16. Abstract

A recently developed method for analyzing unsteady airfoil stall was refined by including nonlinear effects in the representation of the inviscid flow. Certain other aspects of the potential-flow model were reexamined and the effects of varying Reynolds number on stall characteristics were investigated. Refinement of the formulation improved the representation of the flow and chordwise pressure distribution below stall, but substantial quantitative differences between computed and measured results are still evident for sinusoidal pitching through stall. Agreement is substantially improved by assuming the growth rate of the dead-air region at the onset of leading-edge stall is of the order of the component of the free stream normal to the airfoil chordline. The method predicts the expected increase in the resistance to stalling with increasing Reynolds number. Results indicate that a given airfoil can undergo both trailing-edge and leading-edge stall under unsteady conditions.

INVESTIGATION OF NONLINEAR INVISCID AND VISCOUS FLOW EFFECTS IN THE ANALYSIS OF DYNAMIC STALL

by Peter Crimi
Avco Systems Division

SUMMARY

A recently developed method for analyzing unsteady airfoil stall was refined by including nonlinear effects in the representation of the inviscid flow. Certain other aspects of the potential-flow model were reexamined and the effects of varying Reynolds number on stall characteristics were investigated. Refinement of the formulation improved the representation of the flow and chordwise pressure distribution below stall, but substantial quantitative differences between computed and measured results are still evident for sinusoidal pitching through stall. Agreement is substantially improved by assuming the growth rate of the dead-air region at the onset of leading-edge stall is of the order of the component of the free stream normal to the airfoil chordline. The method predicts the expected increase in the resistance to stalling with increasing Reynolds number. Results indicate that a given airfoil can undergo both trailing-edge and leading-edge stall under unsteady conditions.

INTRODUCTION

Unsteady airfoil stall is a problem of particular concern in the design and operation of helicopter rotors. Periodic stall and unstall of the blades at high advance ratio cause severe oscillatory control loads, increased vibration levels and, under some circumstances, a torsional aeroelastic instability, effectively limiting aircraft performance (Ref. 1). As a result, the problem has been the subject of considerable research (Refs. 2-5, for example).

A method was recently developed for analyzing dynamic stall of a helicopter rotor blade. The method, which is described in Ref. 6, employs a model for each of the basic flow elements involved in the unsteady stall of a two-dimensional airfoil in incompressible flow. The interactions of these elements are analyzed by forward integration in time, with the aid of a digital computer. Results are in good qualitative agreement with measured loads, both dynamic lift overshoot and unstable moment variation being in clear evidence in the computed loading. A number of approximations were employed in the formulations which caused substantial quantitative differences, however.

One of the approximations most open to question was the use of a linearized representation of the potential flow. This study was directed, first, to refining the model of the potential flow by introducing second-order terms. Certain other aspects of the model for a stalled airfoil were also considered. The method was then used to investigate the effects of varying Reynolds number and to determine the relative importance of leading-edge and trailing-edge stall under unsteady conditions.

SYMBOLS

b	airfoil semichord, m
$C_{m\ c/4}$	moment coefficient, $C_{m\ c/4} = m/(2\ \rho U^2 b^2)$
C_n	normal-force coefficient, $C_n = n/(\rho U^2 b)$
C_p	pressure coefficient, $C_p = 2\ (p - p_\infty)/(\rho U^2)$
c	airfoil chord, m
k	reduced frequency, $k = \omega b/U$
l	lift per unit span, N/m
ℓ	length of dead-air region, m
m	moment per unit span about quarter-chord, N
n	force normal to chord line per unit span, N/m
p	static pressure, N/m^2
p_∞	free-stream static pressure, N/m^2
q	fluid speed at airfoil surface, m/s
$Re_{(\ )}$	Reynolds number based on length indicated by subscript
r_o	leading-edge radius, m
T	airfoil section thickness distribution, m
t	time, s
U	free-stream speed, m/s
u_e	fluid speed external to boundary layer
(x, y)	foil-fixed coordinates, with origin at midchord
α	angle of attack, deg or rad
γ	vortex strength, m/s
δ^*	boundary layer displacement thickness, m

θ_p	pitch angle, deg or rad
ρ	fluid density, kg/m^3
σ	source strength, m/s
τ_w	wall shear, N/m^2
ϕ	perturbation velocity potential m^2/s
ω	frequency of pitch oscillation, rad/s

DESCRIPTION OF BASIC METHOD

The previously developed method for analyzing dynamic stall is outlined briefly below. Details can be found in Ref. 6.

When the flow is attached (Figure 1a), the flow elements represented are: (1) a laminar boundary layer extending from the stagnation point over the leading edge; (2) a leading-edge separation bubble (if separation occurs prior to transition); (3) a turbulent boundary layer from the reattachment point of the leading-edge bubble (or the transition point) to the trailing edge; and (4) a potential flow over the airfoil, including the effects of a vortical wake generated by the variation in time of the circulation about the airfoil. If the airfoil undergoes leading-edge stall (Figure 1b), the flow elements modelled are: (1) a laminar boundary layer to the point of separation; (2) a laminar constant-pressure shear layer to the point of transition; (3) a turbulent constant-pressure shear layer; (4) a turbulent pressure-recovery region; and (5) a potential flow over the airfoil and external to the viscous mixing region, again including a vortical wake. If trailing-edge stall occurs (Figure 1c), the flow elements represented are: (1) the laminar boundary layer; (2) the leading-edge bubble (if laminar separation occurs prior to transition); (3) the turbulent boundary layer; (4) a turbulent constant-pressure shear layer; (5) a turbulent pressure-recovery region; and (6) a potential flow with vortical wake. These elements were formulated as follows.

Potential Flow

Given the airfoil section characteristics and motions, together with the distribution of pressure in the dead-air region if the airfoil is stalled, the flow and pressure over the airfoil must be determined to compute the integrated load and analyze the boundary layer. The problem was formulated by imposing linearized boundary conditions of flow tangency and pressure, using a perturbation velocity potential derived from source and vortex distributions. The resulting coupled set of singular integral equations is solved by casting the singularity distributions in series form and solving for the unknown coefficients by imposing boundary conditions at prescribed points.

Figure 1 FLOW ELEMENTS

Boundary Layer

Because the relative importance of the individual elements of the boundary layer flow as they affect dynamic stall could not be established in advance, the representation in Ref. 6 was made as general as possible. The method of finite differences for unsteady flow, with variable step size in both streamwise and normal directions, was employed with the error in each finite-difference approximation of second order. The Cebeci-Smith eddy-viscosity model (Ref. 7) is used to compute turbulent shear.

Dead-Air Region

The function of the model of the dead-air region is to define the streamwise distribution of pressure in that region, given the locations of the separation and recovery points and the pressure at the recovery point. The dead-air region is assumed to consist, in the most general case, of a laminar constant-pressure free shear layer from separation to transition, a turbulent constant-pressure mixing region, and a turbulent pressure-recovery region. The laminar shear layer is analyzed by the method of Ref. 8, assuming quasi-steady flow. The turbulent mixing and pressure-recovery regions are analyzed using the steady-flow momentum integral and first moment equations. Profile parameters in those regions are assumed to be universal functions of a dimensionless streamwise coordinate, with those functions derived from an exact viscous-inviscid interaction calculation. Matching of approximate solutions for the mixing and pressure-recovery regions at their interface completes the analysis.

Leading-Edge Bubble

The leading-edge bubble on an unstalled airfoil is analyzed using the same basic relations employed for the dead-air region. Given the boundary-layer parameters at separation, the length of the bubble and the amount of pressure rise possible, for that length, in the pressure recovery region, are computed. That pressure rise is compared with the rise in pressure in the potential flow over the length of the bubble. If the latter is greater than the former, the bubble is assumed to have burst, and the stall process is initiated.

Loading Calculation Procedure

Calculations proceed by forward integration in time, given the blade motions as a function of time. If, at a given instant, the airfoil is not stalled, the potential flow is computed, and the boundary layer and leading-edge bubble are analyzed to check for bubble bursting. If the airfoil is stalled, the pressure distribution in the dead-air region is computed, the potential flow evaluated, and the boundary layer is analyzed to locate the separation point. The last two steps are repeated iteratively until assumed and computed separation points agree. Rate of growth of the dead-air region is determined from an estimate of the rate of fluid entrainment derived from the potential-flow solution. In the case of leading-edge stall, unstall is determined by first postulating its occurrence and analyzing the leading-edge bubble which would then form to ascertain whether that event did in fact occur. During unstall, the dead-air region is washed off the airfoil. The rate of wash-off is normally taken to be the free-stream speed. There is some indication, though, that the rate should be considerably less than that value, as is discussed subsequently.

FORMULATION OF POTENTIAL FLOW TO SECOND ORDER

The following specifically concerns the derivation of the perturbation velocity potential to second order for unsteady, attached flow. The formulations derived are also used to compute flow and loading when the airfoil is stalled. However, in the latter case, while the solution is uniformly valid to first order, strictly consistent accounting of second-order terms was not attempted. A complete development to second order could not be justified without a corresponding refinement of the analysis of the dead-air region, which would be outside the scope of the present study.

The problem of an airfoil in unsteady flow, including nonlinear effects, has been treated by several investigators. Representative of these studies is the work of Giesing (Ref. 9), who used a finite-element approach to obtain numerical solutions for arbitrary transient motions, and Chen and Wirtz (Ref. 10), who employed an expansion of the acceleration potential to obtain integrated loading to second order for oscillatory pitching and plunging.

The approach taken here was dictated primarily by the requirement for compatibility with the formulation of the linearized problem in Ref. 6. The velocity potential and boundary conditions were systematically expanded, following the general procedure used in Ref. 11 for the steady problem, as follows.

The perturbation velocity potential can be written in the form

$$\phi(x, y, t) = \frac{1}{2\pi}\int_{-b}^{b} \sigma(\xi, t)\tan^{-1}\left(\frac{y}{x-\xi}\right)d\xi$$

$$-\frac{1}{2\pi}\int_{-b}^{x_o} \gamma(\xi, t)\ln\left(\sqrt{(x-\xi)^2 + y^2}\right)d\xi \qquad (1)$$

where coordinates (x, y) are fixed to the airfoil, with origin at midchord. The surface of the airfoil, of chord 2b, is located at $y = \pm T(x)$, $-b \leq x \leq b$ (consideration has been limited to symmetric airfoils). Coordinate x_o in Eq. (1) locates the end of the shed vortex wake.

Wake displacement effects have been omitted. Their contribution to the boundary conditions is of third order. While there is a second-order effect from wake displacement on the pressure at the airfoil surface, the contribution is symmetric and so does not affect integrated load. In any case, that term has reduced frequency as a factor, so for all practical purposes it can be regarded as third order.

The potential is required to satisfy

$$\frac{V_\infty + \partial \phi / \partial y}{U_\infty + \partial \phi / \partial x} = \pm T'(x) , \quad \left\{ \begin{array}{l} y = \pm T(x) \\ -b \leqslant x \leqslant b \end{array} \right. \qquad (2)$$

where U_∞ and V_∞ are apparent free-stream components, including effects of foil motions.

The source and vortex distribution strengths are taken to be sums of terms of ascending order in angle of attack or a similar small parameter, i.e.,

$$\sigma = \sigma_1 + \sigma_2 + \ldots$$

$$\gamma = \gamma_1 + \gamma_2 + \ldots$$

If the derivatives of ϕ in Eq. (2) are expanded in Taylor series about $y = 0$, terms of like order are assembled, and symmetric and antisymmetric contributions separated, in the usual manner, it results that

$$\left. \begin{array}{l} \sigma_1 = 2\, U\, T'(x) \\ \dfrac{1}{2\pi} \displaystyle\int_{-b}^{x_o} \dfrac{\gamma_1(\xi, t)\, d\xi}{x - \xi} = w(x, t) \end{array} \right\} \qquad (3)$$

$$
\left.
\begin{aligned}
\alpha_2 &= \frac{2U}{\pi} \frac{\partial}{\partial x} \int_{-b}^{b} \frac{T'(\xi)\, d\xi}{x - \xi} \\
\frac{1}{2\pi} \int_{-b}^{x_o} \frac{\gamma_2(\xi, t)\, d\xi}{x - \xi} &= - \frac{\partial}{\partial x} (T\,\gamma_1)
\end{aligned}
\right\} \qquad (4)
$$

where U is free-stream speed and w is the downwash imposed by foil incidence and motions.

The second of Eqs. (3) is, of course, the one solved in Ref. 6, using a Glauert-type trigonometric expansion of γ_1. Comparing Eqs. (3) and (4), it is seen that γ_2 can be computed using the same procedure as for γ_1, with $-(T\,\gamma_1)'$ substituted for w.

Some difficulty was encountered in implementing Eqs. (4), because T was originally formulated as a rather slowly converging trigonometric series. As a result, the derivative of $T\,\gamma_1$, in series form, did not converge satisfactorily. The difficulty was resolved by replacing the original series for T with the following more rapidly converging one:

$$
T = b \sin\theta \left[\frac{1}{2} (1 - \cos\theta) \frac{r_o}{b} + \sin\theta \sum_{n=1} t_n \sin n\theta \right]
$$

where r_o is leading-edge radius, and $x = b\cos\theta$.

The same basic procedure as the one developed by Lighthill for steady flow (Ref. 11) was followed in deriving the formula for the flow at the surface, q. The x-component of q, denoted q_x, is of the order of free-stream speed U, while the y-component, q_y, is of first order in whatever expansion parameter one chooses to use. Thus,

$$
\begin{aligned}
q &= q_x \sqrt{1 + (q_y/q_x)^2} \\
&= q_x + \frac{1}{2} \frac{q_y^2}{q_x} + \dots \\
&= q_x + \frac{1}{2} \frac{q_y^2}{U} + \text{higher order terms.}
\end{aligned}
\qquad (5)
$$

while

$$q_x = U \cos \theta_p \pm \frac{1}{2}(\gamma_1 + \gamma_2) + u_s$$

$$+ \frac{1}{2\pi} \int_{-b}^{b} \frac{(\sigma_1 + \sigma_2)\, d\xi}{x - \xi} + UTT'' + \text{third-order terms.}$$

$$q_y = U \sin \theta_p - \frac{1}{2\pi} \int_{-b}^{x_o} \frac{\gamma_1\, d\xi}{x - \xi} \pm v_s \pm UT'$$

$$+ \text{second-order terms.}$$

where θ_p is pitch angle and u_s and v_s are contributions from the source distribution representing the dead-air region when the airfoil is stalled (see Ref. 6). If these expressions for q_x and q_y are substituted in Eq. (5), a term which is singular at the leading edge due to a factor $(b + x)^{-1/2}$ is obtained, just as in the linear approximation. However, there is also a second-order term which is singular due to a factor $(b + x)^{-1}$, namely $U [TT'' + \frac{1}{2}(T')^2]$, which is approximately equal to $-.25\, Ur_o/(b + x)$ near the leading edge. A uniformly valid approximation for q is obtained, using Lighthill's procedure, by subtracting off the singular part of the offending term and multiplying by the factor

$$\left(\frac{b + x}{b + x + r_o/2}\right)^{\frac{1}{2}}$$

which restores the complete expression to its original form, to second order, some distance from the leading edge, and makes the result finite at the leading edge. The complete expression for q, uniformly valid to second order, with attached flow, is then

$$q = \left(\frac{b + x}{b + x + r_o/2}\right)^{\frac{1}{2}} \left\{ U \cos \theta_p \pm \frac{1}{2} (\gamma_1 + \gamma_2) + u_s + UTT'' \right.$$

$$+ \frac{1}{2\pi} \int_{-b}^{b} \frac{(\sigma_1 + \sigma_2)\, d\xi}{x - \xi}$$

$$+ \frac{1}{2U} \left[U \sin \theta_p - \int_{-b}^{x_o} \frac{\gamma_1\, d\xi}{x - \xi} \pm v_s \pm UT' \right]^2$$

$$\left. + \frac{U r_o}{4(b + x)} \right\}$$

The pressure coefficient on the airfoil is computed from

$$C_p(x, \pm T(x), t) = 1 - \left(\frac{q}{U}\right)^2 - \frac{1}{U^2} \frac{\partial}{\partial t} \phi(x, 0^{\pm}, t) \qquad (6)$$

The derivative of ϕ in Eq. (6) is computed by the same formulas as in Ref. 6, except that the second-order corrections are added to the source and vortex strenths. A term of second order which derives from the Taylor expansion of ϕ about y = 0 has been omitted from Eq. (6) for the same reasons wake displacement effects were neglected.

RESULTS OF COMPUTATIONS

All calculations were performed for a modified NACA 0012 airfoil section. The section and a list of offsets are shown in Fig. 2. Unless otherwise noted, chordal Reynolds number was 2 million.

Preliminary Calculations

Computations were performed for transient pitching at a dimensionless rate $\dot{\theta}b/U$ of .025 and a chordal Reynolds number of 3 million, in order to determine whether quasi-steady flow could be assumed in the analysis of the laminar and turbulent boundary layers, and so effect a substantial savings in computer storage requirements and running time. Results for the laminar boundary layer are shown in Fig. 3, in which are plotted the external flow magnitude u_e, displacement thickness δ^* and wall shear τ_w as a function of distance along the airfoil surface from the stagnation point. Results obtained by omitting time derivatives are seen to be virtually identical to those using the complete boundary-layer equations.

It should be noted here that the point of vanishing wall shear is not generally coincident with the separation point in unsteady laminar flow. It was shown in Ref. 12, though, that a sufficient condition for identifying the separation point is that the boundary layer equations become invalid downstream of the true separation point. In the method of analyzing the boundary layer used here, there is a good indication of when that event occurs, since the solution is obtained by iteration on the wall shear. When that iteration diverges, then presumably there is no solution to the boundary layer equations and unsteady separation has occurred. It was found that, for the results of Fig. 3, the points of vanishing wall shear and separation are nonetheless coincident, for all practical purposes, since the iteration on wall shear diverged at the first streamwise station downstream of the point where the wall shear went to zero.

A slight difference between the quasi-steady and unsteady result was discernable near separation of the turbulent boundary layer downstream of reattachment of the leading-edge bubble, as shown in Fig. 4. However, the difference in separation points, 3.5 percent of chord, is less than the acceptable error of 5% used in the overall

iteration for trailing-edge stall. The assumption of quasi-steady flow appears to be justified, then, at least for those flow conditions and airfoil motions normally experienced by a helicopter rotor blade. That assumption was therefore employed for all subsequent calculations.

Effect of Second-Order Terms

In order to assess the importance of the added terms in the potential flow model, a number of calculations were performed for direct comparison with results obtained using

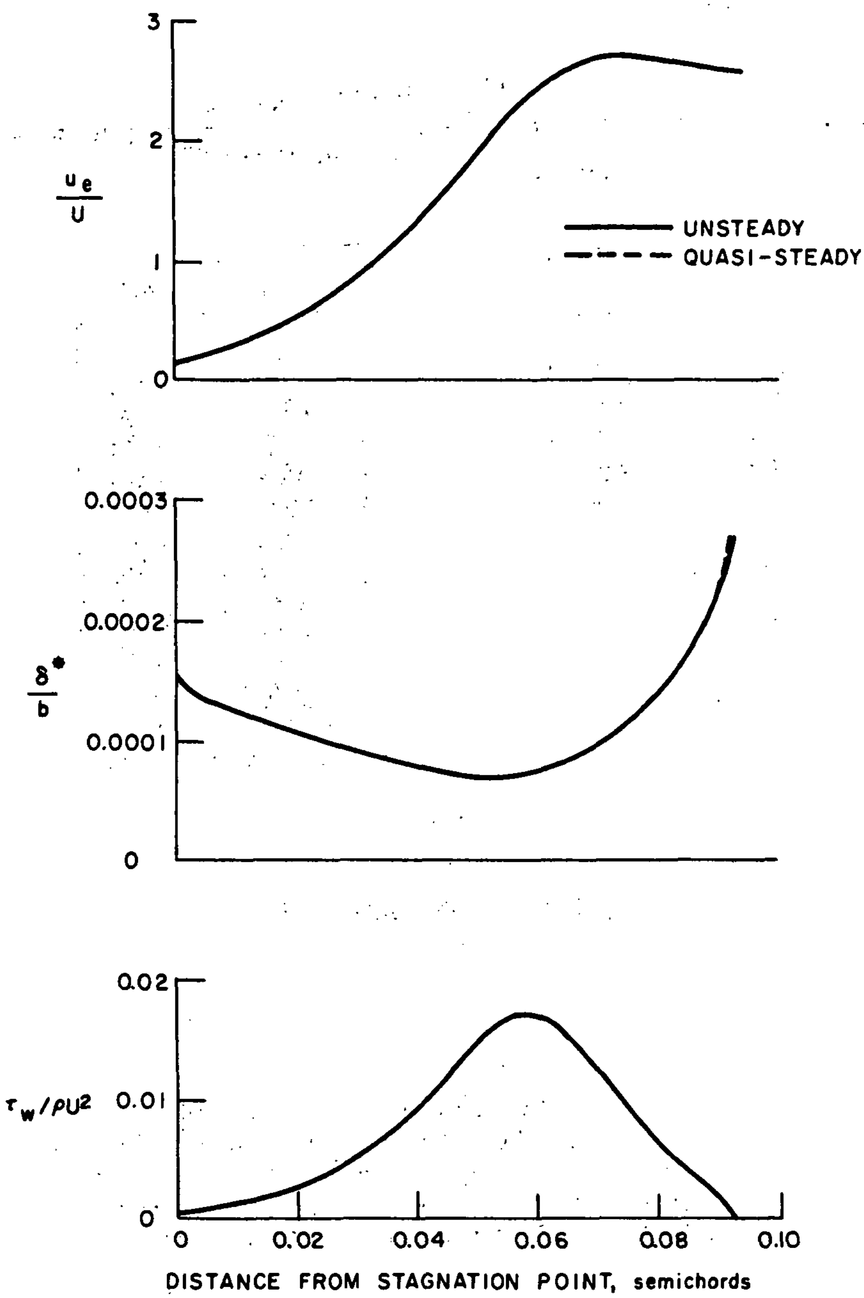

Figure 3 COMPARISON OF RESULTS OF LAMINAR BOUNDARY LAYER ANALYSES

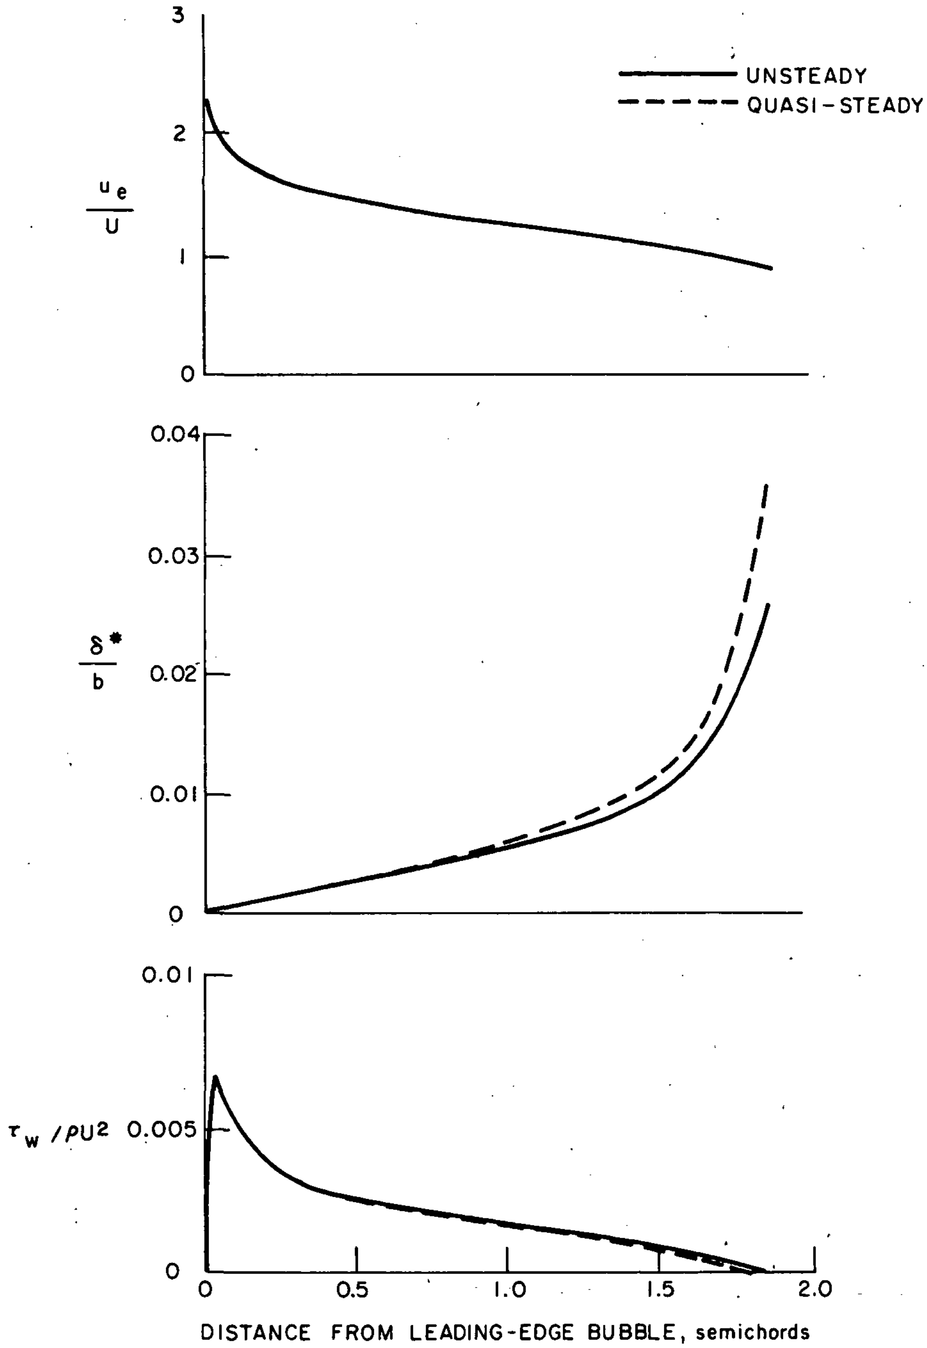

Figure 4 COMPARISON OF RESULTS OF TURBULENT BOUNDARY LAYER ANALYSES

a linearized potential-flow formulation. Cases of both transient and sinusoidal pitching motions were considered.

Time histories of normal force and moment coefficient and length of the dead-air region for a linearly varying pitch angle are shown in Fig. 5. The refined solution is seen to produce somewhat less dynamic overshoot of normal force than the linear formulation. However, the relative overshoot is about the same, the maximum static C_n for the linearized case being somewhat larger than when second-order terms are included.

A comparison of the variation of static normal-force and moment coefficients with angle of attack, generated by series of transient pitch calculations, is shown in Fig. 6. Including second-order terms is seen to reduce both the maximum C_n and the stall angle of attack, and increase the slope of the C_n curve below stall. The increase in $dC_n/d\alpha$ is due to nonlinear thickness effects. The theoretical value of the slope for the airfoil analyzed is 6.82 per radian, while the computed value is 6.76; the slight difference is believed to be due to numerical inaccuracies.

Including second-order terms significantly improved the representation of the pressure distribution. The predicted moment coefficient below stall using the nonlinear potential model is essentially zero, as it should be. The linear solution makes the center of pressure somewhat aft of the quarter-chord, the shift being due to the Lighthill correction which was used to remove the leading-edge singularity.

Results for sinusoidal pitching at a reduced frequency of .13 are compared in Fig. 7, where C_n and $C_{m\ c/4}$ are plotted against instantaneous pitch angle. The dashed curves are the static variations of the coefficients. The corresponding measured loading variation, from Ref. 2, is shown in Fig. 8. Including second-order terms is seen to cause some dynamic overshoot, while none had been obtained with the linear model. The overshoot is still considerably less than what was measured, however. The nonlinear terms are seen to cause unstall to be initiated at a pitch angle somewhat above the static stall angle, while the linear solution has unstall starting slightly below that angle.

Results for pitching at a reduced frequency of .26 are shown in Fig. 9. The comparable measured loading is shown in Fig. 10. The same effects of the second-order terms are evident at the higher frequency, but the relative differences are somewhat less.

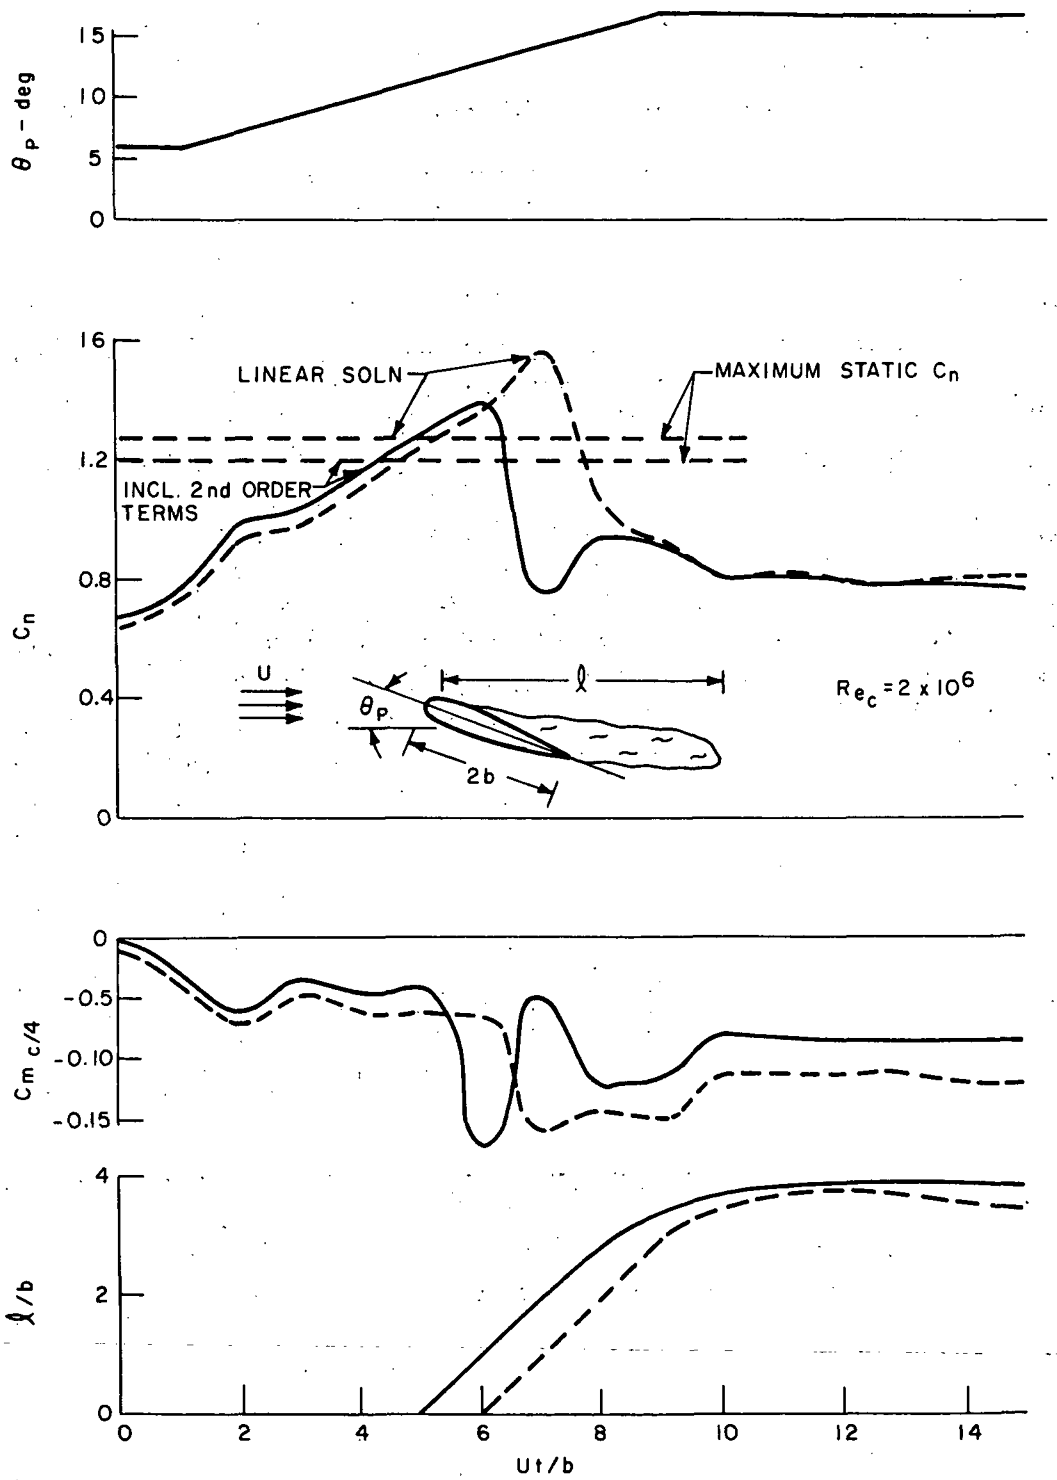

Figure 5 COMPARISON OF COMPUTED LOADING TIME HISTORIES DURING TRANSIENT PITCHING

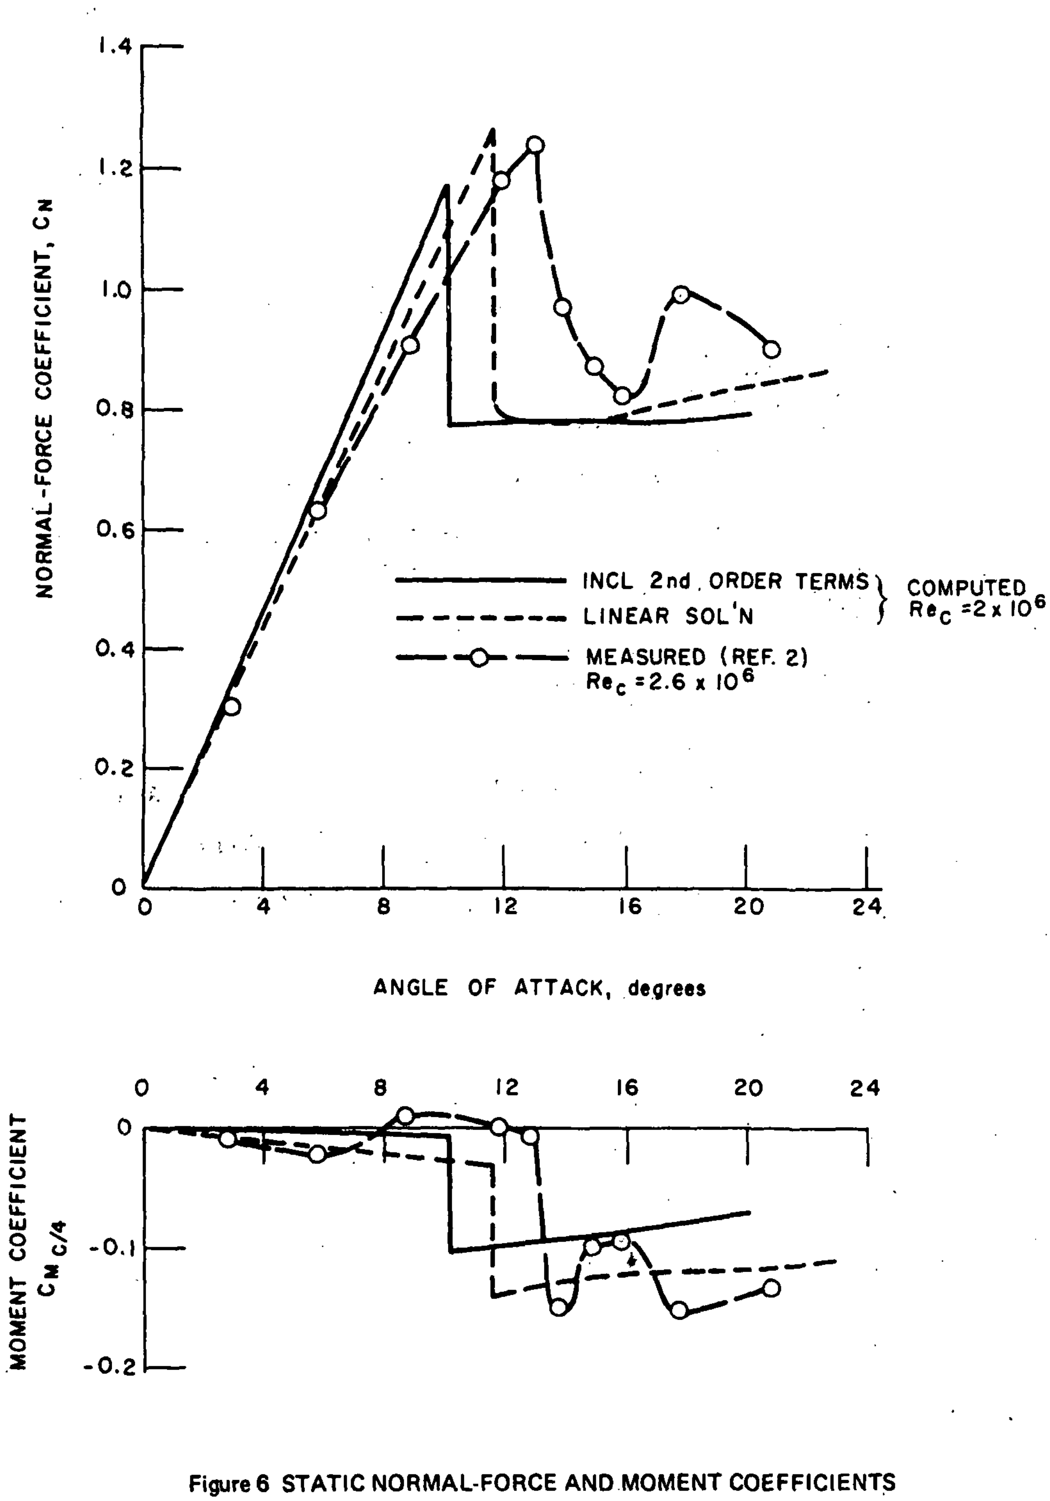

Figure 6 STATIC NORMAL-FORCE AND MOMENT COEFFICIENTS

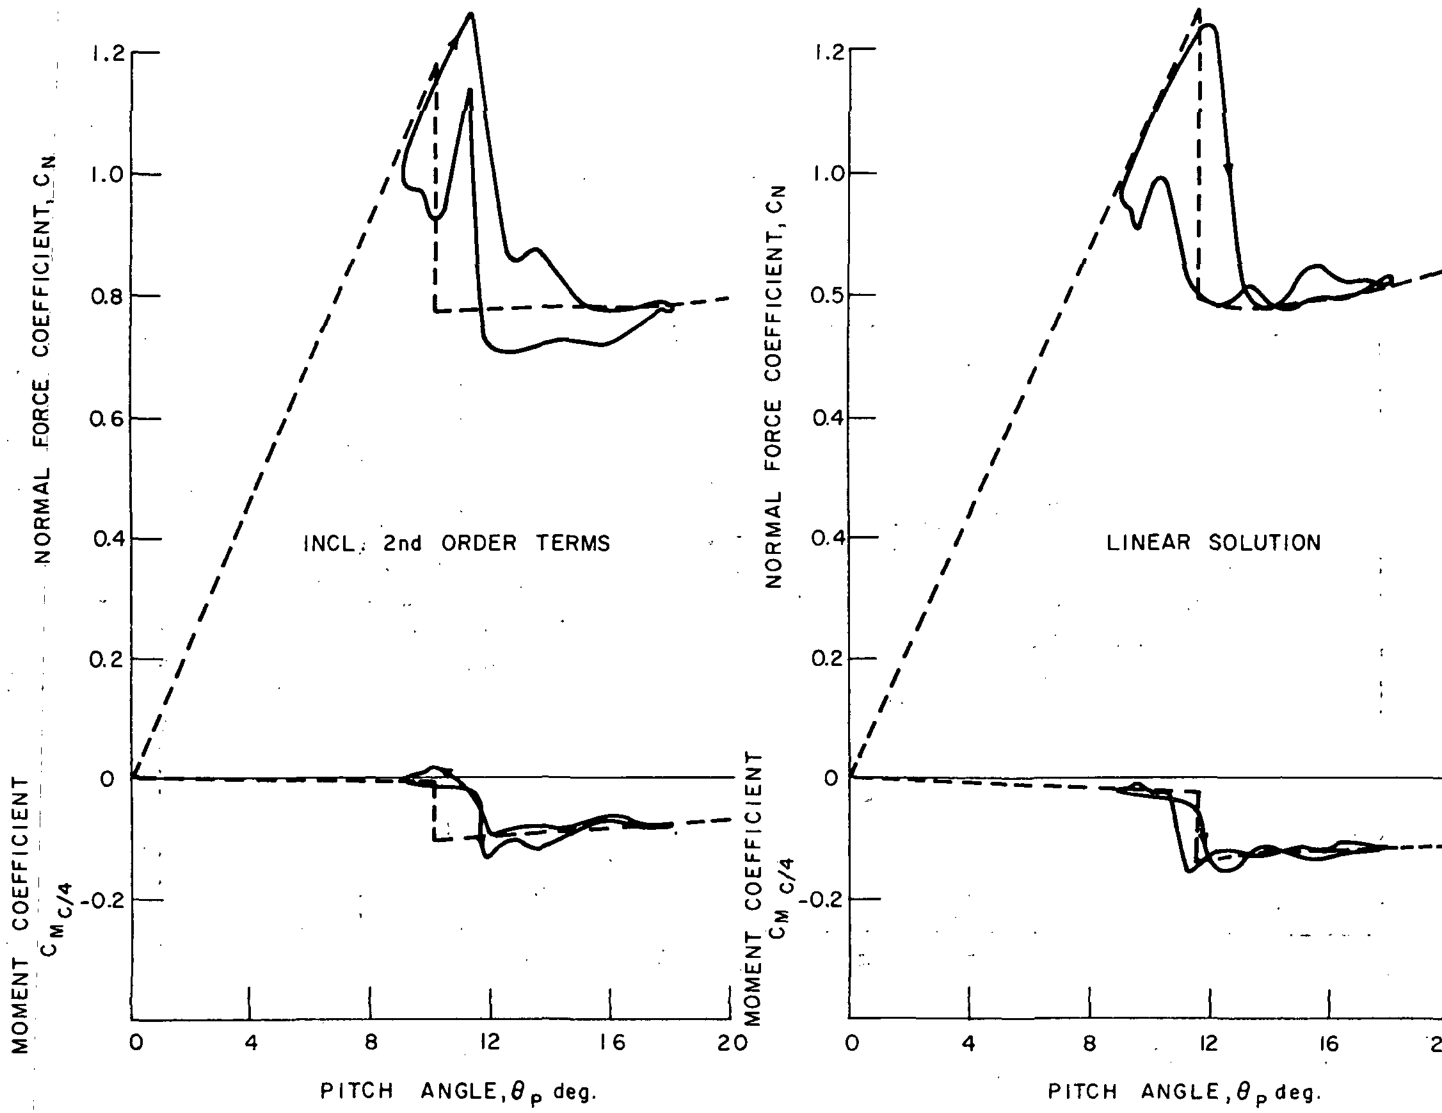

Figure 7 COMPARISON OF COMPUTED LOADINGS DURING SINUSOIDAL PITCHING, k = .13

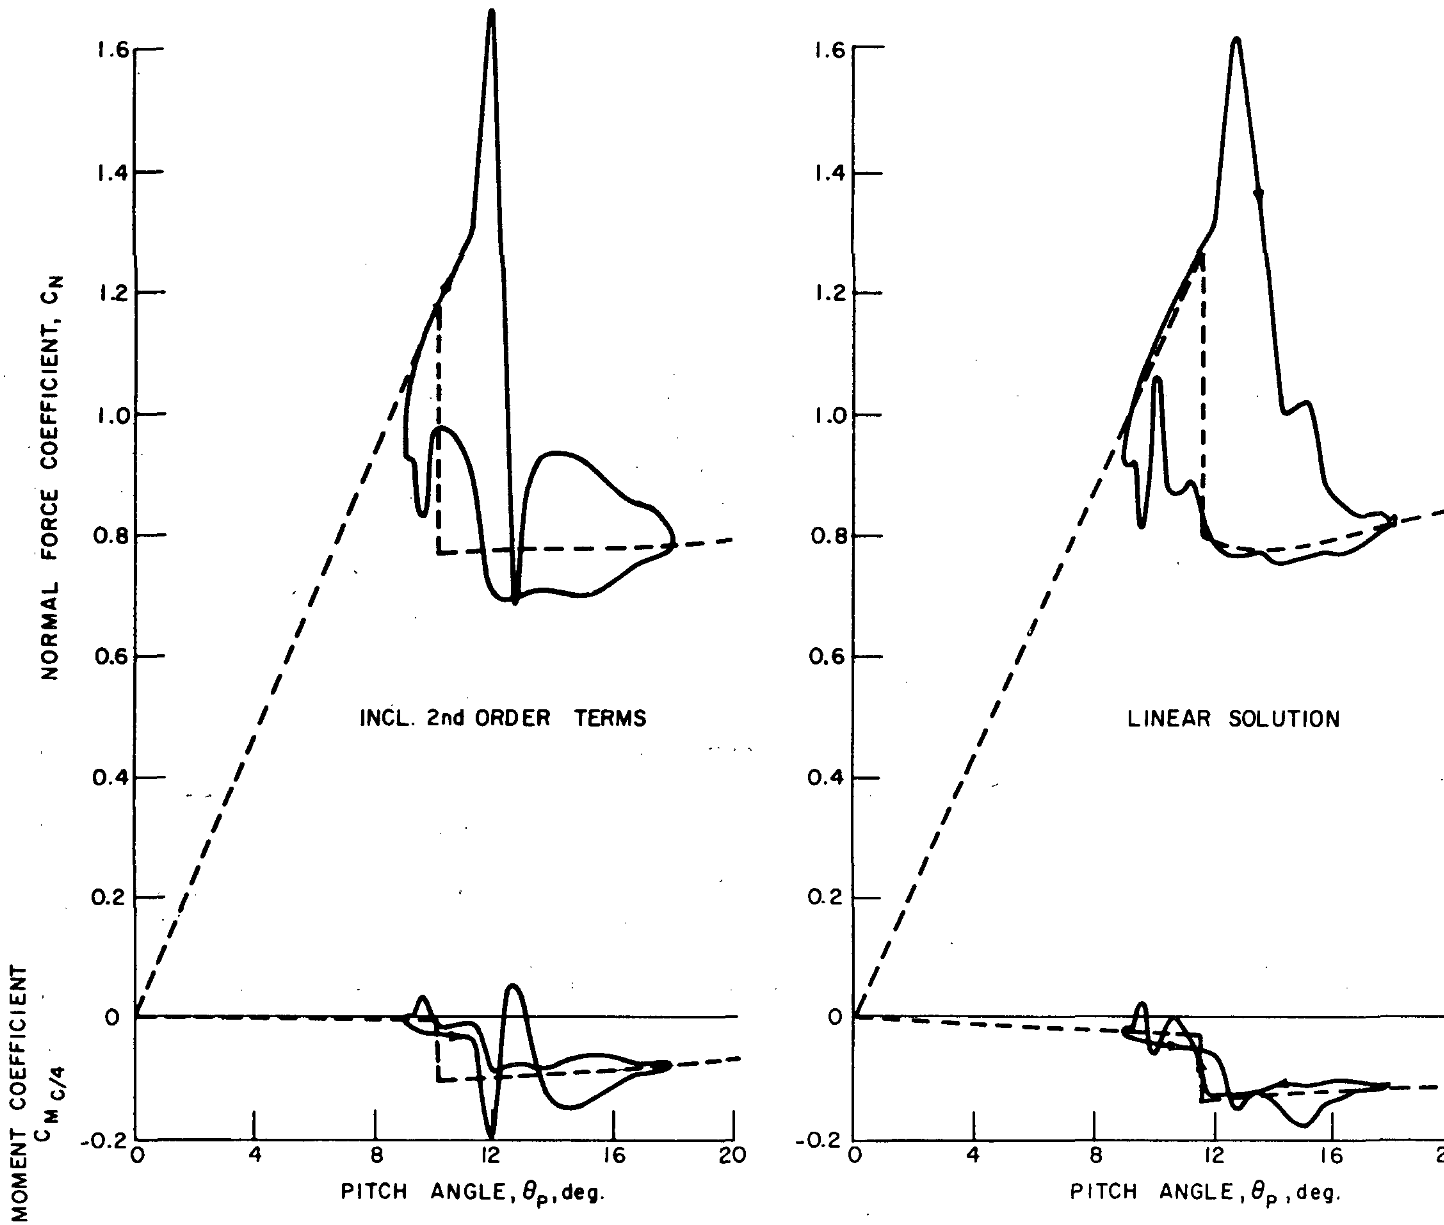

Figure 9 COMPARISON OF COMPUTED LOADINGS DURING SINUSOIDAL PITCHING, k = .26

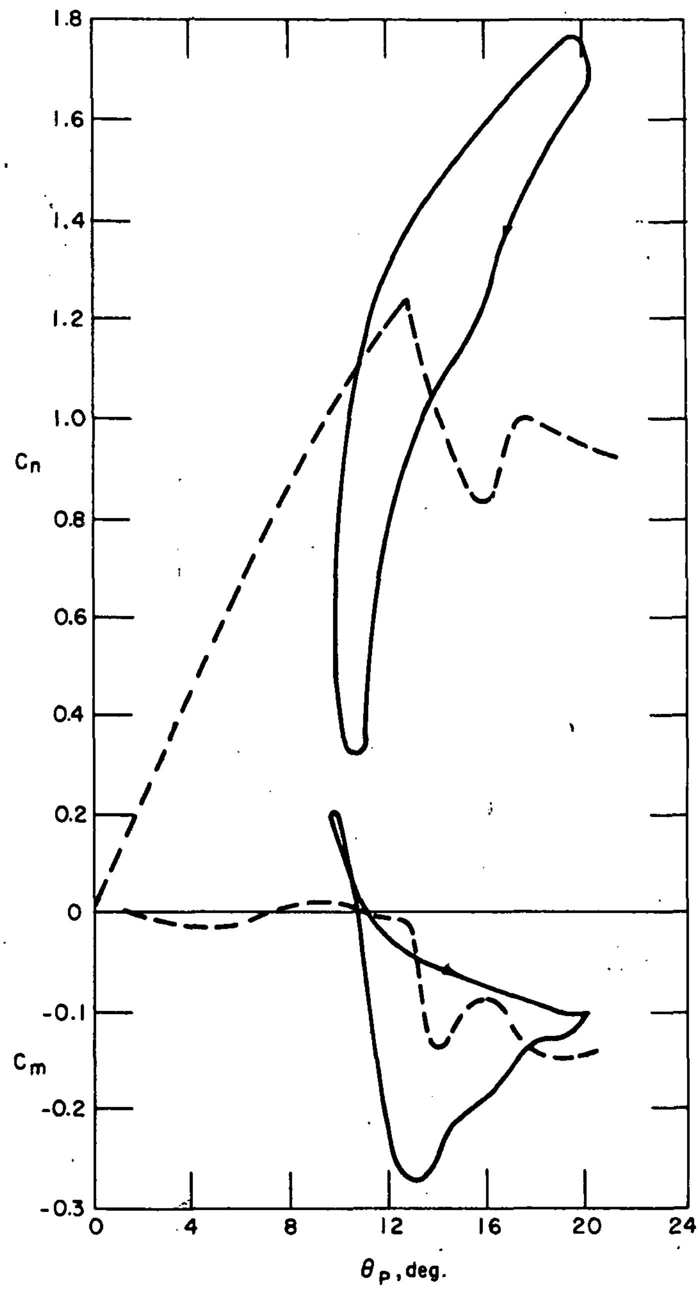

Figure 10 MEASURED LOADING WITH k = .252 (from Ref. 2)

While a nonlinear potential-flow model improves the predicted loading somewhat, substantial quantitative differences between computed and measured results are still evident. The analysis does serve to demonstrate that the errors in the original potential-flow model were not contributing to any great extent to those differences. Attention can now be directed to other factors in improving the method, as discussed in the next section.

Effect of Dead-Air Region Growth Rate

As was noted in the previous description of the basic method, rate of growth of the dead-air region is computed from an estimate of rate of entrainment obtained from the potential-flow solution. That estimate, which is proportional to the net source strength in the dead-air region, can only be reasonably justified when the length of the dead-air region is near its steady state value. However, a value for the growth rate is needed at the onset of leading-edge stall, when the region does not yet extend beyond the trailing edge, and is much less than its steady-state length of between two and three chords. It was beyond the scope of the original study to attempt a definitive analysis of this complex unsteady interaction of viscous and inviscid flows, so the growth rate was arbitrarily made equal to the free stream speed at the onset of leading-edge stall.

Subsequent calculations revealed, though, that one of the factors contributing to lift overshoot is an increment in lift induced on the aft portion of the airfoil when the dead-air region still terminates upstream of the trailing edge. This effect is discussed in more detail in Ref. 6. It would appear, then, that if the initial growth rate of the dead-air region were reduced, more overshoot would result.

A series of transient pitch calculations were carried out, parametrically varying initial growth rate ℓ_0, to verify that this is the case. The loading time histories obtained are shown in Fig. 11. As expected, the overshoot in C_n is increased substantially by reducing ℓ_0. The time to reach steady state is, of course, increased as well.

The greatest differences between computed and measured loading during oscillatory pitch are the amount of lift overshoot and the amounts of lift and moment hysteresis. It would appear, then, that considerable improvement in the agreement would result if ℓ_0 were reduced. The following arguments are put forth as justification for doing that.

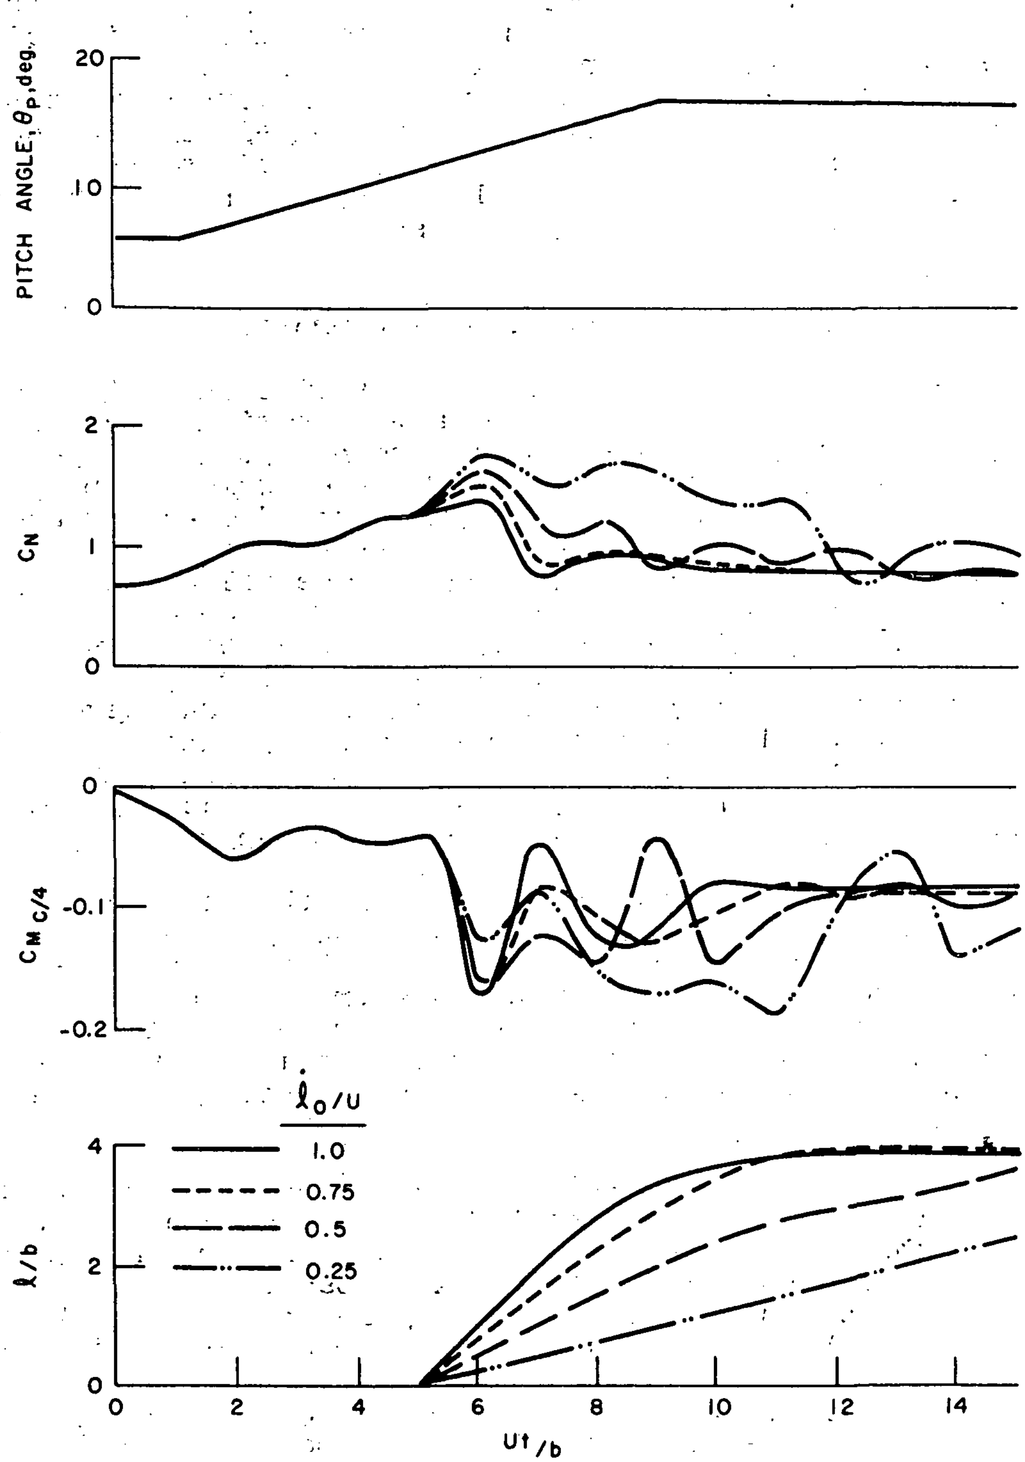

Figure 11 EFFECT OF $\dot{\ell}_0$ ON LOADING DURING TRANSIENT PITCHING

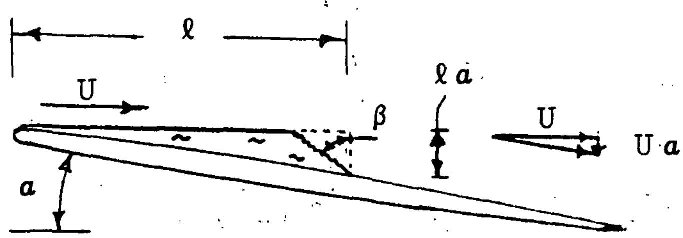
The dead-air region consists of fluid garnered from the free stream by the combined action of viscous shear (mostly turbulent, probably) and pressure gradients. Let it be assumed that this assimilation of fluid mass takes place primarily at the downstream end of the dead-air region, and that the fluid is trapped in the funnel-shaped region subtending an angle β, as sketched below (lengths and velocities shown are approximate, assuming angle of attack α is small).



Let f be the fraction of fluid entering the funnel which ultimately becomes part of the dead-air region. Then the rate of increase of the mass of trapped air is given, approximately, by

$$\dot{m} = f \left[\rho (\ell\alpha \tan \beta)(U \alpha) \right]$$

But $\dot{m}$ is proportional to the rate of increase of area; $\dot{m} \approx \rho \ell \dot{\ell} \alpha$. Equating the two rates, it follows that

$$\dot{\ell} \approx (f \tan \beta) U \alpha$$

Thus, if $f \tan \beta$ is a number of order one, or less, $\dot{\ell}_o$ is of the order of $U\alpha$, rather than U.

Convincing evidence that $\dot{\ell}_o$ must be substantially less than U was obtained by recomputing the loading for oscillatory pitching with k = .13, using a value of .25U for $\dot{\ell}_o$. Presumably the process of unstall, in which the free stream recaptures the fluid in the dead-air region, is similar to that of stall onset, so the rate of wash-off of the dead-air region during unstall was also reduced from U to .25U. The resulting curves of C_n and $C_{m\,c/4}$ vs. pitch angle are shown in Fig. 12. The computed variation of C_n

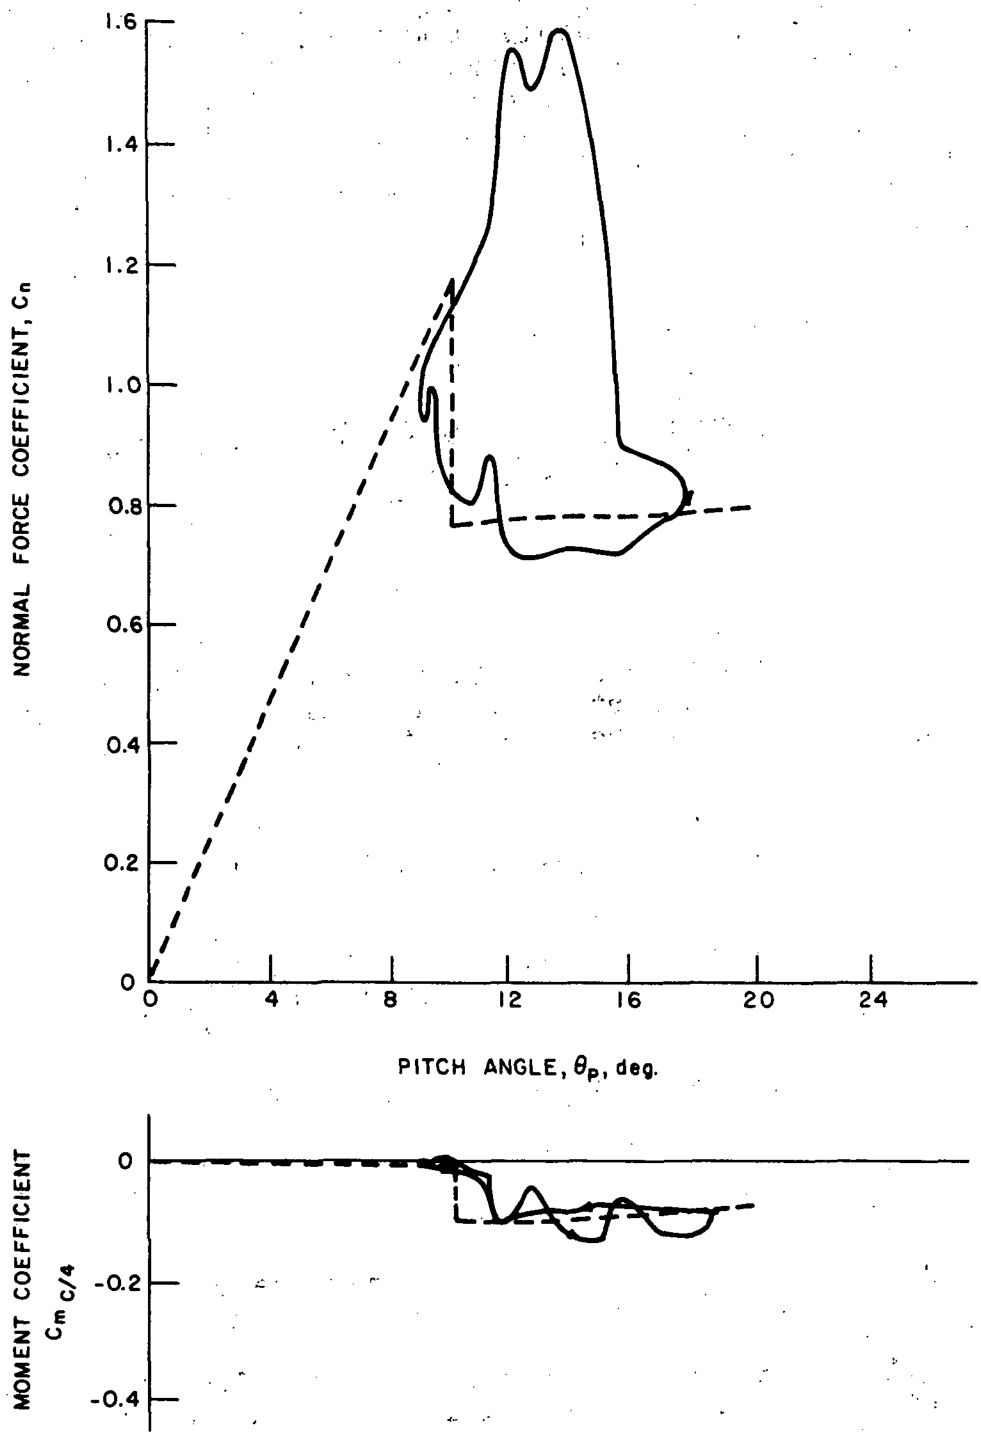


Figure 12 COMPUTED LOADING DURING SINUSOIDAL PITCHING
WITH ℓ_0 = .25 U AND k = .13

is now seen to be in quite good agreement with the measured loading, Fig. 8. Maximum normal force is predicted almost exactly, and the areas within the loops are roughly the same. The moment variations still differ appreciably, the main discrepancy being between when the airfoil starts pitching down and where unstall begins. There is apparently considerably more suction over the aft portion of the airfoil in the dead-air region than what is predicted. The assumption of quasi-steady flow in the dead-air region is the most likely cause for this difference.

The load during oscillatory pitching with $\dot{\ell}_o$ and wash-off rate of .25U was also computed for k = .26, with the results shown in Fig. 13. Again, the agreement with the measured loading, Fig. 10, is much improved, the peak C_n computed being 1.88 while the measured maximum is 1.77. The inadequacy in the model of the dead-air region with θ_p decreasing is also evident at the higher frequency.

It might be conjectured that the wash-off rate should be less than the initial growth rate of the dead-air region, since reentrainment presumably is dominated by viscous shear, rather than pressure gradients. Therefore, the effect of changing the ratio of $\dot{\ell}_o$ to wash-off rate was investigated by repeating the oscillatory pitching calculations using a wash-off rate of .1U, with $\dot{\ell}_o$ again being .25U. The results for k of .13 and .26 are shown in Figs. 14 and 15, respectively. The loading variation is seen to be quite insensitive to wash-off rate, regardless of the reduced frequency or the value of $\dot{\ell}_o$, so making it equal to $\dot{\ell}_o$ would appear to be a reasonable approximation.

Effect of Reynolds Number on Stall Characteristics

Stall characteristics of a given airfoil are necessarily a function of Reynolds number, because of the role played by the boundary layer in the stall process. Specifically, one would expect that an airfoil which is subject to leading-edge stall at a certain Reynolds number would undergo trailing-edge stall at a much higher Reynolds number, since transition would then preclude formation of a leading-edge bubble. At intermediate Reynolds numbers, presumably either type of stall could occur. Calculations were performed to investigate the effect of varying Reynolds number on dynamic and static stall characteristics in this intermediate range of Reynolds numbers.

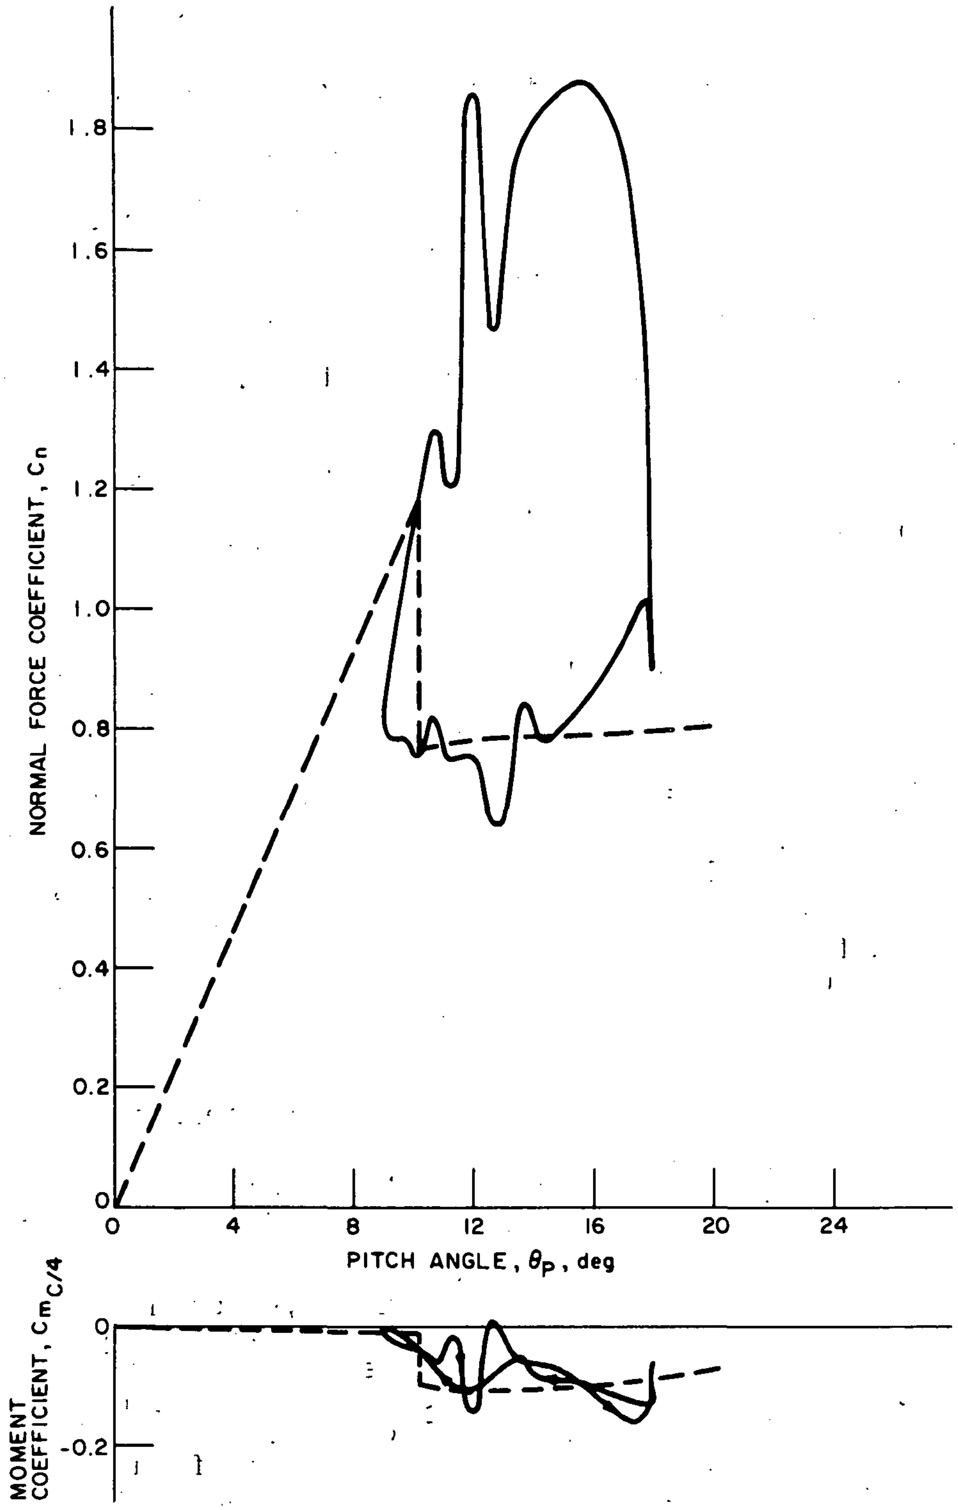

Figure 13 COMPUTED LOADING DURING SINUSOIDAL PITCHING WITH $\dot{\ell}_o = 0.25U$ AND $k = 0.26$

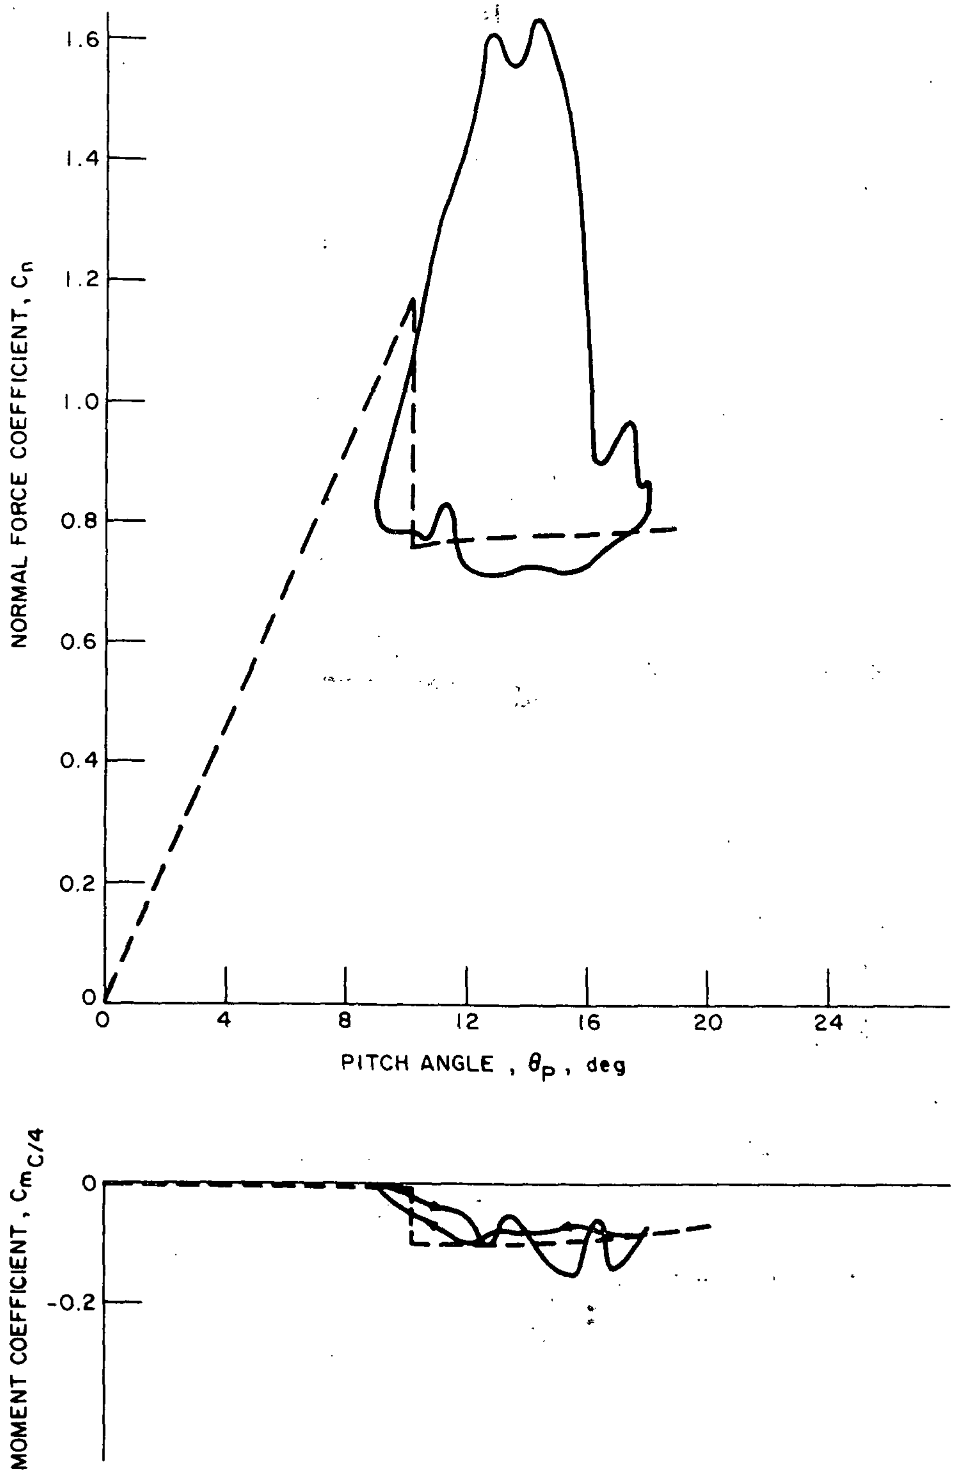

Figure 14 COMPUTED LOADING DURING SINUSOIDAL PITCHING WITH WASH-OFF RATE OF 0.1U, $\dot{\ell}_o$ = 0.25U, k = 0.13

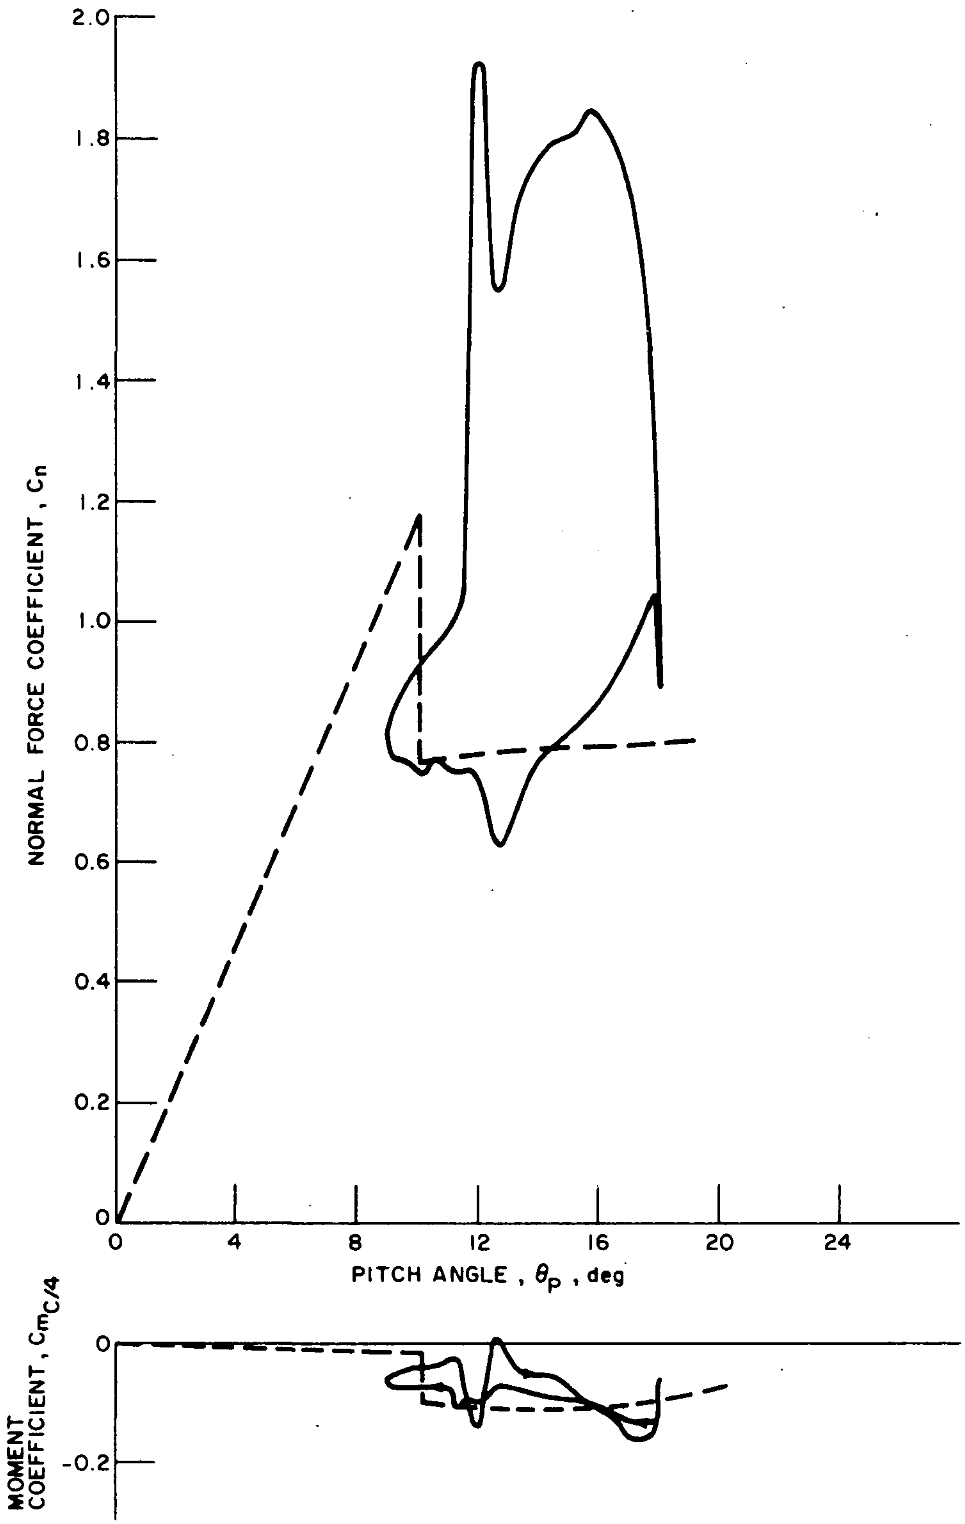

Figure 15 COMPUTED LOADING DURING SINUSOIDAL PITCHING WITH WASH-OFF RATE OF 0.1U, $\dot{\ell}_o$ = 0.25U, k = 0.26

The loading resulting from transient pitching through stall was analyzed for chordal Reynolds numbers of 3 and 6 million, for comparison with the previous results obtained at a Reynolds number of 2 million. Pitch angle was again varied linearly with time up to a prescribed value and then held constant.

Increasing Reynolds number to 3 million caused a marked increase in the resistance to bursting of the leading-edge bubble. The airfoil does not undergo leading-edge stall for pitch angles as high as about 16 degrees, but does experience trailing-edge stall between about 12 and 16 degrees. At a steady-state pitch angle of 15.8 degrees, separation of the turbulent boundary layer has progressed upstream to near the quarter-chord point.

An interesting phenomenon is encountered during pitching through higher angles. As the separation point of the turbulent boundary layer moves up the chord, the resistance of the leading-edge bubble to bursting continuously decreases, even though the circulation and loading on the airfoil are decreasing as well. The reason for this is that the separated region has relatively little effect on the flow in the immediate vicinity of the leading edge, even though it reduces the loading over the rest of the airfoil. At a sufficiently high incidence, the bubble bursts and leading-edge stall ensues. Results for a case in which both trailing-edge and leading-edge stall occur are shown in Fig. 16, where the loading and the separation point location x_s are plotted against time for pitching up to 18 degrees. Note that very little C_n overshoot is predicted in this case.

As expected, a further increase in Reynolds number to 6×10^6 increases the resistance to both leading-edge and trailing-edge stall. When the steady-state pitch angle is 15.8 degrees, the separation point is only about .1c from the trailing edge. At a slightly larger pitch angle, that point moves rapidly up the chord. Figure 17 shows the loading and x_s variations with time for pitching up to 16.3 degrees. The steady-state separation point is seen to be about .35c from the leading edge in this case. No C_n overshoot at all is predicted for this case.

Leading-edge stall ultimately occurs at high pitch angles for $Re_c = 6 \times 10^6$, as well, but the separation point of the turbulent boundary layer very nearly encroaches on the leading-edge bubble before the bubble bursts. The distance separating them is only about .01c.

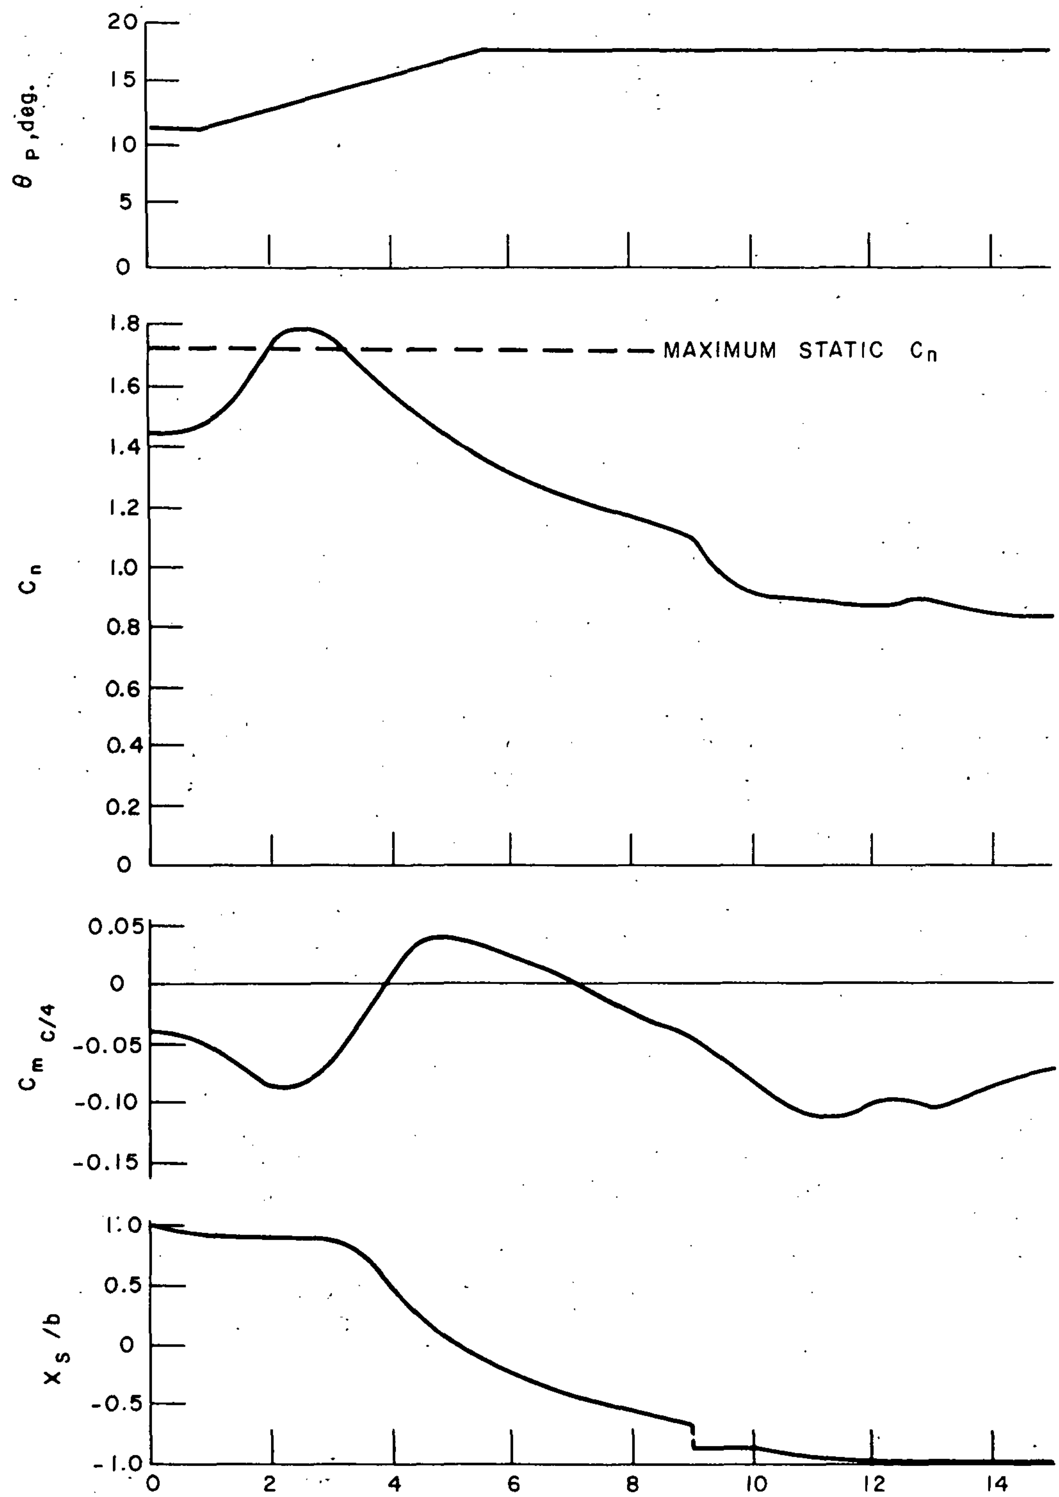

Figure 16 LOADING AND X_s VARIATION DURING TRANSIENT PITCH, $Re_c = 3 \times 10^6$

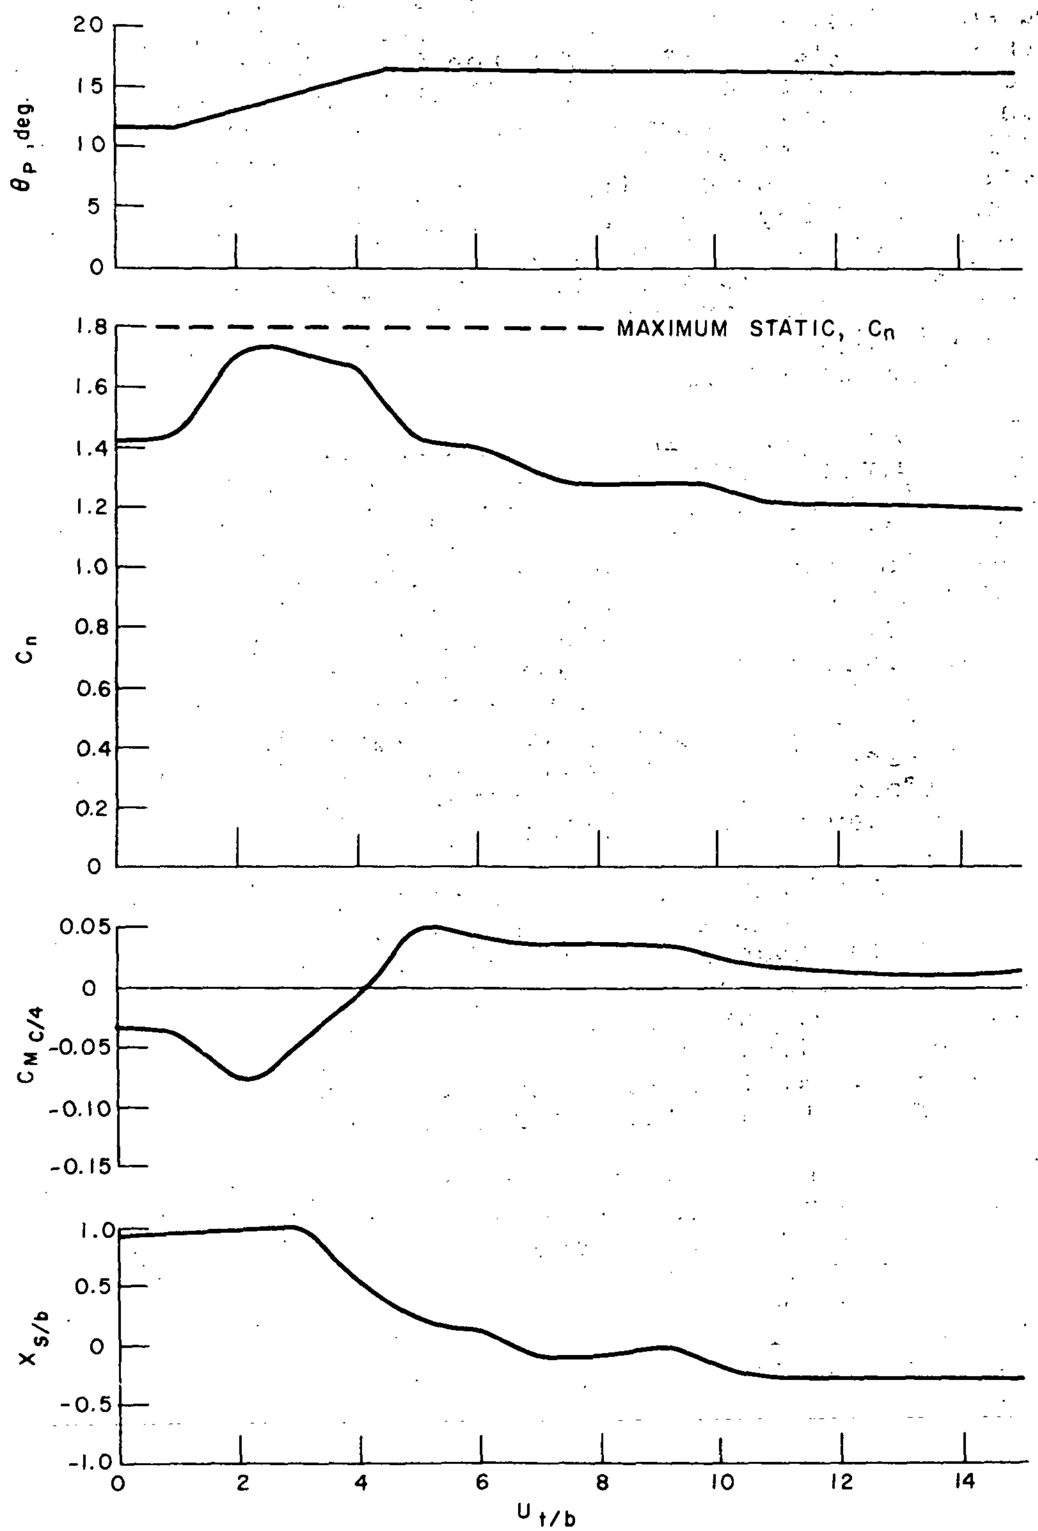

Figure 17 LOADING AND X_s VARIATION DURING TRANSIENT PITCH, $Re_c = 6 \times 10^6$

Results are summarized in Fig. 18, which shows the computed variation of static normal-force and moment coefficients with angle of attack for the three Reynolds numbers considered. A flagged symbol indicates that the airfoil was undergoing trailing-edge stall. Results of measurements for different Reynolds numbers for the section analyzed are not available. However, data in Ref. 13 show that a regular 0012 section at Reynolds numbers between 3 and 6 million has a maximum lift coefficient of about 1.6, generated at an angle of attack of 16 degrees, which agrees fairly well with the computed values of maximum C_n of 1.7 at $Re_c = 3 \times 10^6$ and 1.8 with $Re_c = 6 \times 10^6$, also occurring at about 16 degrees angle of attack.

The rapid falloff in normal force with angle of attack at higher Reynolds numbers is quite different from the behavior of thicker airfoils undergoing trailing-edge stall, the falloff in the latter case being more gradual (see Ref. 14). The reason for the sharp drop-off is apparently that the pressure rise is quite steep near the leading-edge, but relatively flat aft of midchord. Thus, the separation point moves rapidly forward, once incipient separation occurs, until it encounters the region of steep gradients near midchord (note the variation of x_s in Figs. 16 and 17). On thicker airfoils, the pressure increase along the chord is more uniform, allowing the separation point to stabilize at points closer to the trailing edge.

One case of sinusoidal pitching through stall was analyzed with $Re_c = 6 \times 10^6$ and $k = .13$. The C_n and $C_{m\ c/4}$ variations with pitch angle are shown in Fig. 19. Only trailing edge stall occurred during the cycle. As can be seen from Fig. 19, the normal force did not exceed the maximum static value. The moment variation exhibits a fairly large unstable (i.e., clockwise) loop, and the moment undergoes rather large positive excursions.

Since no direct determination of the type of stall has been made in the tests carried out to date, it is not clear whether the lack of lift overshoot in the calculations is symptomatic of trailing-edge stall or is an indication of an inadequacy in the analytic model. If the latter is the case, the most likely source of the problem would seem to be, again, the assumption of quasi-steady flow in the dead-air region.

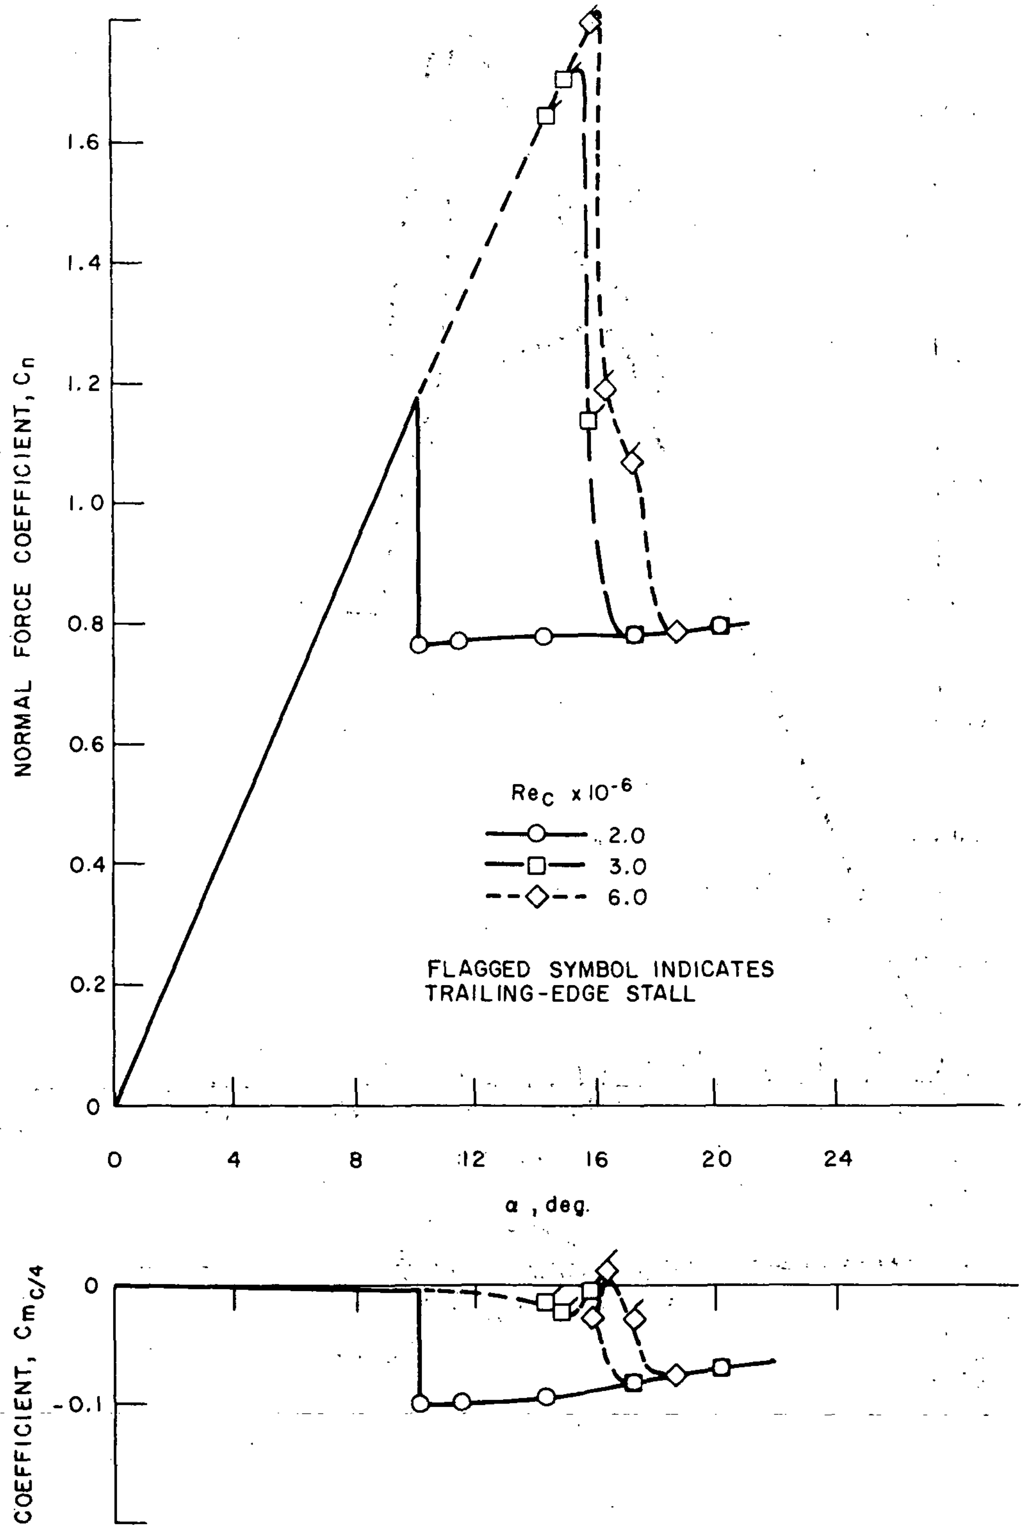

Figure 18 COMPUTED STATIC NORMAL-FORCE AND MOMENT COEFFICIENTS

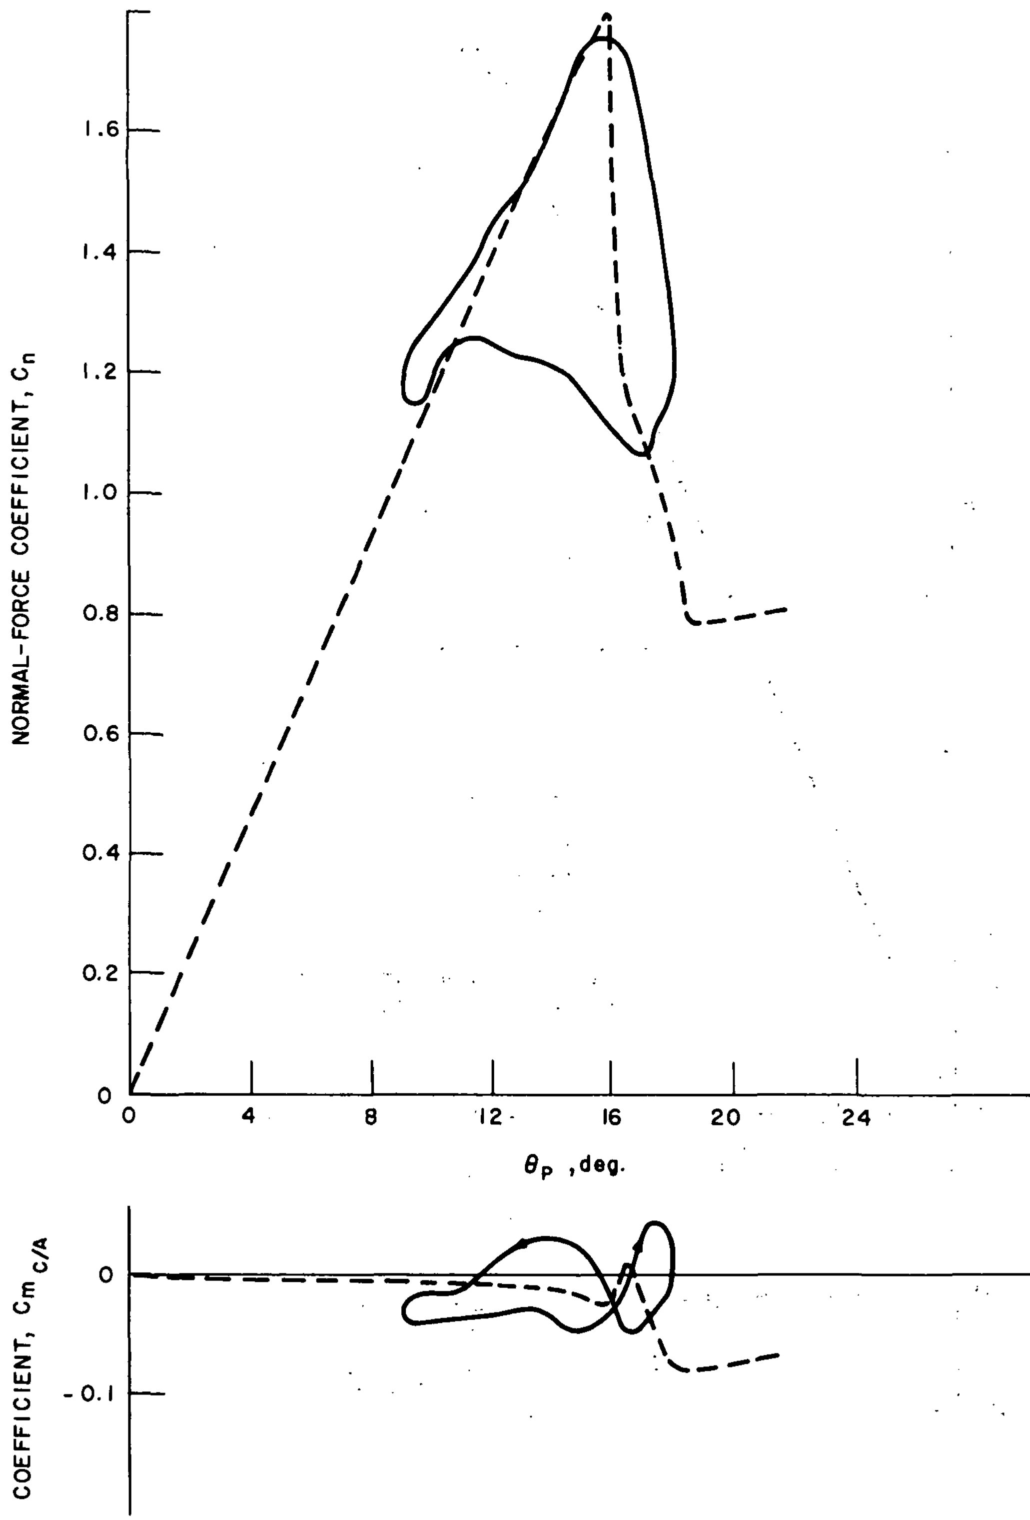

Figure 19 COMPUTED LOADING DURING SINUSOIDAL PITCHING,
k = .13, $Re_c = 6 \times 10^6$

CONCLUDING REMARKS

The representation of the potential flow in a previously developed method for analyzing dynamic stall has been refined by including second-order terms. The effects of growth rate of the dead-air region during leading-edge stall and the effect of Reynolds number on stall characteristics were also investigated. Results can be summarized as follows.

Including second-order terms improves the representation of the flow and chordwise pressure distribution on the airfoil below stall, but does not appreciably reduce the large quantitative differences between computed and measured results for sinusoidal pitching through stall.

The amount of lift overshoot during dynamic stall is a strong function of the rate of growth of the dead-air region at the onset of leading-edge stall. Much improved agreement between theory and test with a smaller growth rate indicates that the growth rate is of the order of the component of the free stream normal to the airfoil chord, but further analytical and experimental study of the stall onset process is needed. In contrast to the strong dependence on growth rate, the loading is quite insensitive to the rate at which the dead-air region is washed off during unstall.

The method predicts an increase in the resistance to both leading-edge and trailing-edge stall with increasing Reynolds number, as expected. Computations indicate that a given airfoil can undergo both trailing-edge and leading-edge stall under unsteady conditions at high Reynolds numbers, and that dynamic lift overshoot is much less when trailing-edge stall occurs. The latter effect may be due to the assumption of quasi-steady flow in the dead-air region.

"The aeronautical and space activities of the United States shall be conducted so as to contribute . . . to the expansion of human knowledge of phenomena in the atmosphere and space. The Administration shall provide for the widest practicable and appropriate dissemination of information concerning its activities and the results thereof."

—NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

TECHNICAL NOTES: Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

TECHNICAL MEMORANDUMS: Information receiving limited distribution because of preliminary data, security classification, or other reasons. Also includes conference proceedings with either limited or unlimited distribution.

CONTRACTOR REPORTS: Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information published in a foreign language considered to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information derived from or of value to NASA activities. Publications include final reports of major projects, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

TECHNOLOGY UTILIZATION PUBLICATIONS: Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Technology Surveys.

Details on the availability of these publications may be obtained from:
