ABSTRACT

Measurements of interplanetary dust via zodiacal light observations and direct detection are discussed for an out-of-ecliptic space probe. Particle fluxes and zodiacal light brightnesses are predicted for three models of the dust distribution. These models predict that most of the information will be obtained at space probe distances less than 1 A.U. from the ecliptic plane. Joint interpretation of the direct particle measurements and the zodiacal light data will yield the best knowledge of the three-dimensional particle dynamics, spatial distribution, and physical characteristics of the interplanetary dust. Such measurements are important for our understanding of the origin and role of the dust in relation to meteoroids, asteroids, and comets, as well as the interaction of the dust with solar forces.
Introduction

The microscopic dust particles are an important constituent of our solar system. A knowledge of the physical and dynamical properties of these dust particles in three dimensions should aid our understanding of the origin and evolution of the planetary system and furthermore of circumstellar dust clouds as detected by infrared astronomy. In this paper we discuss the type of dust measurements suitable for an out-of-ecliptic mission and the information which could be expected from these measurements.

The interplanetary dust can be explored from space probes by two complementary methods:

1. Direct detection of individual particles intercepted by a sensor. Velocity and mass parameters can be derived and, depending on the specific experiment, information on the chemical composition. Recent experiments have extended the limiting sensitivity down to masses of about $10^{-16}$ g at impact velocities of approximately 20 km/s (Hoffman et al. 1975).

2. Zodiacal light observations. Measurements of the brightness, color, and polarization of sunlight scattered by the dust particles give information on the average scattering properties and the spatial distribution of the dust along the line of sight (ref. Leinert 1975).

Direct detection has the advantage of defining a complete set of parameters for individual particles but the drawback of
sampling only a small number of particles. The zodiacal light
observations sample a large volume of space, but the information
on the physical properties of the particles is indirect.

Combined data from these two methods can be valuable especially
if the direct detection instrument is sensitive enough to cover
the entire mass range which may contribute to the zodiacal light.
The combined data can in principle specify particle velocities,
orbits, size, mass range, spatial distribution, and the general
physical composition of the dust grains (structure, density
etc.). These parameters are necessary for an understanding of
the dynamical history of the dust particles, their relation to
cometary and asteroidal material, and their interaction with it.

Extensive ground-based photometry and polarimetry of the zodiacal
light has been carried out (see for example Weinberg 1964,
Dumont and Sánchez 1975). However, observations from the earth
alone have the fundamental drawback that the spatial distribu-
tion and the particle scattering function can not be uniquely
separated, unless some assumptions are made about the decrease
of particle number density with solar distance and about the
independence of dust composition from the position in the solar
system (Dumont and Sánchez 1975). Information about the valid-
ity of such assumptions can be obtained by zodiacal light pho-
tometry and polarimetry from space probes still in the ecliptic
plane but far from the earth's orbit (Giese and Dziembowski
The zodiacal light experiments on Pioneer 10/11 and Helios provide the brightness and polarization of the zodiacal light as a function of heliocentric distance in the ecliptic plane, (Hanner et al. 1975, Link et al. 1975) from which the large-scale spatial distribution in the ecliptic between 0.3 and 3.3 A.U. can be derived.

Impact detectors with increasing sophistication have been used to measure particle fluxes and velocities by experiments on the space missions of Pioneer 8/9, Prospero, NEOS 2, Pioneer 10/11, and Helios (Berg et al. 1971, Budford 1975, Dietzel et al. 1973, Hoffmann et al. 1975, Humes et al. 1974, Soberman et al. 1974). Pioneer 8/9 and submicron-sized impact craters on lunar surface samples showed the existence of a component of small particles moving outward from the sun under the influence of non-gravitational forces (Berg and Grun 1973, Fechtig et al. 1974).

The interplanetary dust forms a non-stable dust cloud in the solar system. The continuous sources are mainly comets, asteroids, and space erosion processes. It is, however, unknown which of these processes contribute to which extent. The main dust sink is, besides impacts on planets and their satellites, undoubtedly the sun: dust particles spiralling into the sun according to the Poynting-Robertson effect (Wyatt and Whipple 1950) presumably lead to a vaporisation near the sun (Sekanina 1975) and hence to a dust stream of submicron-sized remnants.
leaving the solar system as a result of the radiation pressure force. These so-called beta meteoroids (Zook and Berg 1975; Zook, in press) are also produced by mutual collisions of meteoroids. Hemenway has suggested that a component of these beta meteoroids is being formed directly at and ejected by the sun (Hemenway et al 1972). In addition to these interplanetary particles, a component of interstellar origin can possibly be expected.

**Models of Out-of-Ecliptic Dust Distribution**

To predict the particle flux and the zodiacal light brightness which might be observed from an out-of-ecliptic probe, we chose three models for the spatial distribution of the dust, as described by Giese (1975).

I : \[ n(r) = n_0 \cdot r^{-\nu} \left( 1 + (\gamma \sin \theta_o)^2 \right)^{-\nu/2}; \gamma = 9.0 \] (Ellipsoid model)

II : \[ n(r) = n_0 \cdot r^{-\nu} \exp \left( -\left( \gamma z \right)^2 \right); \quad \gamma = 2.5 \] (Gauss model)

III : \[ n(r) = n_0 \cdot r^{-\nu} \exp \left( -|\gamma \sin \theta_o| \right); \quad \gamma = 3.0 \] (Fan model)

Here \( n(r) \) is the particle number density as a function of distance \( r \) (A.U.) from the sun, \( n_0 \) is the number density at 1 A.U. in the ecliptic plane, \( z \) (A.U.) is the distance above or below the ecliptic plane, and \( \theta_o \) is the heliocentric ecliptic latitude.
(\sin \theta = z/r). We have set the parameter \( v = 1.0 \), consistent with the Pioneer 10/11 and Helios zodiacal light data. The flattening parameter \( \gamma \) was adjusted for each model to give the ratio 0.32 for the brightness of the zodiacal light at the ecliptic pole to the brightness in the plane at elongation 90\(^\circ\), as observed by Dumont (1973).

Contours of equal dust density are illustrated in Figures la, lb, and lc respectively for the three examples. All three models predict that the dust is considerably concentrated toward the ecliptic plane. In comparison, the spatial distribution of radio meteors derived by Southworth and Sekanina (1973) shows a similar \( z \)-dependence at a \( x \)-distance of 1 A.U., but an increasing number density beyond 1 A.U. in the ecliptic plane.

The 0.5 contour in our examples ranges from \( z = 0.2 \) to 0.4 A.U. at \( x = 1.0 \) A.U.. The spatial density at 1 A.U. away from the ecliptic is at most 0.1 \( n_0 \). Thus, observations of the zodiacal light and direct detection of particles will take place mainly at space probe distances less than 1 A.U. from the ecliptic.

**Direct Detection**

Direct measurements from an out-of-ecliptic mission could help to identify the various sources and sinks of the non-stable dust cloud. On the basis of the results of Pioneers 8/9 and HEOS 2
missions in the ecliptic at 1 A.U. and on the basis of the three models referred to above, the number of events per orbit were computed for a detector surface of 100 cm\(^2\) and a space probe on a circular orbit of 1 A.U. radius having an ecliptic inclination of 30° or 60° or 90° respectively. Two cases of vehicle stabilisations (spinner with axis perpendicular to the orbital plane and three-axis stabilisation) were considered. The results are presented in Table 1 excluding or including the case of particles coming directly from the sun (marked 'no sun particles' or 'sun particles').

From these data it is evident that, while such a particle detection experiment is not able to differentiate among the various models of the spatial distribution directly, it could provide information on the role of the sun as a possible dust sink or source. Furthermore, the event rate is sufficient to continue analysis of enough individual particles to look for differences in composition between particles with low- and high-inclination orbits.

**Zodiacal Light**

The brightness and polarization of the zodiacal light can be predicted theoretically as a function of observing direction and observer's position in the solar system for any spatial distribution. If one assumes, that the average scattering properties of the particles are independent of location in the
solar system, then the brightness variation with spacecraft position is directly related to the spatial distribution of the dust (Hanner and Leinert 1972). Models for the zodiacal light distribution over the sky as seen from an out-of-ecliptic space probe were discussed by Giese (1971). By use of the same program we have computed for our three dust models the variation of zodiacal brightness for an out-of-ecliptic space probe on a circular orbit of 1 A.U. radius as a function of the $z$ distance between the spaceprobe and the ecliptic plane. The maximum value $z_m$ of $z$ is related to orbital inclination $i$ by $z_m = (1 \text{ A.U.}) \cdot \sin i$. For the scattering function a simple diffraction plus isotropic reflection form (albedo = 1) was chosen. The size distribution adopted was a 3-part power law $n(a)da = a^{-K}$ with $K = 2.7; 2; \text{ or } 4.33$ in the regions of particle radii from 0.008 to 0.16; 0.16 to 29; or 29 to 189 $\mu$m, and $n_0 = 3.7 \cdot 10^{-13}; 4.3 \cdot 10^{-15}; \text{ or } 7.4 \cdot 10^{-18}$ particles/cm$^3$ in each regime, respectively. This is a fair approximation taking into account both the distribution of particle radii as derived by Grün (1975) from direct measurements (Fechtig et al. 1974), and the brightness of 200 stars of tenth magnitude per square degree (200 $S_{10}$) found by Dumont and Sánchez (1975) at $\varepsilon = 90^\circ$ elongation in the ecliptic.

Figs. 2a through 2c present the decrease of zodiacal light brightness with increasing orbital altitude $z$ of the probe for the three models of Fig. 1. The viewing direction from the
probe is parallel to the ecliptic plane and perpendicular to
the sun (Fig. 2a); in the positive z direction (Fig. 2b); or
parallel to the negative x direction (Fig. 2c). In all cases
the models predict brightness values easily observable \( \gtrsim 10 \, S_{10} \)
at space probe z distances up to 0.4 A.U. (Model II) or up to
approximately 1 A.U. (Models I and III), and at the same time
observable differences between the models, particularly in the
case of Model II with its flattened outer contours. Even if
the density does not follow the functional forms we have chosen
as examples, the brightness variation with space probe z dis-
tance at a constant observing direction will give a measure of
the rate of dust decrease away from the ecliptic plane. To
look for any systematic changes in the average scattering prop-
ties of the particles (size, composition) with z distance,
polarization measurements as a function of elongation are neces-
sary, in addition to brightness observations (see Giese and
Dziembowski 1969).

Interstellar Dust

The existence of an interstellar component in the solar system
dust cloud has been proposed by Greenberg (1969) and others.
Even if such small particles are excluded from the inner solar
system by radiation pressure, they might be observable with a
sensitive detector at large heliocentric distance, during the
transfer orbit of an out-of-ecliptic probe. If we take, for example, a number density of $3 \cdot 10^{-13}$ particles/cm$^3$ of interstellar origin and a relative velocity of 30 km/sec between the particles and a 100 cm$^2$ detector, 8 such particles should be detectable each day.
Conclusion

A joint dust experiment which combines direct detection of the velocity and mass of individual particles with measurements of the zodiacal light brightness and, if possible, polarization will best serve the purpose of an out-of-ecliptic mission. These two complementary methods together will give a picture of the three-dimensional dynamics and spatial distribution of the interplanetary dust. Such a picture will help to clarify the relation of dust particles to cometary and asteroidal material as well as the interaction of the dust with the solar radiation field. The influence of the sun on particle motions and physical characteristics has a significance for the role of the dust in the early evolution of the solar nebula and early phases of stellar evolution.
