Abstract

The current ATF2 Ultra-Low beta proposal was designed to achieve 20nm vertical IP beam size without considering the multipolar components of the FD magnets. In this paper we describe different scenarios that avoid the detrimental effect of these multipolar errors to the beam size at the interaction point (IP). The simplest approach consists in modifying the optics, but other solutions are studied as the introduction of super-conducting wigglers to reduce the emittance or the replacement of the normal-conducting focusing quadrupole in the Final Doublet (NC-QF1FF) with a super-conducting quadrupole one (SC-QF1FF). These are fully addressed in the paper.

INTRODUCTION

ATF2 is a test facility with the aim of testing the FFS design that has been proposed in [1]. To prove the CLIC 3TeV chromatic level, it has been proposed the ATF2 ultra-low $\beta^*$ [2] lattice in which the $\beta^*$ has been reduced by a factor of 4 with respect to the ATF2 $\beta^*$ designed one, see Tab. 1.

The ILC project and the ILC low-power [3], would also strongly benefit from this test, in particular by gaining experience in exploring larger chromaticities and facing increased tuning difficulties for this smaller beam size.

The ATF2 UL $\beta^*$ Proposal aims for a vertical beam size close to 20nm if no errors are considered. At this chromatic level, the lattice aberrations dominate the beam size at the IP. In fact, when the measured multipolar components of the current final doublet are considered in the simulations, the horizontal IP beam size ($\sigma_x^*$) increases considerably, and the vertical IP beam size ($\sigma_y^*$) suffers from a dramatic increase as the horizontal emittance $\epsilon_x$ increases. The plot in Fig. 1 shows this undesired situation.

These values of $\sigma_x^*$, $\sigma_y^*$ are obtained as rms values, however in ATF2, a beam shintake monitor (BSM) is installed at the IP in order to measure the nanometer beam, see [4]. The beam size obtained by the BSM is smaller than the RMS, because the tails are less weighted in the calculation, this effect is even more accentuated when the beam is measured fitting a Gaussian, the last method is named the core method.

The MAPCLASS code [6] is a very useful tool that allows to study the beam properties order by order. It shows that both, octupolar and dodecapolar skew components of the final doublet focusing quadrupole (QF1FF) are responsible for this behaviour, as can be seen from Fig. 1.

DIFFERENT SCENARIOS

To overcome the described problem, different solutions can be considered:

- To use super-conducting quadrupole
- To run the machine at lower horizontal emittance
- To reduce the $\beta$-function at QF1FF

Super-conducting quadrupole

The super-conducting magnet has a better performance than the normal-conducting ones, taking advantage of the...
winding construction scheme. This allows at every construction stage to measure the present components and to adapt the following windings to minimise or emphasise specific components. BNL is designing a dedicated superconducting lattice to measure the present components and to adapt the following windings to minimise or emphasise specific components. BNL is designing a dedicated superconducting quadrupole and sextupole for ATF2, see [5]. In the last measurement data, excellent results were obtained, which are summarised and compared to the normal-conducting multipole in Tab. 2.

Reducing the $\beta_x$-function at QF1FF

The strategy to design an effective lattice, is to reduce the $\beta_x$-function at QF1FF by half, thus the impact of the QF1FF multipole on the beam size is reduced. However, the horizontal beam size at the IP increases a factor $\sqrt{2}$, since a parabolic behaviour describes the $\beta$-function along the drift between the FD and the IP.

To work out the new lattice, all quadrupoles and sextupoles strengths of the Final Focus are matched using MADX and MAPCLASS-CODE to reach the new $\beta^*$ value. In order to reduce the $\sigma_y$ at the IP, no constraints are given to the $\beta, \alpha, \eta$, functions at the IP. The obtained results are presented in Fig. 4, with the new $\beta^*_y=8.3\mu m$, and $\beta^*_y=31.6\mu m$. Approximately $\sigma_y$ has been reduced 3.5 times and it is worth mentioning that also the octupolar component has been reduced. Further information can be found in [12]

TUNABILITY OF THE ULTRA-LOW $\beta^*$

As the vertical $\beta^*$-function is reduced the chromaticity rises up, therefore the tuning difficulty of the FFS increases. The tuning procedure is the process of bringing the system to its ideal performance under realistic lattice errors conditions.

A statistical study formed by a hundred of seeds of the ATF2 ultra-low $\beta^*$ has been carried out, where the following Gaussian random distribution has been assumed:

- Transverse misalignment: 30 $\mu m$ to all magnets.
- Tilt: 50 $\mu rad$ for the final doublet magnets.
- 300 $\mu rad$ for sextupoles.
- 100 $\mu rad$ for quadrupoles.
Figure 4: (top): Vertical beam size $\sigma_y$ at the IP versus horizontal emittance for three different orders: quadrupolar, octupolar and dodecapolar. (bottom): Horizontal beam size $\sigma_x$ at the IP versus horizontal emittance for the same orders.

- Strength: $10^{-4}$ relative error to all magnets.

In order to perform as a real tuning as possible, the vertical beam size is evaluated in terms of a convolution between the Shintake monitor interference field and the beam profile. A 10% random error is assigned to the $\sigma_y^*$ obtained value.

Starting from this initial configuration, the tuning algorithm consists on the following steps:

- Optimisation of misalignments and tilts
- Dispersion correction: $\eta_x, \eta_y$
- Coupling correction: $<x, y>, <x, py>$
- Optimisation of magnet strengths

These steps are iterated several times to assure the convergence of the system. The corrections of dispersion and coupling, are carried out using dedicated knobs in order to speed up the tuning process.

The results are presented as histograms in Fig. 5, and summarized in Tab. 3.

CONCLUSIONS

The progress on the ATF2 ultra-low $\beta^*$ proposal has been presented. It has been shown three different possible solutions to overcome the multipole issues, namely emittance reduction, use of a superconducting quadrupole and ATF2 ultra-low $\beta^*$ lattice.

The first two solutions require cryogenics equipment, which indeed is an undesired situation.

Referring to the tunability of the developed lattice and according to $\sigma_y^*$ and number of required iterations for convergence ($\approx 17000$), the results are not satisfactory, therefore an improvement of the algorithm is needed. In this sense the development to intermediate lattices is ongoing in order to easily reach the goal. The following step in the tuning is to include the ground motion into simulations and to crosscheck the results with PLACET [13].
