ABSTRACT

Criteria for selection of a mini-computer for use as a core resident acquisition system are developed for the ODU Mobile Air Pollution Laboratory. A comprehensive data acquisition program named MONARCH has been instituted in a DEC-B/E-6K 12-bit computer. Up to 32 analog voltage inputs are scanned sequentially, converted to BCD, and then to actual numbers. As many as 16 external devices (valves or any other two-state device) are controlled independently. MONARCH is written as a foreground-background program, controlled by an external clock which interrupts once per minute. Transducer voltages are averaged over user specified time intervals and, upon completion of any desired time sequence, outputted are: day, hour, minute, second; state of external valves; average value of each analogue voltage (E Format); as well as standard deviations of these values. Output is compatible with any serially addressed media.

/ INTRODUCTION

The need for development of a computer based data acquisition and control system arose during the evolution of a comprehensive Mobile Air Pollution Laboratory at Old Dominion University. This laboratory, housed in a mobile trailer (see figure 1), monitors at four different heights the following environmental parameters: wind speed and direction; temperature; concentrations of ozone (O_3) ; nitrogen oxides (NO, NO_2, NO_x) ; carbon monoxide (CO); total hydrocarbons (THC); and sulfur compounds (H2S, SO2). Additionally measurements at one height are: relative humidity; insolation; atmospheric pressure; and the b-scattering coefficient (visibility). All of these analog voltage instruments were initially measured sequentially by a multipoint recorder which produced 14,000 data points per level per day. Transcription and averaging of this data base required more effort than maintenance of the instruments during the course of month-long field experiments. It soon became obvious that a computer based data acquisition and control system must be installed to provide near real time analysis of the environmental parameters and to provide convenient expansion and modification via software when additional instrumentation became available. This system was named MONARCH.

A detailed analysis of present and future requirements for MONARCH suggested the following hardware configuration.

1. Data acquisition. A mixture of analog voltage, bridges, and digital BCD input channels must be available. The software must select order and frequency of scanning for a high precision low-speed A/D. All inputs to the A/D are set in the range -10.00 to +10.00 volts, so that each input slot has its own amplifier to change the incoming voltages to this range. Cost constraints prohibited use of a programmable gain amplifier.

2. All data averaging is done in software.

3. Master Control. A crystal controlled clock provides interrupts once per minute. Software design is based upon counting clock interrupts. When read, the clock provides Julian date, hour, minute, and second in three 12-bit BCD words.

ł

4. Control Functions. Computer must initiate all scans of instruments, read the clock, and be able to control external valves for level shifting as well as inserting scrubbers, span and zero gases at appropriate times into air pollution instruments.

5. Input/Output. The entire system should work in a conversional mode so that field personnel may control its actions. Output medium should be versatile so that changes from paper tape to cassette tape or to tele-communications is possible.

Criteria were established for selection of a computer for MONARCH. Realizing that none of the investigators had ever dealt with minicomputers or assembly languages, one of the major criteria for selection was the existence of clearly worded comprehensible software documentation. Other criteria were: ease of interfacing, possibility of future expansion, cost, availability of service and software personnel, and our in-house hardware capability. The final selection of the minicomputer was a PDP8/E with 8K 12-bit word core memory.

HARDWARE CONFIGURATION

A block diagram of the hardware system is shown in figure 2. All I/O is handled by a 33ASR teletype. The clock was built in-house and interfaced to the PDP8/E. The clock (device code 13) interrupts once per minute and provides day (000-365), hour (00-24), minute and second (00-60) in three 12-bit words. It can be reset manually to $000^{d}10^{h}00^{m}00^{s}$.

The valve control unit (device code 15) accepts from the PDP8/E one 12bit word. Each bit (0 or 1) controls the state of one valve system. Once a valve is set via software command it maintains that state until it is reset. This device is expandable to 36 valve states.

Since MONARCH can control measurements at four levels (15, 25, 50, 75 feet) three of the value states are used (figure 3). Four glass and teflon manifolds are brought into the trailer where each molecular instrument is attached to each manifold via 1/4" I.D. teflon tubing. Switching is accomplished by values A, B, C which are solenoid activated teflon 3-way divert values. This arrangement leaves eight unused states for cycling of scrubbers. If zero air or span gases are desired, they are easily incorporated with these additional value states.

Device 14 is the A/D scanner and input level shifters for 14 input data channels. It is expandable up to 18 additional analog channels. Channel selection is via transfer of a positive binary number from the accumulator to the decoder where the appropriate channel is selected and its mercury relay is closed and data conversion begins. Upon finish of data conversion this device interrupts and one 12-bit BCD number can be read by the computer. Thus this device both accepts and sends information. If digital information is available from any instrument, they can be assigned their own device codes as needed.

DATA ACQUISITION SOFTWARE

MONARCH operates with the interrupt enabled, and a background program which endlessly rotates one bit through the link and accumulator of the PDP8/E. When the indicator selector switch is in the AC setting, one light moves across the display at a rate and direction dependent upon the switch registers (1). Any similar program can be substituted.

An initial start up sequence, START, operates with interrupt off and a dialogue takes place between the operator and MONARCH (figure 4). This sequence sets the number of levels, instruments, samples per instrument per minute, the length of time MONARCH spends per level and time periods between zero and span cycles. At the end of START all software counters are initialized. MONARCH gives messages to the operator, sets the valves and then halts.

MONARCH operates using a Digital Equipment Corporation 23-bit floating point package (FPP) (2), series of teletype service routines, and a BCD-binary conversion subroutine. Use of the FPP enables accuracy of six significant digits and greatly enabances the ease of arithmetic and data manipulation as well as I/O operations. Figures 5 through 10 give the flow diagram for MONARCH. A listing of MONARCH in PAL III assembly language constitutes Appendix A.

After the operator has interacted with MONARCH and supplied the required information, the computer halts. Upon pressing the CONTINUE switch, all flags are cleared, the interrupt is turned on and the background program is entered. At this point we will assume four levels, 14 instruments, five minutes per level and 100 samples per instrument per minute. At the first clock interrupt (Zeroth minute) MONARCH goes to location 0000 and executes the instruction stored in location 0001 which is an effective jump to the Service routine. The Service routine stores the current value of the accumulator and link. Location 0000 has stored in it the next instruction that was to be performed before interrupt occurred. The SERVE routine is a skip chain which tests to see which device needs attention. At this moment the clock is determined and a jump to CLKSER occurs. Since this is the first clock interrupt, the clock is not read. Several counters are incremented (counted up to zero), and the scanner is instructed to start conversion on instrument 14. Then the program jumps to EXIT where the accumulator and link are restored, and program control is returned to background.

The next interrupt is the scanner signalling that instrument 14 has finished conversion. A jump to SERVE of durs where the scanner is detected and a jump to SCNSER happens. SCNSER clears the scanner interrupt flag, sends one 12-bit BCD word to the accumulator. Since the A/D has been designed to accept -10 to +10 volt signals, it is necessary to do ermine the algebraic sign of the data. This is implemented in hardware. If the least significant digit (LSD) is 0, then the number is negative. If 1, it is positive. This means valid outputs from the A/D are even numbers (negative); odd numbers (positive) over the range -998 to +999. Over range is signalled by all bits zero and must be differentiated from real zero by software if needed.

SCNSER checks the LSD and converts BCD to bindry via a service routine, BCDBIN. The floating point package (FPP) is endered and the one word binary data is converted to floating point (3 words). This data is level shifted to all positive (range 0 to 2000) and added indirectly to the 14th floating point buffer location. The Buffer was set to zero in START. Next the scanner is sent instructions to process instrument 13 and control is passed to background.

This process continues until SCNSER detects the fact that each instrument has been read the specified number of times (100, in this example). At that point the scanner is not sent a start conversion signal and program returns to background to wait for the second clock interrupt.

This procedure (clock interrupt, read sequentially each instrument 100 times, wait until clock interrupts) continues until the fourth clock interrupt. At that time a value in the NO_x instrument is energized and the same procedure continues.

At the fifth clock interrupt a new sequence is initialed. First, the valve state (level) is changed. The clock is now read (BCD 3 words). The clock words are masked and converted to binary, and then to 12-bit words corresponding to units of seconds, minutes, days, tens of seconds, minutes, days, and hundreds

of days. Next the state of the NO_x valve is changed. Data output is now indicated via the routine DTAOUT. An example output is shown in table 1. Extensive use is made of the FPP and teletype routines for output and format control (may be FORTRAN E or F format). Output is sequentially printed on three TTY lines; Line 1: DAY, HOUR, MIN., SEC., VALVE LEVEL CODE. Line 2: DATA FROM INSTRUMENT ONE TO SEVEN. Line 3: DATA FROM INSTRUMENT EIGHT TO FOURTEEN. Each outputted value is a decimal number and each are separated by blanks except carriage return line feed at the end of lines. The values are the arithmetic mean of the voltages of each instrument averaged over the number of times it was read. DTAOUT then zeroes all the data storage buffer and returns to background via EXIT. Since the output is to TTY paper tape, a maximum of 600 characters may be punched before the next interrupt occurs. DTAOUT operates with the interrupt off, so that no confusion is possible.

Included in the SERVE Skip Chain are two other service routines. TTYSER gives a warning to the operator if the TTY keyboard is struck. This can be used to input and modify future states of the program. ERROR is a routine at the bottom of the skip chain which can only be entered if interrupt occurs when no real device has caused such. This routine gives an error message and returns to background. It is of importance in cases where the electromagnetic environment is noisy.

FUTURE EXPANSION PLANS

Even though MONARCH presently resides in an 8K machine, it is entirely contained in Field ϕ (Lower 4K memory). The upper 4K memory is not used. Thus, MONARCH can be used with only minor modification in any 4K PDP 8 system. Since the instruction set utilized is shared by the PDP/5 system, MONARCH will work in these older machines if the interrupt service routine is modified. If mass

storage devices are incorporated for I/O operations, then the TTY service routines and FPP FOUT function must be modified.

The present version of MONARCH is fixed to a previously existing four-level value structure shown in figure 3. If the number of external levels are increased, additional value routines are necessary. Decreasing from four levels requires no change. If zero and span cycles are desided, they may be inserted in the ZERO routine or they may be assigned levels five and six and thus will automatically be cycled through in the same time intervals as the first four levels.

Many of the instructions used in the floating point package are not currently used. Additional storage may be obtained by deleting these. Examples would be the floating trig and log functions. One modification that would be desirable, from a data analysis viewpoint, would be the incorporation of statistical variances of the quantities being measured. This could be implemented without greatly increasing data storage requirements (it would double - $14 \times 3 \times 2 = 84 - 12$ bit words). Presently, the data storage buffer has stored in each location (3 word) the sum of the data from each instrument over the sample interval. Using the FSQU instruction and doubling the size of the buffer, one could have stored

 $\sum_{i=1}^{N} \mathbf{x}_{i}$

and

 $\sum_{i=1}^{N} x_{i}^{2}$

where Xi is the measurement, N is the number of times the quantity is measured. At output, it is a simple matter to output (already done)

$$\langle x \rangle = \frac{1}{N} \sum_{i=1}^{N} x_i$$

and also

$$\sigma^2 = \langle x^2 \rangle - \langle x \rangle^2 = \frac{1}{N} \sum x i^2 - \left(\frac{1}{N} \left(\sum x i\right)\right)^2$$

The variances have physical interpretations for meteorological quantities (wind speed, temperature, etc.) which are related to turbulence. Variances should be known so that estimates of the reliability and validity of the data may be obtained.

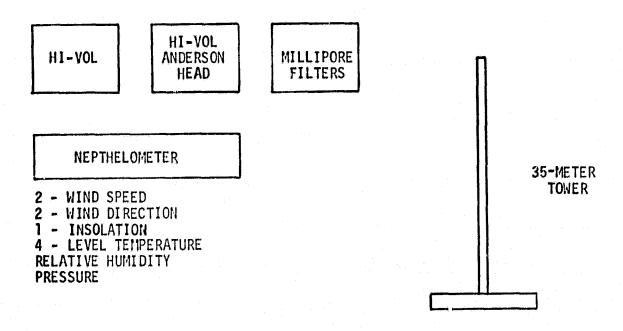

If reliable calibration equations are available, the floating point package can be used to provide output in engineering units directly. Although this may appear to be a desired goal in design of MONARCH, it can easily produce invalid results if calibration of any instrument changes. As a check against this happening for the computer hardware, it is suggested that at least one data port be used to monitor a fixed voltage (Standard cell).
