ABSTRACT

We have monitored a type II outburst of the Be/X-ray binary MXB 0656–072 in a series of pointed *RXTE* observations during October through December 2003. The source spectrum shows a cyclotron resonance scattering feature at $32.8^{+0.5}_{-0.4}$ keV, corresponding to a magnetic field strength of $3.67^{+0.06}_{-0.04} \times 10^{12}$ G and is stable through the outburst and over the pulsar spin phase. The pulsar, with an average pulse period of 160.4 ± 0.4 s, shows a spin-up of 0.45 s over the duration of the outburst. From optical data, the source distance is estimated to be 3.9 ± 0.1 kpc and this is used to estimate the X-ray luminosity and a theoretical prediction of the pulsar spin-up during the outburst.

Key words. X-rays: stars – stars: magnetic fields – stars: pulsars: individual: MXB 0656–072

1. Introduction

MXB 0656–072 was first classified as a transient source by Clark et al. (1975) when detected at 80 mCrab on 1975 September 20 by *SAS-3*. Subsequently *Ariel V* observed the source at 50 and 70 mCrab on 1976 March 19 and 27 respectively (Kaluziński 1976). Kaluziński's comments that MXB 0656–072 may more closely resemble a long term variable source as opposed to a transient possibly led to it being classified as a Low Mass X-ray Binary in the catalogue of Liu et al. (2001).

The source, which has been dormant and unobserved since 1975/1976, made a reappearance in the X-ray sky in a large, extended outburst during 2003 October. During this outburst, which lasted over 2 months and reached an X-ray luminosity of 200 mCrab, it was identified as a pulsating X-ray binary with a pulse period of 160.7 s (Morgan et al. 2003) and with an optical counterpart of spectral type O9.7Ve (Pakull et al. 2003), re-categorising it as a High Mass X-ray Binary. Time-resolved *B* and *R* photometry (Bartolini et al. 2005) of the optical counterpart during this outburst revealed no optical periodicity at the X-ray pulse period. Orbital parameters of the system remain undetermined.

Preliminary analysis of the phase averaged spectrum by Heindl et al. (2003) showed that the continuum could be fit with a power law with an exponential cutoff. A cyclotron

resonant scattering feature with a centroid energy of 36 ± 1 keV was discovered by Heindl et al. (2003).

The strong magnetic fields found near the polar caps of neutron stars quantise the ambient electron energies into Landau levels. Photons at these resonant electron energies are scattered, creating cyclotron resonant scattering features (CRSFs) in the observed spectrum. The energy of the fundamental CRSF is approximated by:

$$E_C \simeq 11.6 \text{ keV} \times \frac{1}{1+z} \times \frac{B}{10^{12} \text{ G}} \quad (1)$$

where z is the gravitational redshift and B the magnetic field strength. Thus measuring the energy of cyclotron features in the spectra of accreting X-ray binaries gives us a direct measurement of the magnetic field of the neutron star.

2. Data reduction

MXB 0656–072 was observed with *RXTE* during 2003 October through 2004 January. Observations coincided with a Type II (Stella et al. 1986) X-ray outburst and data were accumulated during both the rise and decline of the outburst. In total, the *PCA* livetime for this set of observations amounts to 95 ks. Figure 1 shows the MXB 0656–072 lightcurve from the All Sky Monitor (*ASM*) aboard *RXTE*

Fig. 1. The ASM lightcurve of MXB 0656–072 during the 2003 outburst with bin sizes of 1 day. Triangles indicate the dates of pointed *RXTE* observations. The arrows indicate the dates at which spectra were compared with each other in order to observe any spectral evolution over the outburst. This is further discussed in Sect. 3.2.

during the outburst. Triangles indicate the dates of pointed *RXTE* observations.

While *Standard2f* mode *PCA* data (with 16 s time resolution and 128 channel energy resolution) were employed to generate phase averaged spectra, the phase resolved spectra and timing results were obtained from observation-specific binned-mode data with a temporal resolution of 250 ms and an energy resolution of 128 channels.

Analysis was performed with *HEASOFT* version 5.3.1 and spectral fitting with *XSPEC* version 11.3.1t. Phase resolved spectra were created using a modified version of the *FTOOL fsebin* developed at the University of Tübingen (Kreykenbohm 2004).

For spectral fitting, *PCA* data (Jahoda et al. 2006) in the energy range 3–22 keV were used, to which we added systematic errors of 0.5%. Below and above this range the systematic errors required are larger to account for the uncertainties in the *PCA* response matrix, so we ignored data outside the 3–22 keV range.

For all spectra we used the *E_8μs_256_DX1F* mode *HEXTE* data (Rothschild et al. 1998), which have a temporal resolution of 8 μs and covers the range 0–250 keV with 256 spectral channels. Electronic thresholds limit the *HEXTE* energy range to 15–250 keV. In all cases, the signal-to-noise ratio was increased by adding together the data from both clusters and generating a new response file with weights 1:0.75 to account for the loss of signal from one of the detectors in the second *HEXTE* cluster. A binning factor of 3 was applied to data in the 70–200 keV range to improve statistical significance of model fitting while still maintaining a reasonable energy resolution. Data above 200 keV were not used.

3. Phase averaged analysis

For the phase averaged spectral analysis, the spectra from all observations through the peak of the outburst (from MJD 52932 to MJD 52964) were added together in an effort to maximise the signal-to-noise ratio.

3.1. Spectral model

In accreting X-ray pulsars the highly ionised accretion stream is channelled onto one or both of the magnetic poles of the neutron star by its strong ($B \sim 10^{12}$ G) magnetic field. Depending on the accretion rate and the strength of the magnetic field, an accretion shock may form. The continuum spectral shape is dominated by Comptonisation of photons by the accretion stream at the magnetic poles. As a comprehensive theoretical spectral model is unavailable, the spectrum is generally modelled as an exponentially cutoff power law, but see Tanaka (1986) for the choice of a Fermi-Dirac Cut Off (FDCO) model or Mihara (1995) for the NPEX model. In addition to this continuum we may observe photoelectric absorption by the accretion stream or stellar wind, an Fe $K\alpha$ fluorescence line and one or more cyclotron resonance scattering features.

In our analysis we describe the continuum using a power law with photon index Γ , with a high energy cutoff at E_{cut} .

$$I_{\text{cont}}(E) = KE^{-\Gamma} \times \begin{cases} 1 & (E \leq E_{\text{cut}}) \\ e^{-(E-E_{\text{cut}})/E_{\text{fold}}} & (E > E_{\text{cut}}). \end{cases} \quad (2)$$

The energy cutoff is smoothed by including a Gaussian absorption line (*gsmooth* in *XSPEC*) with an energy dependent width, at the continuum cutoff energy. Without a smoothing function the energy cutoff forms a discontinuity in the model and this results in residuals which can easily be mistaken as arising from

Table 1. Spectral parameters (as defined in the text) for the phase averaged spectrum. The model consists of power law with a smoothed high energy cutoff, photoelectric absorption, a CYCLABS cyclotron feature, a Gaussian Fe line and a blackbody component. The flux in the Fe emission line is represented by a_{Fe} , in photons $\text{cm}^{-2} \text{s}^{-1}$. Uncertainties are at 90% confidence intervals.

Parameter	Value
N_{H}	$7.28 \times 10^{21} \text{ cm}^{-2}$
Γ	$0.89^{+0.07}_{-0.05}$
E_{cut}	$15.5^{+0.2}_{-0.2} \text{ keV}$
E_{fold}	$11.8^{+0.2}_{-0.3} \text{ keV}$
T	$0.86^{+0.08}_{-0.14} \text{ keV}$
E_{c}	$32.8^{+0.5}_{-0.4} \text{ keV}$
W_{c}	$11.8^{+1.0}_{-1.1} \text{ keV}$
D_{c}	$0.38^{+0.02}_{-0.02}$
E_{Fe}	$6.48^{+0.03}_{-0.03} \text{ keV}$
σ_{Fe}	$0.36^{+0.06}_{-0.06} \text{ keV}$
a_{Fe}	$0.0195^{+0.001}_{-0.001}$

a cyclotron feature (Kretschmar et al. 1997; Coburn 2001). Although we attempted to use the FDCO and NPEX models to describe the continuum, we found that the best-fit continuum was indeed a power law with a smoothed high-energy cutoff.

The spectral shape is insensitive to the HI column density and in order to include some estimate of the column density a value of $7.28 \times 10^{21} \text{ cm}^{-2}$ was estimated over a cone of radius 1° in the direction of the source (Dickey & Lockman 1990). The column density, N_{H} , was fixed at this value for subsequent spectral fitting.

Modifying the continuum is a CRSF modelled with the CYCLABS model, which has the analytical form shown below:

$$\text{CYCLABS}(E) = D_{\text{c}} \frac{(W_{\text{c}}E/E_{\text{c}})^2}{(E - E_{\text{c}})^2 + W_{\text{c}}^2} \quad (3)$$

where E_{c} , D_{c} and W_{c} are the cyclotron energy, depth and width respectively (Makishima et al. 1990; Mihara et al. 1990). Using other continuum models (FDCO and NPEX) did not alter the presence of the cyclotron feature.

We model a strong Fe $K\alpha$ fluorescence feature with a Gaussian emission line and determine the equivalent width to be 3.66 keV. In addition we include a blackbody component to account for the excess flux at the soft end of the spectrum. The blackbody component has a temperature of $0.86^{+0.08}_{-0.14} \text{ keV}$ and can be attributed to emission from an accreting polar cap, in a manner similar to Coburn et al. (2001) in the case of X Per.

The fit to the phase averaged spectrum results in $\chi_{\text{red}}^2 = 1.1$ with the spectral parameters given in Table 1. The spectrum is shown in Fig. 2.

The cyclotron feature at $32.8^{+0.5}_{-0.4} \text{ keV}$ is clearly visible in the residuals. A harmonic with width $16^{+20}_{-14} \text{ keV}$ and depth $0.19^{+0.26}_{-0.16}$ may be present at twice the fundamental energy, but detection is marginal, as can be interpreted from the uncertainties in the line parameters. Assuming that the cyclotron line at 32.8 keV is the fundamental ($n = 1$) and a gravitational

redshift of $z = 0.3$ for a typical neutron star mass of $1.4 M_{\odot}$ and radius of 10 km, we can estimate the magnetic field from Eq. (1) to be $3.67^{+0.06}_{-0.04} \times 10^{12} \text{ G}$.

Note the systematic feature in the residuals at $\sim 10 \text{ keV}$. This feature is evident in the spectra of a number of accreting X-ray binaries (GS 1843+00, Her X-1) (Coburn 2001). It has been observed in spectra accumulated by *Ginga* (Mihara 1995) and *BeppoSAX* (Santangelo et al. 1998) as well, and should be accounted for in future continuum models of accreting X-ray pulsars. A more comprehensive review of this feature can be found in Coburn (2001).

3.2. Spectral evolution over outburst

In order to determine whether there was any significant change in the spectral shape or the cyclotron feature during the outburst we compared the spectral parameters at various dates through the outburst. These dates are indicated by the arrows in Fig. 1 and further information is shown in Table 2.

Note that the fourth spectrum is obtained by adding observations over a five day range in order to have signal-to-noise ratios similar to those of the first 3 datasets. We find that, on average, the spectral fits have $\chi_{\text{red}}^2 \sim 1.2$, except for 2003 November 16–20 which has $\chi_{\text{red}}^2 = 1.7$. The power law index stays between 0.9 and 1.1 during this time and there is very little change in E_{cut} and E_{fold} , which have values close to those given in Table 1. The cyclotron parameters over this time interval are shown in Fig. 3. Noting that the error bars represent 90% uncertainty levels it is clear that the cyclotron feature is stable over the outburst.

4. Phase resolved analysis

If the rotation and magnetic axes of the neutron star are not aligned, the observer sees X-ray emission modulated by the pulsar spin period. Due to the fact that cyclotron features are strongly dependent on viewing angle, phase resolved spectroscopy is a tool well-suited to studying cyclotron features.

Pulse profiles and phase resolved spectra were generated by performing a barycentric correction of the bin times for the *PCA* data and the photon arrival times for the *HEXTE* data for two 15 ks observations at the peak of the outburst. Orbital modulation was not accounted for as the orbital ephemeris of the system is still unknown. The pulse period was determined by running a Lomb-Scargle analysis (Press & Rybicki 1989; Lomb 1976; Scargle 1982) on the barycentre-corrected lightcurves. The lightcurves were then folded at the pulse period of 160.4 s to produce the pulse profiles shown in Fig. 4.

4.1. Pulse profiles

The pulse profiles are single-peaked and sinusoidal through all energy bands and show the pulsed fraction $((F_{\text{max}} - F_{\text{min}})/F_{\text{max}})$ increasing steadily from 26% in the 2–5 keV band up to 40% in the 30–60 keV band. The pulse shape is consistent with what one would expect from viewing just a single magnetic pole radiating isotropically as a blackbody, including the effects of gravitational bending around the neutron star

Fig. 2. The spectrum of MXB 0656–072 from 3–120 keV. The crosses show the data, the smooth curve shows the unfolded spectrum and the histogram the model fit. In the second panel the residuals, plotted as $\Delta\chi^2$, are shown for the case in which no CRSF is included in the model. In the lower panel, these residuals are shown again – this time including a CRSF in the model.

Table 2. Dates and *PCA* livetimes of observations used to determine the spectral evolution over the outburst.

Date	MJD	Livetime (ks)
2003-10-20	52 933	11
2003-10-30	52 943	8
2003-11-06	52 950	15
2003-11-(16–20)	52 96(0-4)	7

Fig. 3. Cyclotron line parameters throughout the 2003 October outburst. The energy and width are in keV.

(Beloborodov 2002). The almost perfectly sinusoidal pulse shapes may indicate that there is no absorption along the accretion column, as it is believed that strong absorption along the accretion column contributes to the complexity of the pulse profile at low energies (Kreykenbohm et al. 2002; Nagase et al. 1983). The pulse profile shape and amplitude support the conclusion reached by Bulik et al. (2003): that the rotation and magnetic axes of accreting pulsars are almost aligned.

4.2. Spectral evolution over Pulse

The data were split into 5 phase bins for analysis, as shown in the topmost panel of Fig. 4. This gives us good statistics at a temporal resolution sufficient to describe this particular pulse shape. Evolution of the spectral parameters with phase is shown in Fig. 5.

For the phase resolved spectra, we used the same model as in Sect. 3.1, however the addition of a blackbody component did not significantly improve the fit, so was not included. Furthermore, a Gaussian absorption component at ~ 10 keV was required to take account of the systematic feature at this wavelength, mentioned in Sect. 3.1.

The cyclotron feature at energy around 32 keV is present through all pulse phases. There are, however, variations in the cyclotron line width. In general, the line is at its narrowest (6^{+3}_{-5} keV) in the peak rise and reaches its broadest (14^{+5}_{-3} keV) during the pulse decline (see Fig. 5.) The cyclotron line depth also shows some variation through phase, in a manner inverse to the continuum power law normalisation coefficient. However, the cyclotron feature in this source shows little variability with phase in comparison with some other sources such as Vela X-1 (Kreykenbohm et al. 2002) and GX 301-2 (Kreykenbohm et al. 2004), which show cyclotron line energy variations of a couple keV throughout the phase.

5. Discussion

5.1. Source distance

As the optical counterpart to MXB 0656–072 has been identified, we can use the optical magnitude and colour to estimate the distance to the source.

The optical counterpart has been identified as an O9.7Ve spectral type star, with an observed $B - V$ colour in the range 0.86 to 1.02 (Pakull et al. 2003) and an observed

Fig. 4. Pulse profile shown in counts s^{-1} . Profiles are plotted twice for clarity.

V -magnitude in the range 12.05 mag to 12.38 mag. For this estimate we shall assume that the variability in the V -magnitude and the $B - V$ colour is due to the circumstellar disk contributing to the V -magnitude. Hence we will use the faintest available V -magnitude value, assuming that this is when the disk is smallest, along with the corresponding bluest $B - V$ colour. We have estimated errors typical for photometry of a 12th magnitude star on a 1–2 m telescope and use $V = 12.38 \pm 0.02$ mag and $B - V = 0.86 \pm 0.03$.

Interstellar reddening is given by:

$$E(B - V) = (B - V) - (B - V)_0 \quad (4)$$

where $(B - V)_0$ is the intrinsic colour. Thus for an O9.7Ve star we expect $(B - V)_0 = -0.28$ (Wegner 1994) and an absolute magnitude of $M_V = -4.2$ mag (Zombeck 1990).

This puts the magnitude of reddening in the V -band at $A = 3.7 \pm 0.1$ mag. Knowing the apparent magnitude, the absolute magnitude and the reddening magnitude allows us to estimate the distance using:

$$D = 10^{1+(m-M-A)/5} = 3.9 \pm 0.1 \text{ kpc.} \quad (5)$$

It is most likely that the optical colour and magnitude used in this calculation were observed at time when the contribution from the Be star disk was not negligible. Hence the above distance estimate will be an underestimate.

Fig. 5. From top to bottom the power law index, the power law normalisation, the cyclotron energy, cyclotron line width and cyclotron line depth are plotted as a function of phase. Error bars indicate 90% uncertainty levels.

5.2. Spin-up trends

Accretion of material onto a pulsar is expected to transfer a significant amount of angular momentum to the neutron star. Thus an accreting X-ray pulsar undergoing an outburst is in a state where the mass (and thus momentum) transfer rate is high and one expects to observe a slight decrease in the pulse period as it is spun-up.

We have analysed all pointed *PCA* data in the 2–20 keV energy range and determined pulse periods as a function of time. Initially, to derive the pulse period, we used a Lomb-Scargle analysis (Press & Rybicki 1989). Since the resulting values had a rather high uncertainty, the method of phase connection (Deeter et al. 1981; Munro et al. 2002) was applied in a second step: average pulse profiles (with an initial period of $P = 160.4$ s) for data sets of individual *RXTE* orbits (of typical length 1 to 3 ks) were produced and phase connected by an integer number of pulse cycles. Using an improved solution for the pulse ephemeris, including \dot{P} , also the larger gaps between data sets could be uniquely bridged. The result is shown in Fig. 6. The measurements are consistent with an initial period of 160.58 s at MJD 52930 and an average spin-up until MJD 52971 of $\dot{P} = -0.0101 \pm 0.0003 \text{ s day}^{-1}$.

After MJD 52971 the accretion rate drops to a level low enough to halt spin-up of the neutron star. This is evidenced by a flattening of the slope in the pulse period vs time plot shown in Fig. 6. The data after MJD 52971 are consistent with a constant period. This levelling off of the pulse period to a constant value after MJD 52971 indicates that the pulse period changes are an effect of accretion torques rather than modulation by the orbital period of the neutron star.

Fig. 6. Pulse period as a function of time through the outburst, with a linear fit to the data.

From the average X-ray flux in the 2–10 keV band ($4.35 \times 10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}$) we can calculate the X-ray luminosity if the distance to the source is known. Using our estimate of $3.9 \pm 0.1 \text{ kpc}$ for the source distance from Sect. 5.1, the X-ray luminosity of the source is $6.6 \pm 0.4 \times 10^{36} \text{ erg s}^{-1}$. Then a straightforward application of the accretion torque model by Ghosh & Lamb (1979) (Eq. (15) with standard neutron star parameters and our own values of $B = 3.67 \times 10^{12} \text{ G}$ and $L_x = 6.6 \times 10^{36} \text{ erg s}^{-1}$) yields a spin-up rate of $\dot{P} = -0.0034 \text{ s day}^{-1}$. This is about a factor of three smaller than the observed value. We do not consider this a problem, as accreting binary pulsars very generally show a broad range of behaviour with respect to the development of their spin periods with time (for reviews see Nagase 1989 and Bildsten et al. 1997). This includes episodes of spin-up and spin-down, depending on the exact conditions of accretion at the time. For a transient in outburst such as MXB 0656-072 one would expect to observe a strong spin-up, since under the greatly increased mass accretion rate, as evidenced by the large increase in X-ray luminosity, the system will tend to be far from any equilibrium condition.

6. Summary

From analysis of the pointed *RXTE* observations of MXB 0656-072 and limited optical data available we can deduce the following:

- The X-ray spectrum continuum is best fit by a power law model with an exponential cutoff, where a Gaussian function with an energy dependent width is used to smooth discontinuities at the cutoff energy.
- A cyclotron resonance scattering feature is present at an energy of $32.8^{+0.4}_{-0.5} \text{ keV}$ and the energy is independent of the continuum model used to describe the spectrum. The CRSF is present at this energy in all observations throughout the outburst. The CRSF is present throughout the entire neutron star spin phase, but the width and depth of the feature show variation through the spin phase.
- Although there is no convincing evidence for higher harmonic cyclotron lines in this data, the possibility of a higher harmonic cannot be ruled out.

- The magnetic field inferred from the cyclotron energy (by assuming that the detected line is the fundamental CRSF) is $3.67^{+0.04}_{-0.06} \times 10^{12} \text{ G}$.
- On the basis of optical photometric data, the distance to MXB 0656-072 is estimated to be $3.9 \pm 0.1 \text{ kpc}$.
- Over the time considered, we have measured a strong spin-up (about 0.45 s in 30 days), which appears quite reasonable under the conditions observed in this high mass X-ray binary in outburst.
