuring wake velocities accurately.

A review of the literature revealed several papers concerning the effect of flow curvature on the formulation and solution of the two-dimensional boundary layer equations. Murphy (Ref. 30) formulated the boundary layer equations with curvature and indicated that even for laminar flow these equations are at their simplest more complex than the no-curvature case. Williams (Ref. 31) obtained a solution for a free jet flowing off a step only by assuming a curvature function which made the boundary layer equations similar (the streamwise coordinate did not appear explicitly). One encounters similar increases in solution complexity when treating three-dimensional boundary layers. Although the problem can be formulated, the computer storage requirements and execution times required with present machines and methods are excessive. Add to this the complexity of curvature and it is understandable why attention is still directed toward solving the simplified problem. Solution to such a problem, hopefully, preserved the qualitative aspects of the physical situation even though it cannot duplicate it quantitatively in all respects.

## PROGRAM FOR DOWNWASH AND

I

# WAKE POSITION CALCULATIONS

\_\_\_\_\_.

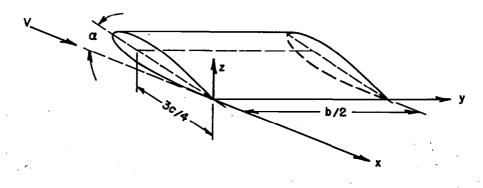

·· -

. .

### GENERAL THEORY

For many years the vertical displacement of the wake centerline location and downwash behind wings has been calculated using a bound vortex and a finite number of trailing vortices. The spanwise curvature of the trailing vortices and their roll-up may be included in the calculation by allowing the vortices themselves to be deflected in both the vertical and spanwise directions (Ref. 13 and 14). Analyses have also been conducted by representing the wing and vortex sheet as a single vortex lattice and using an iterative solution procedure with boundary conditions of no flow normal to the vortex panels to determine the wake location (Ref. 15). Because of the paneled wake procedure (lattice) achieves only a slight improvement in wake location at a large increase in computer cost , the WASH program presented here uses a method similar to those given in References 13 and 14. For simplification the x, y, and z coordinates are non-dimensionalized by the wing semispan, and a unity freestream velocity is assumed since only ratios of induced velocities to freestream velocity are required to estimate the downwash and sidewash angles.

The first step in computing the downwash characteristics and wake position is that of representing the wing by a bound vortex at the wing quarter-chord and by a trailing vortex system running aft from the quarterchord line. The symmetric half-wing is placed in the coordinate system shown in Figure 6. The root chordline is in the xz-plane at y = 0, with the origin at the trailing of the wing root. The root chordline has an incidence,  $\alpha$ , with the negative x-axis.

# Figure 6. Definition of coordinate system and wing placement used in WASH program.

The analysis will be limited to unswept wings; therefore, the x and z coordinates of the wing quarter-chord are given by

$$x_b = -\frac{3c \cos \alpha}{2b}$$
 and  $z_b = \frac{3c \sin \alpha}{2b}$ 

where

 $(x_b, y_b, z_b)$  = the coordinates of the bound vortex normalized by the semispan

b = wing span  $c \doteq$  wing root chord  $\alpha$  = wing angle of attack.

The strength of the bound vortex is calculated using Equation 2 once the section lift coefficient distribution is known. Although the WASH program was designed to use the output of the three dimensional aerodynamic characteristics program given in Reference 4, any procedure may be used to calculate the section lift coefficients. The lift coefficients at 10 different normalized spanwise stations must be read into the WASH program. The speci-fication for both is ordered from positive wing tip to wing root\* (see Figure 7).

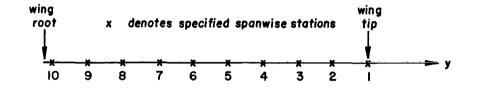

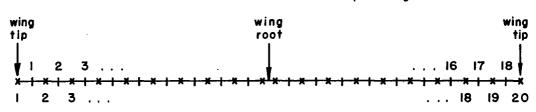

Figure 7. Ordering scheme for spanwise station and section lift specification.

Recall of course that the wing and its flow field is being represented by a system of horseshoe vortices. The initial streamwise position of the various trailing vortices is defined by assuming the vortices are shed at stations midway between the 10 specified y values on each semi-span, i.e., on each half of the lifting line. In carrying out the computations, advantage can be taken of the assumed symmetry in the loading and the geometry. In this fashion, the section lift coefficients as well as the input y stations and the positions of the shed vortices for the negative y axis can be defined. A schematic of the

<sup>\*</sup> The root value for y cannot be zero; it may be a very small number, but because of the technique used for estimating the bound vortex contribution, the value must be non-zero.

20 stations at which the section lift coefficients are specified and the 18 shed vortex stations for the entire wing is given in Figure 8.

#### x denotes specified spanwise stations for complete wing

Figure 8. Reordered specified spanwise stations and shed vortex stations for complete wing.

Once the bound vortex strength is calculated using Equation 1 at the specified y stations, the strength of the shed vortices is computed by the change in  $\Gamma$  from one station to the next. Thus, for the right half of the wing the trailing vortex system is similar to that given in Figure 9.

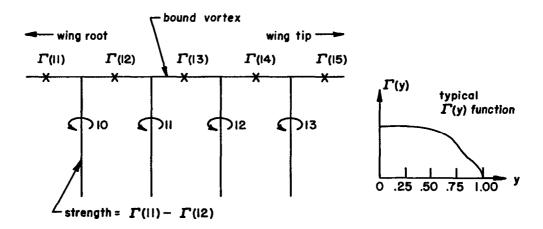

Figure 9. Example of indexing procedure used for the trailing vortex system on the right half of the wing with a typical  $\Gamma(y)$  distribution.

Each initial trailing vortex is made up of two straight line segments, one from the bound vortex to the trailing edge and another from the trailing edge to infinity in the x-direction parallel to the freestream (see Figure 10).

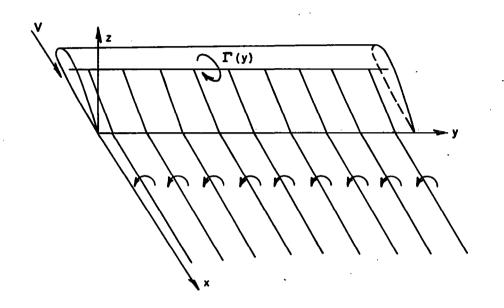

Figure 10. Example of initial approximation of trailing vortex system.

The net velocity induced by the vortex system at a point in the vicinity of the wing is computed by summing the contributions from the bound vortex and every straight line segment of each trailing vortex. The velocity induced at a point due to a vortex is defined by the Biot Savart law (Equation 2). An alternate form of this equation for straight line filaments is given in Reference 5 as

$$dW = \frac{\Gamma}{4\pi} \frac{\sin \theta \, d\ell}{r^2}$$
(24)

where dW = total velocity induced at a particular point by a filament dL $\Gamma = strength$  of the vortex filament

- r = distance to increment of filament at the point the velocity is induced
- $\theta$  = angle between the length r and the filament.

The contribution of the bound vortex is calculated by integrating Equation 24 from the negative wing tip to the positive tip. Expressing sin  $\theta$  and r in terms of the x, y, and z coordinates, and noting that dl becomes dy, the induced velocity at a point (x, y, z) due to the bound vortex is written as

$$W_{b} = \int_{-1}^{1} \frac{\Gamma(y_{0}) b/2 \sqrt{(x - x_{b})^{2} + (z - z_{b})^{2}} dy_{0}}{4\pi [(x - x_{b})^{2} + (y - y_{0})^{2} + (z - z_{b})^{2}]^{3/2}}$$
(25)

where all coordinates are non-dimensionalized by the semispan. Equation 25 may be solved numerically, or if a functional form is known for  $\Gamma(y_0)$ , it may be integrated in closed form. In order to use the closed form technique, two successive specified values of  $\Gamma(y)$  for the bound vortex were fitted using the cubic spline given in Reference 33 matching first and second derivatives at the end points. The cubic spline fit is of the form

$$\Gamma(\gamma) = A_{1j}\gamma^{3} + A_{2j}\gamma^{2} + A_{3j}\gamma + A_{4j}$$
(26)

where  $y_{j} \leq y \leq y_{j+1}$ , j = 1, 2, ..., 19.

Note that for each of the 19 intervals the cubic coefficients depend on the interval  $(y_j, y_{j+1})$  in which the spanwise station lies, but they are constant in a given interval. It is this variation of the coefficients that gives the spline fit its remarkable curve fitting properties. Using the cubic representation Equation 25 is integrated (Ref. 34) in each of the 19 intervals yielding the total velocity induced by the bound vortex at the point (x, y, z). This total velocity is divided into a freestream component, u, and a vertical or downwash component, w, by the relation given below:

$$u_{b} = W_{b}(x - x_{b})/\sqrt{(x - x_{b})^{2} + (z - z_{b})^{2}}$$

$$w_{b} = W_{b}(z - z_{b})/\sqrt{(x - x_{b})^{2} + (z - z_{b})^{2}}$$
(27)

w and W are defined as positive in the negative z direction, and u is positive in the positive x direction. Since the bound vortex is always parallel to the y-axis, there is no sidewash component in  $W_b$ . The streamwise component  $u_b$  is usually very small compared with the freestream velocity. The velocity induced by a trailing vortex is calculated by summing the effect of each straight line segment of the vortex. The total velocity induced at a point by a straight line vortex segment is also calculated using Equation 24; the evaluation is however, much simplier than the bound contribution because  $\Gamma$  along all segments of a trailing vortex is constant. Thus, expressing dl and r in terms of  $\theta$ , one has

$$W_{t} = \frac{\Gamma}{4\pi} \int_{\theta_{A}}^{\theta_{B}} \frac{\sin \theta}{h} d\theta$$
 (28)

where

W<sub>t</sub> = is the total velocity induced at a point (x, y, z) by a vortex of length AB,

 $\theta_A$  and  $\theta_B$  = angles between the length r and the filament at points A and B respectively, and h is the perpendicular distance from the point (see Figure 11).

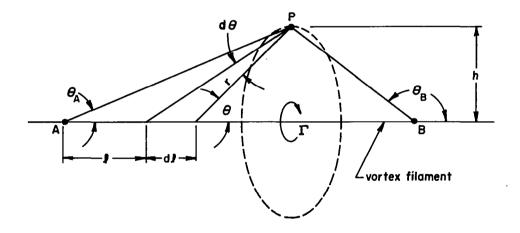

Figure 11. Nomenclature diagram for velocity induced by a straight-line vortex filament (Ref. 5).

Carrying out the integration indicated in Equation 28 yields

$$W_{t} = \frac{\Gamma}{4\pi h} \left(\cos \theta_{A} - \cos \theta_{B}\right) . \qquad (29)$$

This total induced velocity must also be divided into its component parts: freestream, sidewash, and downwash velocities. As seen in Figure 12, the total induced velocity at  $P_o$  due to a line vortex from  $P_1$  to  $P_2$  of strength  $\Gamma$  may be rewritten as

I

$$W_{t} = \frac{\Gamma(\cos \theta_{1} + \cos \theta_{2})}{4\pi b/2 d_{01} \sin \theta_{1}}.$$
 (30)

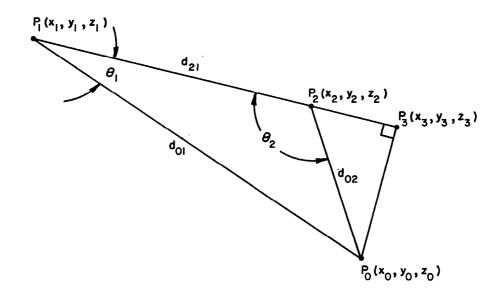

Figure 12. Schematic for velocity induced at  $P_0$  due to a vortex from  $P_1$  to  $P_2.$ 

The components are derived using the following relations to obtain the direction cosines:

$$d_{21} = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}$$
  

$$d_{01} = \sqrt{(x_0 - x_1)^2 + (y_0 - y_1)^2 + (z_0 - z_1)^2}$$
  

$$d_{02} = \sqrt{(x_0 - x_2)^2 + (y_0 - y_2)^2 + (z_0 - z_2)^2}$$
(31)

$$\begin{aligned} \theta_{1} &= \cos^{-1} \left[ \left( d_{21}^{2} + d_{01}^{2} - d_{02}^{2} \right) / \left( 2 d_{21} d_{01} \right) \right] \\ \theta_{2} &= \cos^{-1} \left[ \left( d_{21}^{2} + d_{02}^{2} - d_{01}^{2} \right) / \left( 2 d_{21} d_{02} \right) \right] \\ x_{3} &= x_{1} + d_{01} \cos \theta_{1} \left( x_{2} - x_{1} \right) / d_{21} \end{aligned}$$
(31)  
$$y_{3} &= y_{1} + d_{01} \cos \theta_{1} \left( y_{2} - y_{1} \right) / d_{21} \end{aligned}$$
(31)  
$$z_{3} &= z_{1} + d_{01} \cos \theta_{1} \left( z_{2} - z_{1} \right) / d_{21} \end{aligned}$$
(31)  
$$c_{1} = \left[ \left( x_{2} - x_{1} \right) \left( z_{3} - z_{1} \right) - \left( y_{3} - y_{1} \right) \left( z_{2} - z_{1} \right) \right] \end{aligned}$$

The components can therefore be written as

$$u_{t} = W_{t} A/\sqrt{R}$$

$$v_{t} = W_{t} B/\sqrt{R}$$

$$w_{t} = W_{t} C/\sqrt{R}$$
(32)

where  $R = A^2 + B^2 + C^2$ .

In summary, the induced velocity components at a point are calculated due to (1) the bound vortex using Equations 25 and 27 and (2) a straight line segment of a trailing vortex using Equations 30 and 32. The velocity due to the entire vortex system is computed by summing the contributions from the bound vortex and each segment of the 18 trailing vortices.

The spanwise curvature in the trailing vortex system is modeled by representing each vortex by a number of straight-line segments which are free to follow the local direction of the flow. The position of these vortex segments is determined using a stepwise downstream marching procedure which will now be discussed. As previously mentioned, the first approximation of the vortex sheet consists of the 18 trailing vortices with 2 segments each, one segment from the bound vortex to the y-axis and another from the y-axis to  $x = \infty$  parallel to the x-axis. Since the actual vortex system behind a wing is displaced in both the y and z directions, the following procedure is used to compute the position of each trailing vortex at a length  $\Delta x$  behind the trailing edge. Noting Figure 13 and considering vortex #10 at station #2, the v and w induced velocity components due to all the other vortices are calculated halfway between stations #2 and #3 (x =  $\Delta x/2$ ) using the y and z coordinates at station #2. The changes in spanwise and vertical position of vortex #10 in moving from station #2 to #3 is approximated by Equations 10 as

$$\Delta y = v \Delta x$$

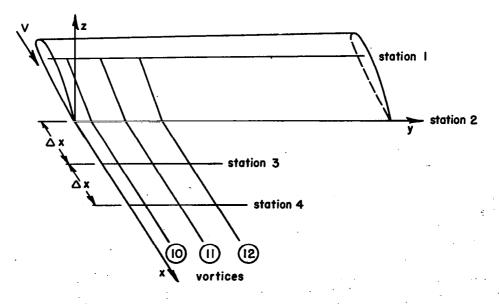

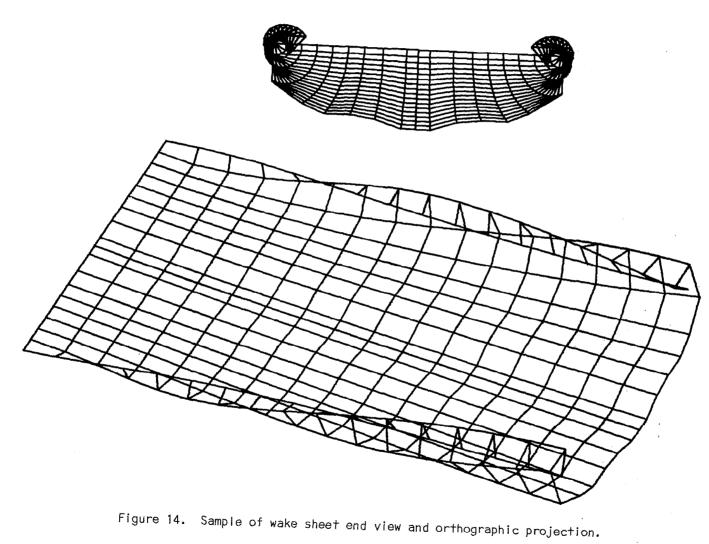

Figure 13. Schematic of downstream stepwise technique used in WASH program.

The position of the vortex at station #2 was (0, y(vortex #10), 0) and the position at #3 becomes ( $\Delta x$ , y(vortex #10) +  $\Delta y$ ,  $\Delta z$ ). A similar procedure is used to calculate the position of the other 17 trailing vortices at station #3. Downstream of station #3 the trailing vortices are assumed to go to infinity in the streamwise direction. After the position is determined at station #3 the procedure is reapplied at stations #4, #5, etc. until the vortex sheet is traced as far downstream as desired. The WASH program prints the coordinates of each vortex as well as the total vortex length from the trailing edge at each downstream station. The procedure discussed above is equivalent to that used in Reference 14 where it was found that for stepsizes as large as .25 semispans an accurate wake location was predicted. Butter and Hancock did note that numerical difficulties were sometimes encountered when more than 5 spanwise stations for the half-wing were used; however, the WASH program using double precision arithmetic utilizes 9 spanwise stations without numerical difficulty as long as the specified y stations are approximately evenly spaced. An example of a wake sheet calculated using the above procedure is given in Figure 14. The two views of this wake sheet were plotted using the PLOT program of Reference 4. The WASH program will punch a data set which may be read directly into the PLOT program; the data set requires only the addition of view cards at the rear defining the type of view desired.

Once the location of the trailing vortex sheet is determined then both downwash and upwash angle may be computed behind and ahead of the wing respectively using the bound vortex and the new vortex sheet. The WASH program is designed to calculate, at the user's option, three basic sets of information:

- (1) downwash and sidewash angles in a plane behind the wing at a constant x-station (a negative value for the x-station yields upwash angles ahead of the wing) indicating the variation with y and z,
- (2) downwash angles in the y = 0 plane of symmetry for 1.75 semispans downstream with z varying from .5 semispans above and below a user specified z-station,
- (3) upwash angles in the y = 0 plane of symmetry for 0.5 semispans upstream with z varying from .25 semispans above and below the leading edge z coordinate.

For each option presented above, a grid of coordinates, at which the downwash information is calculated, must be established. The first option was originally designed to compute the downwash in any x = constant plane at all the grid points determined by y varying from 0 to 1.1 semispans in steps of .05 semispans with z ranging from .25 semispans above and below a specified z station in steps of .05 semispans. This required calculating downwash and sidewash angles at 253 points. Numerical difficulties were usually encountered at one or more of the grid points because of the grid points being located very near a vortex segment. The vortex velocities by definition are unbounded

at the vortex center; thus, unrealistic velocities may be predicted if the grid point is too near a vortex segment. To correct this difficulty an attempt was made to determine an optimum distance to a filament such that the filament's contributions would be included or excluded depending on whether the distance to the filament was greater or less than the optimum. While this procedure was successful in producing reasonable values of downwash angle, it does not guarantee a smooth variation in downwash in either the y or z direction since the downwash at one of two closely-spaced points may include the contribution from a filament while the downwash computed at the other point may not.

To insure a smooth variation, the following procedure is used. The userspecified x-station at which the downwash information is required must be a multiple of the stepsize; for upwash calculations any negative x-station ahead of the wing leading edge may be used. The y and z coordinates for the 6 most inboard vortices on the positive y-axis are used to establish a new grid system. Using the y coordinate at one of the six vortices as constant, the total flow angularity (vector sum of downwash and sidewash angles) and the sidewash and downwash angles are calculated for z ranging from .25 semispans above and below the z coordinate of that vortex. This procedure is also carried out for the other five most inboard vortices yielding a grid system similar to that given in Figure 15.

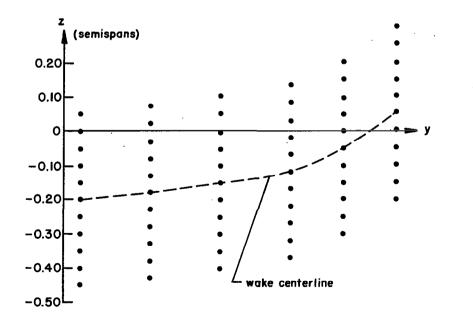

Figure 15. Example spacing for downwash calculations using NXORY=1 option (spanwise variation).

The numerical difficulties encountered because of the contribution of the vortex segment to the field in its immediate vicinity are eliminated by (1) excluding, for example, the contribution of vortex 11 when calculating the flow angles above and below the z coordinate of vortex 11, and (2) calculating downwash above only the six most inboard vortices which, for x-distances comparable to horizontal tail locations, have not rolled-up and therefore do not pass above or below another vortex trace. The exclusion of vortex 11 when determining the flow angles above and below it will not affect the downwash; however, the sidewash will be in error. Since the downwash and not sidewash is tolerated. The option discussed above is produced when the input variable NXORY is specified as 1 and STAT is read as the desired x-station in semispans. A detailed description of these and the other necessary input variables is given in the User Instructions section of Appendix A.

Option number two in the WASH program computes the downwash angles in the plane of symmetry, y = 0. The grid is specified by varying x from .25 to 1.75 semispans behind the trailing edge in steps of .05, and z ranging from .5 semispans above and below a midpoint z-value specified as the variable STAT. As above, numerical difficulties were encountered in some cases using this option because the most inboard shed or trailing vortex on a half-wing may be too close to some of the grid points. To remedy the problem in general, the downwash angles were calculated using only the 8 most-outboard vortices on both sides of the y = 0 plane, and the WASH program is written in this fashion. However, if the user desires to include the effect of the inboard vortex, the DO LOOP parameter may be changed from 8 to 9 on card PLA 110 of the WASH program. Inasmuch as the computations are made in the plane of symmetry, only half the wing need be analyzed to compute the downwash, and the sidewash is identically zero. This downwash information is computed in the plane of symmetry when the variable NXORY = 2 and STAT is the desired midpoint value of z in semispans.

If NXORY = 3, then upwash information is calculated in the plane of symmetry. The grid points at which upwash is computed are established by x ranging from the wing leading edge value of x at the wing root to .5 semispans ahead of the leading edge in steps of .05 semispans, and z varying from .25 semispans above and below the leading edge z coordinate. The upwash is calcuated using all 18 trailing vortices without numerical difficulty. It should be pointed out however that the upwash values at the leading edge are excessively large because of the proximity to the bound vortex at the wing quarter-chord.

The WASH program is made up of a mainline, four subroutines, and a function subroutine. The mainline is the control center for reading and writing the specified and calculated information as well as the coding responsible for tracing the position of the vortex system downstream. The mainline calls the following subroutines: (1) SPLINE to obtain a spline fit of the bound vortex strength versus semispan distance, (2) WB which computes

the induced velocity components at a point due to the bound vortex using the function WBB, (3) WTRALL to calculate the induced velocity components at a point due to a straight-line trailing vortex segment, and (4) PLANE to determine the downwash information in the plane specified by the user. The mainline contains the coding responsible for tracing the shed vortices downstream using a maximum of 18 steps behind the trailing edge. Using this deflected vortex system the downwash information is calculated at each of the grid points given by subroutine PLANE for the user specified plane of interest.

The program listing, sample data set, and sample output are presented along with User Instructions in Appendix A. The next section of this report presents a brief discussion of results obtained by running the program for several test cases, some of which are compared with experimental data.

#### DISCUSSION OF PROGRAM RESULTS

Results given by the WASH program were compared with two separate examples of USA 45 wings (Ref. 7) at different angles of attack, and, in addition, a sample calculation of the wake sheet location and downwash at the tail was obtained for the ATLIT (Advanced Technology Light Twin) aircraft. The theoretical section lift distribution taken from Reference 7 and given in Figure 16 served as the basis of the calculations in the WASH program. Figures 17 and 2 show the experimental lines of constant downwash angle in the plane of symmetry behind the wing and the angles predicted in Reference 7, respectively. The results of the WASH program are given in Figure 18. Reference 7, notes that the theoretical downwash of Figure 2 along the wake centerline at large distances (two semispans) appears to be approaching a value of 7.8°, while the experimental value is less than 6.6°. Reference 7 indicates that the theoretical value given in Figure 2 is too large because the method did not include spanwise curvature. The WASH program, which includes spanwise curvature, gives a value closer to the experimental result in the vicinity of the horizontal tail location. Near the wing trailing edge the theoretical method of Reference 7 over-predicts the downwash angles while the WASH program underpredicts it as compared with the experimental value. It should be noted that some difference between theory and experiment may be attributed to the fact that the  $\Gamma$  distribution is theoretical rather than experimental.

The experimental I distribution given in Figure 19 for the USA 45 airfoil was inserted in the WASH program to compare the spanwise variation in downwash with experimental values presented in Figure 20. The WASH program results are presented in Figure 21. A comparison of these two figures indicate that the total flow angular deviations computed by WASH are smaller in general than the experimental values; also, Figure 20 depicts positive sidewash angles both above and below the wake centerline while WASH predicts positive below and negative above as would be expected by vortex theory.

The wake sheet is given for each USA 45  $\Gamma$  distribution discussed above in Figures 22 and 23. Each wake sheet figure was obtained by executing the plot data set from the WASH program in the PLOT program of Reference 4. While both distributions are for the same airfoil section, an examination of Figures 16 and 19 gives an indication of how wake sheet shape is affected by the section lift distribution.

NASA is currently supporting the development of the ATLIT aircraft to investigate the potential of new aerodynamic techniques for improving the performance of light twin engine aircraft. A three-view of the ATLIT is given in Figure 24 and a perspective view is given in Figure 25. A contributer to this program, N. C. State University, is currently involved in both a performance prediction and a flight evaluation program for the ATLIT, the results of which should be published as a NASA Contractor's Report early in 1977. In conjunction with this program, it was decided to analyze the ATLIT wing using the WASH program to find the downwash characteristics at the horizontal tail in the plane of symmetry. The section lift coefficient distribution of the wing with fuselage was obtained by the methods given in Reference 4. The nacelles were neglected for this test case. The program input data set is given in Figure A-2. Figure A-3 gives typical program output: tabulated data for the spanwise variation of the downwash and sidewash in the plane of the horizontal tail, the downwash in the plane of symmetry, and the upwash ahead of the wing for a wing lift coefficient of 1.22. The wake sheet plot (Figure 26) indicates that the high wing aspect ratio (ten) yields relatively low values of downwash in the vicinity of the horizontal tail. Figure 27 is included to show the variation of upwash ahead of the wing in the plane of symmetry along with the downwash variation behind the wing. The excessively large upwash angles at the leading edge are due to the nearness of the bound vortex at the wing quarter-chord.

The cases presented above, although limited in number, show good agreement with experimental data. These test cases also indicate the type of information yielded by the WASH program; to the extent that interference effects from the fuselage and horizontal tail can be neglected, the program fulfills the design objectives of defining both the wake sheet location in the vicinity of the horizontal tail and the downwash distribution in both the spanwise and freestream directions. The program's capability for computing upwash ahead of the wing has also been demonstrated.

### PROGRAM FOR VELOCITY

## PROFILE CALCULATION

#### GENERAL THEORY

Once the location of the wake sheet centerline has been established using the WASH program, a viscous solution behind the wing may be obtained by solving the two-dimensional boundary layer equations along wake streamlines defined by the shed vortex paths. This same technique was applied to boundary layer solutions over arbitrary bodies with good success in Reference 4, and the results should be reasonable in this application as long as (1) the spanwise flow is small compared to the freestream flow, and (2) the streamline curvature is not large. These conditions of course are violated as one moves downstream from the wing tip and the vortices begin to roll-up. However, for streamlines which pass near the horizontal tail the conditions for the use of two-dimensional boundary layer analysis are usually satisfied quite well. Thus, this approach should be adequate for the purpose of this study which is to determine the magnitude and direction of the flow in the vicinity of the horizontal tail. The WASH program permits only nine shed vortices to the half-wing; thus, probably no more than the three most inboard vortex traces will pass inboard of the tail tip section.\*

As noted in the literature review, the inclusion of curvature in the boundary layer equations greatly increases the complexity. In order to determine whether or not curvature effects should be included in the analysis results from several executions of the WASH program were examined. When vortices for typical cases of spanwise lift distributions were traced downstream, it was found that while the inboard vortex streamlines were deflected in the vertical and spanwise directions, the curvature of these streamlines was small due to the relatively slow rate of change of downwash and sidewash angles (see Figures 14 and 26) along a given vortex path. Since the curvature of the inboard vortices is small, it should not play a dominant role in a boundary layer solution near the horizontal tail. Consequently, the curvature terms in the boundary layer equations were neglected, greatly simplifying the solution process.

In order to find the flow velocities along streamlines in the vicinity of the horizontal tail including the effects of fluid viscosity, the computer program WAKE was written. Given an initial velocity profile at the airfoil trailing edge<sup>++</sup>, the nonsimilar two-dimensional boundary layer equations are solved using a finite difference method with even stepsize in the transverse direction and unequal stepsize in the streamwise direction. The remainder of this section will be concerned with a discussion of the WAKE program theory.

The boundary layer equations (Equations 11 and 12) are written in a form more amenable to numerical solution through use of both the stream function  $\psi$ (defined by  $u = \frac{\partial \psi}{\partial y}$  and  $v = -\frac{\partial \psi}{\partial x}$ ) which automatically solves Equation 11, and a proper scaling of the x and y variables. The scaling variables  $\eta$  and  $\xi$ and the stream function  $\psi$  were assumed to be of the form

<sup>\*</sup> Because of typical span loadings, the third vortex out from the fuselage will probably be positioned at around 0.4 semi-spans, a location which should be further outboard than the tip of the horizontal tail plane on most light aircraft.

<sup>++</sup>The computer program providing this initial velocity profile is given in Ref. 4.

$$\eta = \frac{\gamma}{\sqrt{100c_d} + x}$$
 and  $\xi = \frac{x}{c}$  (33)

and

$$\psi(x,y) = \bigcup_{\infty} \sqrt{100c_d + x} f(\xi,\eta)$$
(34)

where 
$$c = wing chord$$
  
 $t = wing thickness$   
 $c_d = wing section drag coefficient$   
 $U_{\infty} = freestream velocity$   
 $\xi = nondimensional distance downstream of the trailing edge$   
 $n = nondimensional, scaled y coordinate normal to the x-direction$   
 $f(\xi, n) = function of \xi and n which will appear as the unknown in the transformed boundary layer equations.$ 

Since the continuity equation is identically satisfied by the definition of the stream function, it is necessary only to solve the momentum equation given by Equation 12 and rewritten, using Equation 13, as

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \varepsilon \frac{\partial^2 u}{\partial v^2} .$$
 (35)

. .

Introducing the definition of the stream function and replacing x and y by the scaled variables, Equation 35 becomes

$$\{ \bigcup_{\infty} f' \} \{ \bigcup_{\infty} \left( \frac{\partial f'}{\partial \xi} \frac{1}{c} + f'' \frac{\partial n}{\partial x} \right) \} - \bigcup_{\infty} \sqrt{100c_d t x} \left\{ \frac{f}{2x} + \frac{\partial f}{\partial \xi} \frac{1}{c} + f' \frac{\partial n}{\partial x} \right\} \left\{ \frac{\bigcup_{\infty}}{\sqrt{100c_d t x}} f'' \right\}$$
$$= \frac{\varepsilon \bigcup_{\infty}}{100c_d t x} f''' , \qquad (36)$$

where the primed quantities denote derivatives with respect to the variable n. Simplifying the above equation, one has

$$\frac{f'}{c} \frac{\partial f'}{\partial \xi} - \left(\frac{f}{2x} + \frac{\partial f}{\partial \xi} \frac{1}{c}\right) f'' = \frac{\varepsilon}{U_{\infty}(100c_{d} + x)} f''' , \qquad (37)$$

or, multiplying by x and rearranging,

$$\frac{\varepsilon}{100c_{d}^{\dagger}U_{\infty}}f^{\dagger}I^{\dagger}I^{\dagger} + \frac{1}{2}ff^{\dagger}I^{\dagger} - \xi\{f^{\dagger}\frac{\partial f^{\dagger}}{\partial \xi} - f^{\dagger}\frac{\partial f}{\partial \xi}\} = 0.$$
(38)

Equation 38 must therefore be solved at every  $\xi$  station (non-similar solution) downstream in order to obtain the velocity as a function of  $\eta$ . It is a third order partial differential equation in f requiring the three boundary conditions:

$$\begin{aligned} u(x, y \to \infty) &= \bigcup_{\infty} \to u(\xi, \infty) = \bigcup_{\infty} \to f'(\xi, \infty) = 1 \\ u(x, y \to -\infty) &= \bigcup_{\infty} \to u(\xi, -\infty) = \bigcup_{\infty} \to f'(\xi, -\infty) = 1 \\ v(x, y = 0) &= 0 \to f(\xi, 0) + 2\xi \left. \frac{\partial f}{\partial \xi} \right|_{\xi=0} = 0 . \end{aligned}$$
(39)

Equation 38 together with the boundary conditions given in Equations 39 is solved in the WAKE program by the finite difference technique described below. Let f' = T; then

$$T'' + \frac{c_1 f}{2} T' - c_1 \xi \{ f' \frac{\partial T}{\partial \xi} - T' \frac{\partial f}{\partial \xi} \} = 0 , \qquad (40)$$

where  $c_1 = 100c_d t U_{\infty}/\epsilon$ .

Simplify Equation 40 to read

$$T'' + \alpha_1 T' + \alpha_2 \frac{\partial T}{\partial \xi} = 0 , \qquad (41)$$

where

$$\alpha_1 = c_1(\frac{f}{2} + \xi \frac{\partial f}{\partial \xi})$$
 and  $\alpha_2 = -c_1\xi f'$ . (42)

Equation 41 has, through this process, been converted into a second order "linear" equation in T with supposedly known coefficients. This equation is solved by assuming a solution to evaluate the  $\alpha$ 's and then, using an iterative process, T is computed numerically and the  $\alpha$ 's are corrected after each iteration until convergence is attained. Consider the grid system shown in Figure 28. If the solution is known at some station m for all n, then using central and backwards difference formulas, the solution is constructed at the station m + 1 for all n. The derivatives are approximated with the following relations taken from Reference 19:

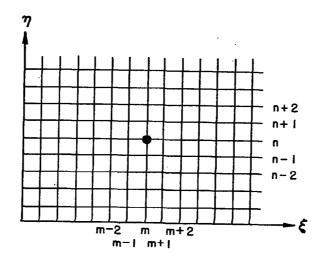

Figure 28. Grid system for finite difference solution.

$$\frac{\partial^{2}T}{\partial n^{2}}\Big|_{n,m+1} = \frac{T_{n+1,m+1} - 2T_{n,m+1} + T_{n-1,m+1}}{(\Delta n)^{2}}$$

$$\frac{\partial T}{\partial n}\Big|_{n,m+1} = \frac{T_{n+1,m+1} - T_{n-1,m+1}}{2\Delta n}$$

$$\frac{\partial T}{\partial \xi}\Big|_{n,m+1} = \left[\frac{h_{2}}{h_{1}(h_{1} + h_{2})}\right]T_{n,m-1} - \left[\frac{h_{1} + h_{2}}{h_{1}h_{2}}\right]T_{n,m} + \left[\frac{h_{1} + 2h_{2}}{h_{2}(h_{1} + h_{2})}\right]T_{n,m+1}$$

where  $h_1 = \xi_m - \xi_{m-1}$ ,  $h_2 = \xi_{m+1} - \xi_m$ , and  $\Delta \eta$  = equal stepsize in the  $\eta$  direction. Equation 41 is now rewritten as

<sup>\*</sup> This method is based on that presented by Cebeci and Smith in McDonnell-Douglas Aircraft Co. Inc. Report No. DAC-67130, October 1968, "A Finite-Difference Solution to the Incompressible Turbulent Boundary Layer Equations by an Eddy-Viscosity Concept".

$$\begin{bmatrix} \frac{1}{(\Delta n)^2} + \frac{\alpha_1}{2\Delta n} \end{bmatrix} T_{n+1,m+1} + \begin{bmatrix} \frac{-2}{(\Delta n)^2} + \alpha_2 \{ \frac{h_1 + 2h_2}{h_2(h_1 + h_2)} \} \end{bmatrix} T_{n,m+1} + \begin{bmatrix} \frac{1}{(\Delta n)^2} - \frac{\alpha_1}{2\Delta n} \end{bmatrix} T_{n-1,m+1} + \alpha_2 \begin{bmatrix} \{ \frac{h_2}{h_1(h_1 + h_2)} \} T_{n,m-1} - \{ \frac{h_1 + h_2}{h_1h_2} \} T_{n,m} \end{bmatrix} = 0$$
(44)  
or,

$$A_n T_{n+1,m+1} + B_n T_{n,m+1} + C_n T_{n-1,m+1} = D_n$$
, (45)

where

$$A_{n} = \frac{1}{(\Delta \eta)^{2}} + \frac{\alpha_{1}}{2\Delta \eta}$$

$$B_{n} = \frac{-2}{(\Delta n)^{2}} + \alpha_{2} \frac{h_{1} + 2h_{2}}{h_{2}(h_{1} + h_{2})}$$

$$C_{n} = \frac{1}{(\Delta n)^{2}} - \frac{\alpha_{1}}{2\Delta n}$$

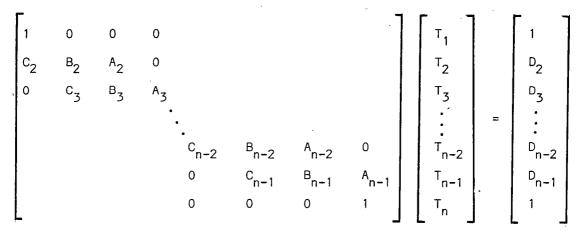

$$D_{n} = \alpha_{2} \left\{ \frac{-h_{2}}{h_{1}(h_{1} + h_{2})} \right\} T_{n,m-1} + \left\{ \frac{h_{1} + h_{2}}{h_{1}h_{2}} \right\} T_{n,m} .$$
(46)

The total number, n , of n-stations must be odd. The bottom of the wake  $(n \rightarrow -\infty)$  is defined by n = 1 while the top  $(n \rightarrow +\infty)$  is defined by n = n . The wake center is defined by n = (n - 1)/2 + 1. The boundary conditions can therefore be specified using the index n as

@ n = 1 
$$T_{n,m+1} = 1$$
  
@ n = n<sub>mid</sub>  $f(\xi,0) + 2\xi \frac{\partial f}{\partial \xi}\Big|_{(\xi,0)} = 0$  (47)

$$e_{n} = n_{max}$$
  $T_{n,m+1} = 1$ .

Equation 45, when written in matrix form, becomes:

The solution procedure for this set of equations can be greatly simplified because the matrix is tridiagonal. If the matrix is denoted by A, then

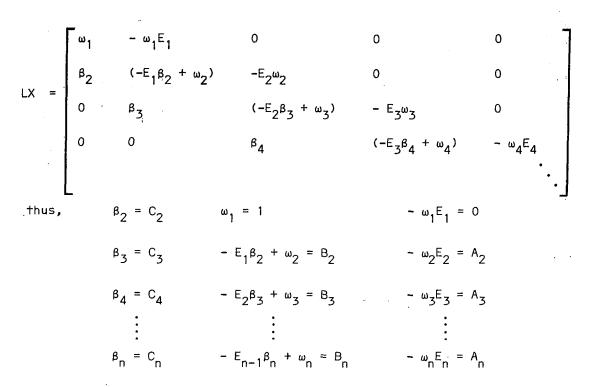

$$A T = D$$
 (49)

Now let

where

$$L = \begin{bmatrix} \omega_{1} & 0 & 0 & & & \\ \beta_{2} & \omega_{2} & 0 & & & \\ 0 & \beta_{3} & \omega_{3} & & & \\ & & \ddots & & \\ & & & \beta_{n-1} & \omega_{n-1} & 0 \\ & & & 0 & \beta_{n} & \omega_{n} \end{bmatrix}, \quad X = \begin{bmatrix} 1 & -E_{1} & 0 & & & \\ 0 & 1 & -E_{2} & & & \\ & & \ddots & & \\ & & & 0 & 1 & -E_{n-1} \\ & & & 0 & 0 & 1 \end{bmatrix}$$

and

Applying the above equations, a step by step procedure is used to evaluate the  $\beta$ 's,  $\omega$ 's, and E's given the  $A_n$ 's,  $B_n$ 's, and  $C_n$ 's. From Equations 49 and 50

$$L X T = D , (51)$$

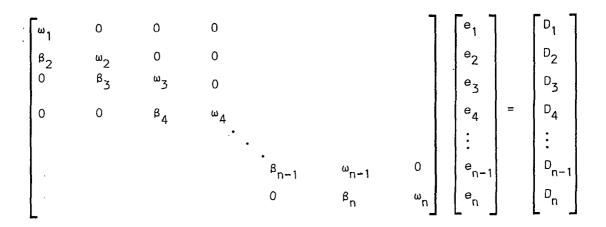

and if

XT=e, (52)

then

$$L = D$$
, (53)

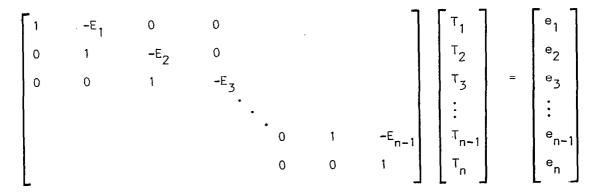

or a second s

If  $e_1 = 1$  and  $E_1 = 0$  then all the e's and E's are evaluated using the relations below

$$e_n = \frac{D_n - C_n e_{n-1}}{B_n + C_n E_{n-1}}$$
 and  $E_n = \frac{-A_n}{B_n + C_n E_{n-1}}$ . (54)

The matrix Equation 52 may now be written as

Starting with T , the n values of T are obtained by using the recursive relation given below:

$$T_n = e_n + E_n T_{n+1}$$
 (55)

These  $T_{n}^{}$  values represent the solution at the  $\xi$  station m + 1.

б4

The general procedure given above may be summarized in the following manner:

- (1)
- The solution is assumed to be known at the station  $\xi_m$  for all n. An approximate solution,  $T_{old}$  is assumed at the  $\xi_{m+1}$  station in (2) order to evaluate the An's, Bn's, Cn's, Dn's, en's, and En's. (This approximate solution at station m+1 is usually taken to be the solution found for station m.)
- Using the computed values of e and E , the solution T  $_{\rm new}$  is calculated using Equation 55. (3)
- (4) T and T are then compared to see if they are the same at every n station to within a certain accuracy; if not the T is set equal to T and steps (2) and (3) are repeated.
- This iteration procedure is continued until  $T_{old}$  and  $T_{new}$  are (5) sufficiently close signaling a converged solution at the  $\xi$  station
- m+1. Usually, no more than two or three iterations are required. (6) The procedure given in steps (1) through (5) is merely repeated for each subsequent downstream station.

As noted in (1) above, the finite difference technique requires that a solution be known at some  $\xi$  station in order to compute solutions downstream. While an actual velocity profile in the wing wake is not known in general, a profile shape can be found at the trailing edge of an airfoil on both the upper and lower surfaces whenever the flow over the airfoil is calculated. One method of finding the viscous solution over an airfoil is given in the 2-D Airfoil program of Reference 4. The flow is computed by solving the boundary layer flow over the airfoil with a momentum integral technique. Using the program output, the velocity profiles on both surfaces may be determined from their respective boundary layer thicknesses and form factors using the equations below:

$$\frac{u}{U_{m}} = \left(\frac{y}{\delta_{11}}\right)$$

 $\frac{(H_u-1)/2}{U_{\infty}} = \left(\frac{Y}{\delta_{\ell}}\right)^{(H_{\ell}-1)/2}$ 

(56)

where

 $\delta$  = boundary layer thickness at the trailing edge H = turbulent form factor of the trailing edge u & l = subscripts denoting upper and lower surfaces.

Although Equations 56 do yield an initial velocity profile, there is still a problem due to the singular nature of the boundary layer equations at the airfoil trailing edge. From Equation 33, it is evident that n is unbounded at  $\xi$  = 0. Some procedure or technique must therefore be used to provide an initial profile downstream of the trailing edge. An investigation of the experimental

data given in Reference 26 and 27 indicated that at small distances downstream of the trailing edge, the velocity profile shape is still much the same as at the trailing edge. Based on this information, the assumption was made that the profile shape at a small distance downstream, say .01 chord lengths, is the same as the profile at the trailing edge. This technique was used to establish a profile at  $\xi = .01$  in the WAKE program, and by assuming this profile satisfies the wake boundary layer equations, the initial requirements for the finite difference solution are satisfied. Although the program permits initial values other than .01 by requiring the value to be read into the program, this value was found to be satisfactory for all test cases presented in a later section of this report. Values of  $\xi$  less than .01 tended to make the maximum value of  $\eta$ too large, requiring an excessive number of steps in the  $\eta$  direction (Equation 33). For values larger than .01 the profile shape can no longer be approximated adequately by the trailing edge profile shape as seen from the experimental profiles.

Another problem which must be discussed arises from the fact that the boundary layer equation (Equation 35) contains no terms to account for pressure fluctuations in the y-direction. In the development of the boundary layer equations the pressure was assumed constant in the direction normal to the flow, eliminating the pressure gradient term. Far downstream this pressure variation is obviously small. Near the airfoil trailing edge, however, the deviations from freestream static pressure may be large. The fluctuations are virtually impossible to predict unless the complete Navier Stokes equations are solved which at the present time is an unrealistic task. The WAKE program was written with the pressure terms excluded with the hope that it would still match experimental data reasonably well. The results obtained indicated that these hopes were attained. Correlations with several test cases are given in the next section of this report.

The eddy viscosity model used in the WAKE program is that given by Equation 13 in the literature review. This model was derived by Prandtl for <u>a</u> <u>fully-developed wake flow</u>. In general, the velocity term in parentheses represents the difference between the maximum and minimum velocity in a profile while b represents the wake thickness or height at a velocity station halfway between the maximum and minimum velocity values. These parameters can be estimated given a velocity profile in a fully-developed wake, but if the initial profile is the trailing edge profile, then another set of parameters must be defined which will correlate with experimental measurement. It should be emphasized that while some experimental data exist for velocity profiles in the wakes of airfoils, these data must be described as very limited (Refs. 7, 26, 27, 28). Noting Figure 29, the velocity difference for the trailing edge profile would always be u since u min is zero, while in the fully-developed profile it is never as large as u max. Also, the wake width at half-depth for the trailing edge profile is always smaller than the same width for a fullydeveloped wake.

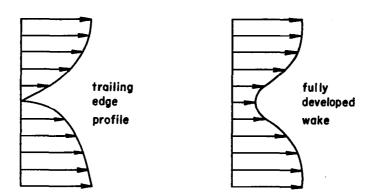

Figure 29. Sample velocity profiles at airfoil trailing edge and in a fully developed wake.

A value for the constant, c, in the eddy viscosity model must also be chosen which will bring about a match between experimental and theoretical data. In Equation 40 the eddy viscosity appears in the parameter c, as

 $c_1 = 100c_d + U_{\infty}/\epsilon$  where  $\epsilon = bc(u_{max} - u_{min})$ .

This may also be written in the following form

$$c_1 = 100c_d t/\epsilon$$
 where  $\epsilon = bc(u_{max} - u_{min})/U_{\infty}$ . (57)

For wakes considered in this report, the maximum velocity in the profile will be the outer edge velocity,  $U_{\infty}$ . Then  $\varepsilon = bc(1 - \frac{u_{min}}{U})$ . If c is defined as a positive constant, then the value of  $c_1$  is obviously positive. By making several test runs of the WAKE program, it was found that at a given distance downstream of the initial profile the larger the value of  $c_1$ , the lower the value of the centerline velocity and the smaller the wake width. Thus, it was necessary to find new definitions of the terms b and  $(1 - u_{min}/U_{\infty})$  to be used

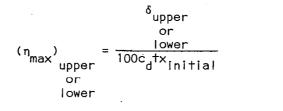

with the trailing edge profile shape to evaluate  $\varepsilon$ . New definitions were sought which would, in general, produce the proper variation of  $\varepsilon$  with wing angle of attack without making the functional relationships more complex. As seen in Figure 29, in order to achieve approximately the same wake widths using these two profiles, the width of the trailing edge profile must be measured at a y station with a larger velocity. Using this new wake width, a relationship was sought between the term  $(1 - u_{\min}/U)$  and the profile drag coefficient. Based on a comparison of many computer runs of the WAKE program and their correlations with experimental profiles, it was found that (1) if b is defined as the wake width at the y station where the velocity is 75 percent of the freestream value, and (2) if  $u_{\min}/U$  is represented by the expression  $(1 - c_d / c_d)$ , then good agreement with downstream wake profiles is obtained.

Having defined new relationships for b and  $(1 - u_{min}/U_{min})$ , the only remaining parameter needed to complete the definition of  $\varepsilon$  is the constant c. While the value of c for wakes behind circular cylinders using the conventional definitions of b and  $(u_{max} - u_{min})$  is given as .047 in Reference 20, little has been published in the open literature regarding the value of c in airfoil wakes. For profiles generated using the WASH program with the new parameters defining the eddy viscosity, a constant value of c = .03 was found to work very well for all the airfoils tested. Although this value produces good correlation, the value of c is read into the WAKE program to allow the user the option of modifying the constant if he desires. The parameters b and  $(1 - c_{din}/c_{d})$  are also defined on cards FIN 51 and 52, respectively, in the program listing given in Appendix B. This permits the user to experiment with new ideas when more experimental data become available.

It is well to note here that a constant value of  $\varepsilon$  for all x locations is realistic only for relatively weak wakes, <u>i.e.</u>,  $C_d \rightarrow 0$ .  $\varepsilon$  is really a measure of the eddy size and intensity in the wake. In high drag situations, large eddies are shed. These have very large internal shears which cause them to disintegrate progressively into smaller eddies with smaller shears as one moves downstream. For such a situation a constant eddy viscosity is obviously not realistic. It will be noted, however, that the procedure for computing the boundary layer on the wing does not admit significant regions of separated flow. Since the wing drag is always relatively small when the boundary layers are attached and since the airfoil boundary layers are computed with constant eddy viscosities, it seems reasonable to continue this practice in the wake computations. As a result, however, the determination of the momentum defect must be limited to those cases where these conditions of unseparated flow and low drag are always satisfied: generally for section lift coefficients of 0.8 or less.

In order to carry out the numerical integration of the WASH program, the user must specify the grid spacing in both the  $\xi$  and  $\eta$  direction. The program is designed to use a maximum of 2001 points in the  $\eta$  direction or 1000 points

on each side of the centerline. The maximum values of n for the initial upper and lower profiles are computed using the boundary layer thickness  $\delta$  in Equation 33:

Dividing the larger of the two n values by 1000 yields the minimum stepsize in n. While the program is written for the general case (unequal stepsize) it is recommended that only even stepsize be used. If the specified even stepsize is too large, very small oscillations in  $u/U_{\infty}$  at the outer edge of the wake profile may result; hence, a stepsize which increases with n would only compound the oscillations. For every case presented in this report a stepsize of .00125 was found to be satisfactory. Using this stepsize and n from Equation 58, the number of points in the n direction may be computed from

NPTS = 
$$2k_1 \eta_{max}/.00125 + 1$$

where NPTS is the total number of n stations for the entire wake and k, is a factor to insure that an n region is defined which is a little larger than the actual wake thickness at the initial station; k, should therefore have a value of 1.1 or 1.2. NPTS must be an odd integer. For the cases presented in this report it was usually specified as 1201, 1401, 1601, 1801, or 2001, depending on the maximum value of n. Since the value of NPTS is directly proportional to execution time it is suggested that less than 2001 points be used if possible; however, inexperienced users will probably want to choose one of the suggested values of NPTS given above depending on the value of  $\eta_{\rm max}$ .

Along with an n stepsize, a stepsize must also be specified in the streamwise or  $\xi$  direction. For  $\xi$  an uneven stepsize which is very small initially and progressively larger downstream is recommended. The WAKE program is designed to use a stepsize which increases every step by the factor (1 + DXSTEP). If DXSTEP = 0 then equal step downstream will be taken. Unequal steps are suggested because the initial solutions are very sensitive to stepsize while downstream they are relatively insensitive. The user must specify both the initial stepsize DX and the stepsize increment DXSTEP. For most of the cases presented here, an initial stepsize in  $\xi$  of .00005 was used with DXSTEP = .05; thus, at every step the stepsize increased by 5 percent from its previous value. Using this stepsize and increment, approximately 150 steps

----

69

(58)

are required to traverse a distance of two chord lengths downstream ( $\xi = 2.0$ ). One disadvantage of the unequal stepsize is that if the solution is desired at  $\xi = 2.0$  it is very difficult to choose DX and DXSTEP so that one of the steps falls on this  $\xi$  station; the solution nearest the desired station must therefore be used. Figure 30 presents a list of downstream station number (NXPRNT in the WAKE program) and  $\xi$  distance for the different stepsize increments .05, .075, and .10 all starting with an initial stepsize of .00005. This data should be helpful in determining the station number at which a solution is printed as well as the total number of steps required downstream (NXSTEP in the program) to achieve a desired  $\xi$  distance.

The WAKE program consists of a mainline and five subroutines. The mainline (1) reads and prints the input data set, (2) calls subroutine PROFIL to obtain the initial profile at  $\xi = .01$ , (3) calls subroutine GETF to obtain a value of f (Equation 41) at the first  $\xi$  station downstream given the derivative f' or T, (4) calls subroutines ABCR, COEFF, and SOLVE to obtain a new value for the profile T at the  $\xi$  station, (5) compares the new profile with the last profile calculated at the  $\xi$  station to see if convergence is attained, and (6) after convergence, prints the solution and repeats the same procedure for the next downstream station. A listing of the WAKE program with user instructions, a sample data set, and sample output are given in Appendix B. The sample data set should be particularly valuable to the unfamiliar user in giving examples of stepsizes and possible print options.

Figure 30. Tabulation of downstream station number and & distance for stepsize increments of .05, .075, and .10.

I

#### DISCUSSION OF PROGRAM RESULTS

Correlations of the WAKE program results with available experimental velocity profiles are presented in Figures 31 through 37. The figures show the experimental data, results obtained by the theoretical method of Reference 7, and the WAKE program results for specified stations downstream of the trailing edge. Each airfoil was analyzed using an initial x/c value of .01 and an eddy viscosity constant of .03. The profiles presented are not intended to show the relative distance of the profile above or below the trailing edge, but only the profile shape about the wake centerline as it moves downstream. In Figures 31 through 34 the WAKE program results are shown for two Reynolds numbers. In order to achieve a theoretical drag coefficient approximately equal to the experimental drag measured in References 26 and 27, it was necessary to run the two-dimensional airfoil program of Reference 4 at a Reynolds number of approximately half (.21 million) the indicated test value of .42 million. Tunnel turbulence or model surface conditions during the wind tunnel test may have produced more drag on the airfoil than would normally be expected at the test Reynolds number. The experimental drag was measured using a momentum rake which indicates the momentum defect in the wake at a station downstream of the trailing edge. Since the velocity profiles depend on drag coefficient, the calculated profiles should agree better with experiment if a theoretical drag coefficient is used which agrees with the experimental value. It was therefore decided to compute and compare profiles using both the specified test Reynolds number and a "corrected" Reynolds number, i.e., one at which the theoretical drag matches the experimental drag.

Figures 31 and 32 show that the WAKE program results agree well with experiment for the symmetrical Joukowski airfoil at both angles of attack (0° and 6°). While results at both Reynolds numbers show good agreement, that for the lower Reynolds number case is better. Although no experimental data were available at x/c = 2.0, the results are shown at this station for this and all other airfoils to give the reader an idea of the profile shape in the vicinity of the horizontal tail.

Figures 33 and 34 present program results for a symmetrical Piercy airfoil at angles of attack of 0° and 6°, respectively. The experimental points were taken from Reference 27. The WAKE program profiles give good agreement with experiment except near the minimum velocity region of the wake centerline. While the method of Reference 7 predicts the minimum velocity quite well, it over-predicts the wake thickness at other velocity stations in the profiles.

Experimental measurements of a modified 15 percent symmetrical airfoil at an angle of attack of 8° are presented in Reference 28, and these results are compared with the WAKE program prediction in Figure 35. Both the WAKE program and the method of Reference 7 predict the profile shape accurately as compared with experimental data except near the outer edge where the experimental data points appear questionable. As a final test case the USA 45 airfoil was analyzed at angles of attack of - 5.3° and 1.6° and compared with experimental data presented in Reference 7. It should be pointed out that the profiles given in Reference 7 were not presented to make comparisons of this type, but rather only to give approximate dynamic pressure profile shapes in the general sense. The reader should bear this in mind when considering these two figures because the experimental profile shapes in Reference 7 have been greatly enlarged to make these comparisons. For the angle of attack - 5.3° the WAKE program did a better job of predicting the profile shape; however, for  $\alpha = 1.6^\circ$  the method of Reference 7 appears to match experiment better.

In general, agreement between the WAKE program profiles and experiment was good and, in most cases, better than the method of Reference 7. The minimum velocity at x/c stations near the trailing edge was generally larger than experiment while centerline velocities at stations greater than 1.0 were generally smaller than experimental values. The correlation of profile width using the WAKE program with experimental profile shape was excellent. The reasons the coefficients of the eddy viscosity were chosen to give a better fit to the experimental data further downstream of the wing rather than at the trailing edge were first that downstream is the region of major interest and second that a boundary-layer-type analysis obviously cannot describe the initial portion of a base flow wake adequately. Thus to favor a data match in a region where the analytical model is known to be inadequate is to lose the opportunity to attain a match in a region where it should be reasonably correct.

#### APPLICATION TO THE CALCULATION OF HORIZONTAL TAIL ONSET FLOW

In the preceding, the programs for determining the wake sheet location and the velocity profile in the wake have been discussed independently; consideration will now be given to combining them so as to compute the onset flow field at an aircraft's horizontal tail. The trailing vortex streamline locations are calculated using WASH. Naturally velocity profile solutions need be computed only along those streamlines which pass near the horizontal tail. Given the section drag coefficient of the wing at the spanwise origin of each streamline used in the computation and the total streamline length to the x-station of interest, WAKE determines the velocity profile centered about the z-location of the wake sheet. The total distance traced by a streamline in going from the y-axis to some downstream x-station is given in the WASH program output in the section specifying the coordinates of the trailing vortex sheet. An example of how these are properly combined is presented in Figure 38 for the ATLIT wing at three stations downstream of the wing trailing edge in the wing plane of symmetry. The profile at the horizontal tail is therefore computed as the profile at the station x/c = 2.0 of Figure 38. Similar profiles may be calculated at other spanwise stations in order to show the spanwise variation of the profiles.

In the strictest sense profiles should be calculated along the 4 or 5 most inboard vortices to describe the spanwise variation of the onset flow at the horizontal tail. However, from a practical point of view unless the spanwise curvature of the wake is large there is, as may be seen in the wake sheet plots, little vertical variation in sheet location for y distance equal to normal tail semispan lengths. Also, a check of Figures 31 through 37 will indicate that at x/c = 2.0 the velocity profiles across the wake are very nearly the same for all airfoils tested, indicating that the effect of spanwise variations in section drag coefficient on the velocity profiles are small. As a result velocity profiles at different spanwise stations will usually have essentially the same velocity deficit. If the spanwise and downstream curvature is small for vortices which pass in the vicinity of the horizontal tail, it is therefore possible to execute only one case of each program and obtain the approximate wake position, flow angularity, and profile shape in the region of the horizontal tail (the most inboard vortex is used). This approximation can be improved if desired by applying the single WAKE program velocity profile to each of the desired spanwise vortex positions calculated in the WASH program. If a more rigorous analysis is desired, a boundary layer solution may be determined along each of the 4 or 5 most inboard streamlines noting the spanwise variation of section drag coefficient.

With the profile shape in the tail region determined estimation of the forces on the tail plane due to the flow angularity and velocity variations can be undertaken. By executing the WASH program for a range of aircraft lift coefficients the wake position as a function of  $C_1$  may be used to determine whether or not the tail ever passes through the wing wake.\* If the tail always remains 10 to 20 percent of a wing chord length above or below the wake, the velocity deficit analysis may be neglected. Even if the tail is always out of the wake, the downwash computations are still important because the change in downwash at the tail with angle of attack must be known in order to predict tail trim angles and longitudinal stability. If the tail does pass through the wake, then the tail must be sized so that it produces the required control force even when the tail is located directly in the wake. The effect of spanwise variation in downwash may be accounted for by assuming it to be similar to a wing twist. While most light aircraft horizontal tails do not have twist, a twist variation can be assumed which will produce a spanwise angle of attack variation similar to that imposed by the downwash variation. This technique can be applied to the three-dimensional program given in Reference 4 when computing tail characteristics.

The determination of the proper flow velocity to use in calculating the aerodynamic characteristics of a section of the horizontal tail flying in a wake is complicated by the fact that the wake momentum defect is confined to a rather thin region which is on the order of the thickness of the airfoil for airfoils at low-to-moderate angles of attack. In this thin region the magnitude of the flow velocity may vary from 0.88 freestream to freestream. Since two-dimensional airfoil analysis has not yet progressed to the point of calculating aerodynamic coefficients in shear flow, it is necessary to find an average velocity squared over the thickness of the airfoil beginning at the point on the velocity profile intersected by a line parallel to the airfoil chord at t/2. This is best done graphically using plots of the  $\frac{1}{2}\rho V^2$  distribution.

If the average  $q = \frac{1}{2}\rho V^2$  varies significantly along the tailplane, its effects can be included in the three-dimensional aerodynamics calculation program (Ref. 4) in several ways: (1) artificially reduce the wing chord in proportion to  $q_{local}/q_{\infty}$ , (2) reduce only the local Reynolds number by the factor  $V_{local}/V_{\infty}$  or some function thereof, and (3) multiply  $C_L$  and  $C_D$  by  $q_{local}/q_{\infty}$ . If these procedures result in significant changes in planform or aerodynamic properties, they cannot be accommodated readily within the framework of the 3-D characteristics program. However, if the changes are small enough to be capable of linear representation, then one of these procedures will serve nicely. Which procedure will yield the best result cannot be stated with certainty since time did not permit them to be investigated in detail. The author is inclined to favor the first as representing the least compromise with physical reality within the context of the two-dimensional airfoil analysis. Since the wake region is quite turbulent, it seems reasonable to insist that when the tailplane enters it, the analysis should consider the airfoil boundary layer fully turbulent from nose to trailing edge.

<sup>\*</sup> Although the analysis does not include the effects of the tail upwash on the wing downwash field, this distortion is not large. The wake position or magnitude is therefore not altered significantly.

.....

•

#### CONCLUDING REMARKS

The present work provides two computer programs useful for predicting the flow magnitude and direction in the region where one would wish to locate an aircraft's horizontal tail (pitch trimming surface). The calculation of the contribution of this surface to the overall aircraft lift, drag, and moment is much enhanced if one has available more realistic values of the onset flow.

WASH ties together for the first time in a computer program a soundlybased inviscid method for determining the shape and location of the downwash wake sheet with a method previously used to determine the spanwise lift distribution for unswept moderate-to-high aspect ratio wings and wing bodies in incompressible flow. Excellent qualitative agreement is obtained with available experimental results. Quantitatively, the predicted flow directions at any point in the downwash field agree to within a degree or so of the measured values. Considering the experimental error present and the effects of boundary layers on the aft fuselage, this is about as good as one could expect. The results show there was little spanwise variation in wake position for normal horizontal tail semispans. Execution time for the program is 15-20 seconds on an IBM 370/165; it is thus a low cost means of mapping the downwash field during design analysis.

WAKE calculates the momentum defect downstream along the wake centerline. It uses as input section drag data developed analytically by the aforementioned spanwise lift distribution program. It provides velocities that are within 2 percent of the measured values at all stations for which data were available on two wings with different airfoil sections. Computation time for the flow along one streamline is 2 min 42 sec. The results indicate that the momentum defect due to wing drag is confined to a region no more than 0.43 m high for typical light aircraft in the cruise configuration. The region of noticeable defect (> 2 percent less than freestream) is only about 0.21 m high. There is little spanwise variation in wake velocity profile for typical light aircraft horizontal tail semispans. Thus, unless there is some compelling reason to locate the trim surface near the wake centerline, use of WAKE is not required.

The flight condition for which this type of information is of most interest is approach. In this configuration the wake is large and the momentum defect significant. While the inviscid downwash calculation as used here applies equally well, the viscous treatment suffers from the fact that the method used to determine the wing drag cannot accommodate separated flows. Further, flows with large separations can not be considered to possess constant eddy viscosities as was assumed here. It is apparent, therefore, that if horizontal onset flow is to be computed during approach the problems of the analytical determination of the correct aerodynamic characteristics of airfoils near stall and the characterization of turbulent flow eddy viscosity magnitude and decay rate in terms of the size of the initial separation must first be solved.

APPENDICES

#### APPENDIX A - WASH PROGRAM

#### User Instructions

The program is written in FORTRAN IV and is designed to run in double precision on an IBM 370-165 computer. This program evaluates (1) the location of the wake centerline by tracing the path of 18 vortices shed at the wing trailing edge, and (2) the total flow angle, sidewash angle, and downwash angle behind an unswept wing in any plane perpendicular to the wake centerline at a specified distance aft of the wing trailing edge or in the plane of symmetry of the wing. Downwash information in a single plane behind the wing using 15 downstream steps requires an average execution time of 20 to 25 seconds. The program requires the specification of the following input data:

<u>Card</u> Number	<u>Variable</u> <u>Name</u>	Variable Description
1	TITLE	The 80 character array which is used as a header to identify output. Termination of execution is achieved by following the last set of wing data to be analyzed by a title card having only the word END in the first three spaces.
2	NSTEP	The number of downstream steps to be taken aft of the wing trailing edge. The total distance the vortex system is traced downstream is given by NSTEP*DX. The maximum value of NSTEP is 18.
2	JPUNCH	The control variable giving the user the option of obtaining a punched plot data set which may be used to plot the vortex system using the PLOT program in Reference 4. JPUNCH=1 gives punched output while the default JPUNCH=0 gives none.
3 3 3 3 3	ALPHA B2 TR CR DX	The wing angle of attack in degrees. The wing semispan in feet. The wing taper ratio (tip chord/root chord). The wing root chord in feet. The step size in the streamwise direction specified as ratio of wing semispan.
4-5	Y	The 10 variable array specifying the Y-coordinates of the positive Y-axis (axis in the spanwise direction) at which the section lift coefficients are read. The order of specification is from positive wing tip to wing root as a ratio of wing semispan (from Y(1) at the tip to Y(10) at the root). All of the Y values <u>must be non-zero</u> .
6-7	CLS	The 10 variable array specifying the section lift coeffi- cients corresponding to the Y-coordinates described above using the same ordering scheme.

0 1	Mauriah La	
<u>Card</u> Number	<u>Variable</u> <u>Name</u>	Variable Description
8	NXORY	The control variable used to specify the type of plane in which downwash calculations are made. NXORY=0 gives no downwash analysis in a plane. NXORY=1 gives downwash information in a Y-Z plane where X is the streamwise direction. The Y-Z plane is located at a value of X = STAT (see next variable). Downwash information is calculated for the 6 most inboard Y-stations at several Z locations. NXORY=2 gives downwash information in the X-Z plane at Y=0 for X values ranging from .25 to 1.75 semispans aft of the trailing edge. Z ranges from .5 semispans above and below a specified midpoint value of Z = STAT (see next variable). NXORY=3 gives downwash (or negative upwash) information in X-Z plane at Y=0 for negative values of X ranging from the. wing leading edge to5 semispans above to .25 semispans below the leading edge value of Z.
8	STAT	Variable used with NXORY to specify in semispans the proper location of the plane of interest. If NXORY=1 then STAT specifies the X-station at which the Y-Z plane is to be located. This distance in semispans may be either positive or negative depending on whether downwash or upwash infor- mation is desired, but it must be measured from the wing trailing edge. If NXORY=2 then STAT specifies in semispans the midpoint of the Z-range for the downwash calculations in the X-Z plane. This Z-range is specified above (positive) or below (negative) the trailing edge in semispans. IF NXORY=3 the variable STAT is not used.

Last Card

Blank.

Cards 1 through 8 represent a complete data set for the WASH Program. Several data sets may be executed for a single program compile by placing subsequent data sets behind the first. More than one plane may be analyzed during a program execution by specifying new values for NXORY and STAT on other cards placed behind card eight and before the blank card.

-.....

The entire program execution is terminated when the END title card is encountered. The format specification for the above data is given in Figure A-1. A sample data set is given in Figure A-2, and the output of this data set is presented in Figure A-3.

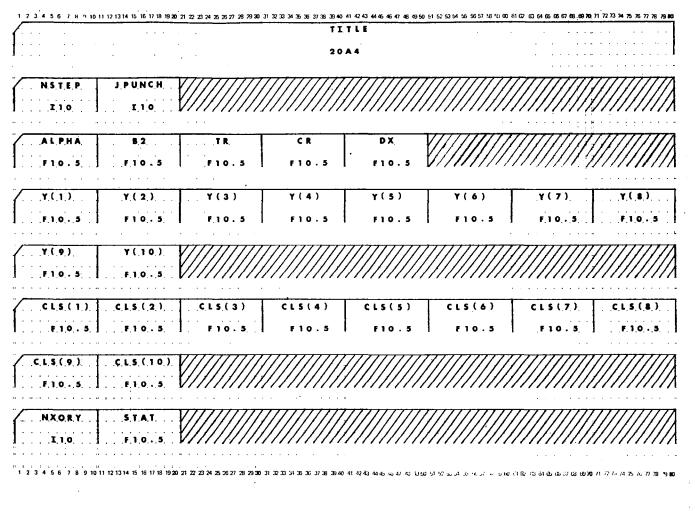

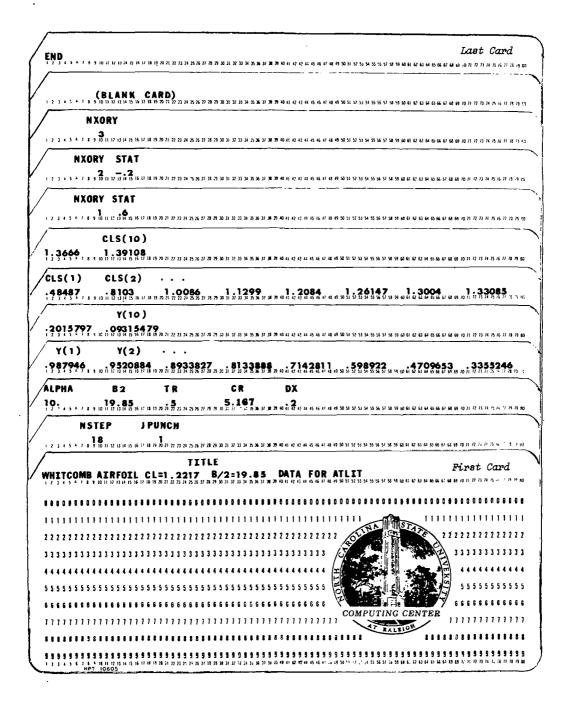

Figure A-1. Format specification of input data for the WASH program.

## APPENDIX B - WAKE PROGRAM

Ĩ

## User Instructions

The program is written in FORTRAN IV and is designed to run in double precision on an IBM 370-165 computer. Using a finite difference technique this program evaluates the velocity profile downstream of a wing trailing edge given the upper and lower surface profile shapes at the wing trailing edge. All the input information can be obtained from the two-dimensional airfoil program in Reference 4. Using 1601 points in the n or normal direction with an initial stepsize of .00005 in  $\xi(x/c)$  and an increment in stepsize of .05, an average execution time of 2 minutes and 42 seconds was required to integrate the boundary layer equations downstream two wing chord lengths. The program requires the specification of the following input data:

<u>Card</u> Number	<u>Variable</u> <u>Name</u>	Variable Description
1	TITLE	The 80 character array which is used as a header to identify output. Termination of execution is achieved by following the last set of profile data to be analyzed by a title card having only the word END in the first three spaces.
2	DETA	Stepsize in the n-direction. A value of .00125 was found satisfactory for most cases, and using this value with a constant stepsize, the total number of n-points, NPTS, can be estimated using the equations given in the text.
2	DX	Stepsize in the X-direction. Best results were obtained for cases analyzed in this report using a very small step- size, .00005 (specified in chords), and unequal spacing using the variable DXSTEP on card 3.
3	X(1)	The station in chords at which the initial velocity profile solution is assumed. A value of .01 was found satisfactory for most wake solutions.
3	CEDDY	A constant used to evaluate the eddy viscosity model required to solve for the velocity profile. A value of .03 correlated best with experimental data.
3	т	The thickness at the spanwise station of interest in chords.
3	CD	The drag coefficient at the spanwise station of interest.
3	CDMIN	The minimum drag coefficient of the wing section at the spanwise station of interest.

<u>Card</u> Number	<u>Variable</u> <u>Name</u>	Variable Description
3	DXSTEP	Stepsize increment in the X-direction. The stepsize in the X-direction is increased by the factor $DX_{step n+1} = (DX_{step n})(1 + DXSTEP)$ . A table is given in Figure 30 which will help in determining the X-value at any station using unequal step increments of .05, .075, and .10.
4	NXPRNT	The NXPRT station numbers at which the user desires to have the velocity profile printed. The maximum number of stations which may be printed is 20 unless the solution is printed at every station (NXPRT=0 and all values of NXPRNT are specified as 0). The station number corresponds to a specific value of X downstream; if equal stepsize in the X-direction is used then the NXPRNT values at the desired X-station are easily calculated. However, for unequal stepsize which is the more useful case Figure 30 will help in determining the step number nearest the X-station at which the velocity profile is desired. The NXPRT values of NXPRNT are read using a 2014 format. If only two stations were of interest then only columns 1-4 and 5-8 would contain integers representing the station numbers. The stations must be specified in the order of increasing station number.
5	DELTAU	The boundary layer thickness in chords at the trailing edge on the upper surface at the station of interest.
5	DELTAL	The boundary layer thickness in chords at the trailing edge on the lower surface at the station of interest.
5	HU	Form factor on the upper surface at the station of interest = boundary layer displacement thickness divided by the momentum thickness at the trailing edge.
5	HL	Form factor on the lower surface at the station of interest = boundary layer displacement thickness divided by the momentum thickness at the trailing edge.

Cards 1 through 5 represent a complete data set for the WAKE Program. Several data sets may be executed for a single program compile by placing subsequent data sets behind the first. The entire program execution is terminated when the END title card is encountered. The format specification for the above data is given in Figure B-1. A sample data set is given in Figure B-2, and the output of this data set is presented in Figure B-3.

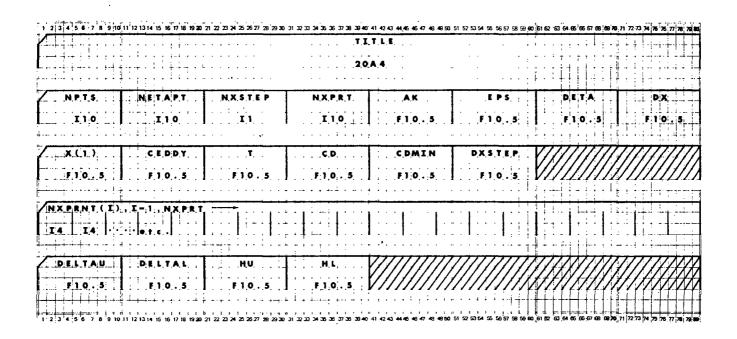

Figure B-1. Format specification of input data for the WAKE program.

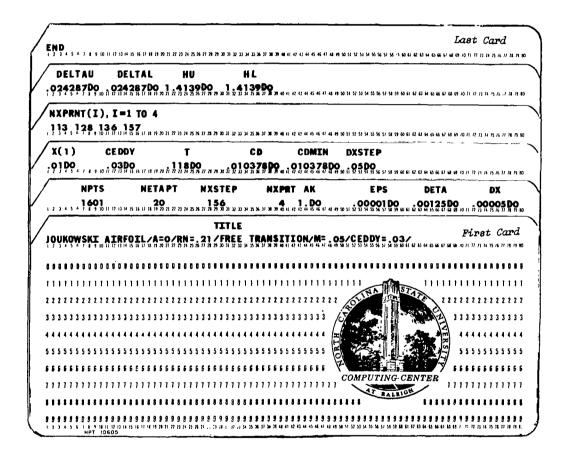

Figure B-2. Example data set for the WAKE program.
