# Video-assisted thoracoscopic muscle transposition for acute empyema

Hideyuki Maeda, Masato Kanzaki\*, Takuma Kikkawa and Takamasa Onuki

## Abstract

Muscle flap transposition is one of the surgical treatment options for empyema with alveolarpleural fistula (APF) or bronchopleural fistula (BPF). This surgical procedure is invasive because it is typically performed by standard thoracotomy. We performed video-assisted thoracoscopic surgery (VATS) debridement, decortication, and obliteration of an empyema cavity using a pedicled latissimus dorsi muscle (LDM) flap harvested through minimal skin incisions for a case of acute empyema with APF. This VATS procedure is effective and less invasive and can be a new option for the thoracoscopic surgical treatment of acute empyema with APF.

**Keywords:** Acute empyema, Alveolarpleural fistula, Video-assisted thoracoscopic surgery

## Background

Muscle flap transposition, a surgical procedure used to reduce the empyema cavity, aims for complete cure by closing fistula and filling dead space. The latissimus dorsi muscle (LDM) flap is the largest well-vascularized muscle flap. When the LDM is harvested by traditional thoracotomy, an extensive skin incision is required. We report a novel approach to harvest the LDM flap through minimal skin incisions by video-assisted thoracic surgery (VATS). Debridement, decortication, and pedicled LDM flap transposition for empyema with alveolarpleural fistula (APF) can be accomplished using this less invasive method.

## Case presentation

A 71-year-old man with diabetes mellitus type 2 taking oral hypoglycemic agents was diagnosed with acute empyema. He was admitted to a hospital where chest tube drainage and antibiotics were commenced soon after admission. *Streptococcus pneumoniae* was detected in the pleural effusion culture. Although his inflammatory status improved after conservative treatment, an air leak from the chest tube continued and he was subsequently transferred to our hospital. Preoperative chest computed tomography (CT) showed a thickened visceral pleura and an APF covered with a bulla (Fig. 1).

## Surgical technique

The patient was anesthetized with general anesthesia, intubated with a double-lumen endotracheal tube intubation, and placed in a left lateral decubitus position. A 5-cm vertical skin incision in front of the anterior edge of the LDM at the third to fourth rib, a 3-cm skin incision at sixth rib and a 5-cm skin incision at the ninth intercostal space were made (Fig. 2a). The LDM was accessed, divided from the lower part to the upper part along the muscle fiber, and half of the muscle was eventually harvested (Fig. 2b). A mini-thoracotomy was performed at the third and sixth intercostal spaces, XXS size wound retractors (Alexis® Wound Retractor, Applied Medical, Rancho Santa Margarita, CA, USA) were placed at both places, and a 30°, 10-mm thoracoscope was inserted. A thickened peel was found covering the lung. The clinical phase was fibrinopurulent (Stage II). The APF covered with a bulla was identified beneath the third intercostal space (Fig. 3a). Bubbles from the fistula were recognized while checking for air leaks. The bulla was dissected, and the bed around the fistula was debrided (Fig. 3b). Direct suturing with a 3-0 polybutester (Vascufil™, Covidien, Dublin, Ireland) was used to close the fistula. After confirming that the air leak had disappeared, a polyglycolic acid (PGA) sheet (NEOVEIL®, Gunze, Kyoto, Tokyo) was attached to cover the fistula and the surrounding pleural defect area. Fibrin glue (Bol-heal®, Kaketsuken, Kumamoto, Japan) was applied to the covered surface, and VATS debridement and decortication

was then performed. The empyema cavity was flushed with warm saline and nine 3-0 polybutester sutures were placed at the edge of the area covered with the PGA sheet to fix the LDM flap under thoracoscopic view. The sutures were placed on the LDM outside the pleural cavity, and tied inside the pleural cavity after the LDM flap was transposed to the empyema cavity through the mini-thoracotomy at the third intercostal

space (Fig. 3c, 3d). A 21-Fr chest tube was inserted, and the wounds were closed in layers.

There was no postoperative air leak, and postoperative pleural effusion culture was negative. The chest tube was removed on the eighth postoperative day, and the patient was discharged on the tenth postoperative day. He has remained well with no signs of APF recurrence (Fig. 4).

**Discussion**

For the management of acute empyema, treatment is primarily based on adequate antibiotic use and proper drainage of the pleural cavity [1, 2]. Previous reports have suggested VATS debridement and decortication as effective and less invasive for patients with acute empyema who are typically in a bad general condition [3, 4]. If acute empyema occurs with APF or BPF, the duration of drainage is prolonged, and some cases progress to chronic empyema. Treatment of empyema with APF or BPF is often complicated. Some cases cannot be treated with a one-stage operation, and a window thoracostomy followed by muscle transposition and thoracoplasty is often needed. Therefore, development of an adequate treatment strategy is required. For our case, we opted for a one-stage VATS debridement, decortications, and obliteration of the empyema cavity using a LDM flap. One-stage operation should be considered for some reasons. First, one-stage operation is beneficial for noncompliant or high-risk patients because the management of such patients with chest drain will be often difficult in outpatients care. In this case, our patient had diabetes mellitus, and he had high risk of recurrence of APF. Second, if initial treatment of at early stage of acute

empyema result in failure, or is too late, the nutritional status of the patient will worsen, and it leads to decrease of muscle bulk. It may affect the outcome of the future muscle transposition because small muscle flap cannot fill the space in the pleural cavity.

VATS allowed us to harvest a sufficient amount of the pedicled LDM flap through three small skin incisions. Although we harvested only half of the LDM, in this case it was enough to obliterate the pleural cavity, because the dead space in the pleural cavity shown in the preoperative chest CT was not large space. It is possible to harvest a more extensive muscle flap if necessary. Therefore, this operative method can be an option of

treatment for patients with empyema with APF or BPF which has a solid and large space in the pleural cavity requires to be filled with large amount of muscle, or has a large parenchymal leak which cannot be sorted by direct closure or intercostal muscle flap. Transposing muscle flap through mini-thoracotomy can be easily and safely performed with excellent visualization using the thoracoscope. We used a PGA sheet to reinforce the closed APF. Although Tsai *et al.* reported the use of bovine pericardium [5], we prefer bio-absorbable material because infection due to foreign body exposure is a concern. In addition, adhesion between the muscle flap and the APF is expected using a PGA sheet.

**Fig. 4** Chest computed tomography image after six months shows right lung expansion and no residual space in the thoracic cavity

## Conclusions

Thoracoscopic surgical treatment for empyema with APF is effective and less invasive than standard thoracotomy. VATS can provide a new treatment option in such cases. Nevertheless, more comparisons with conventional open thoracotomy procedures are needed.

## Consent

Written informed consent was obtained from the patient for publication of this Case report and any accompanying images. A copy of the written consent is available for review by the Editor-in Chief of this journal.

## Abbreviations

APF: Alveolarpleural fistula; BPF: Bronchopleural fistula; VATS: Video-assisted thoracoscopic surgery; LDM: Latissimus dorsi muscle; CT: Computed tomography; PGA: polyglycolic acid.
