Probabilistic $\pi$-Calculus and Event Structures$^1$

Daniele Varacca$^a$ Nobuko Yoshida$^b$

$^a$ PPS - Université Paris 7, France

Abstract
This paper proposes two semantics of a probabilistic variant of the $\pi$-calculus: an interleaving semantics in terms of Segala automata and a true concurrent semantics, in terms of probabilistic event structures. The key technical point is a use of types to identify a good class of non-deterministic probabilistic behaviours which can preserve a compositionality of the parallel operator in the event structures and the calculus. We show an operational correspondence between the two semantics. This allows us to prove a "probabilistic confluence" result, which generalises the confluence of the linearly typed $\pi$-calculus.

Keywords: Event structures, probabilistic processes, $\pi$-calculus, linear types

1 Introduction and motivations

Probabilistic models for concurrency have an extensive literature: most of the studies concern interleaving models [19,25,9], but recently, true concurrent ones have also been studied [18,1,28,31]. This paper presents an interleaving and a true concurrent semantics to a probabilistic variant of the $\pi$-calculus. The variant we consider is similar to the ones presented in [14,6], yet contains important differences. The main difference, which motivates all the others, is the presence of types.

The various typing systems for mobile processes have been developed in order to provide disciplines to control non-deterministic behaviours statically and compositionally. In probabilistic concurrency, a restriction of non-determinism becomes more essential, for example, for preservation of the associativity of parallel composition or to guarantee freedom from any specific scheduling policies [28]. This paper performs an initial step towards a "good" typing discipline for probabilistic name passing, which can preserve expressiveness and can harmonise with existing probabilistic concurrent semantics and programming languages [22,10,7].

We present a typing system for the probabilistic $\pi$-calculus, inspired from a linear typing systems for the $\pi$-calculus [3,35]. The linearly typed $\pi$-calculus can embed a family of $\lambda$-calculi fully abstractly. Linearly typed processes enjoy several interesting properties.

In particular they are guaranteed to be *confluent*, that is the computation they perform is deterministic. In the true concurrent setting, confluence can be viewed as absence of conflicts, or *conflict freeness*. In a conflict free system, one can have different partial runs, for instance because one chooses to execute different subsystems. However, under some basic fairness assumptions, and if we abstract away from the order in which concurrent events happen, the system will always produce the same run.

In [30], we extend the linear $\pi$-calculus by adding a nondeterministic choice. The typing system no longer guarantees conflict freeness, but the more general behavioural property of *confusion freeness*. This property has been studied in the form of free choice Petri Nets [23.8]. Confusion free event structures are also known as concrete data structures [4], and their domain-theoretic counterpart are the concrete domains [17]. In a confusion free system, all nondeterministic choices are *localised* and are independent from any other event in the system. In the probabilistic setting [28], the intuition is that local choices can be resolved by a local coin, or die. The result in [28] show that probabilistic confusion free systems are *probabilistically confluent*. We have argued that confluence entails the property of having only one maximal computation, up to the order of concurrent events. It is then reasonable to define probabilistic confluence as the property of having only one maximal probabilistic computation, where a probabilistic computation is defined as a probability measure over the set of computations.

We provide an interleaving and a true concurrent semantics to this probabilistic $\pi$-calculus. The interleaving semantics is given as Segala automata [25], which are an operational model that combine probability and nondeterminism. The nondeterminism is necessary to account for the different possible schedulings of the independent parts of a system. The true concurrent semantics is given as probabilistic event structures [28]. In this model, we do not have to account for the different schedulings, and that leads to the probabilistic confluence result (Theorem 6.2), one of the main original contributions of this work.

In order to relate the two semantics, we show how a probabilistic event structure generates a Segala automaton. This allows us to show an operational correspondence between the two semantics.

Types play an important role for a compositional semantics, which is given as a clean generalisation of Winskel’s original event structure semantics of CCS [32] to the $\pi$-calculus. In this sense, this work offers a concrete syntactic representation of the probabilistic event structures as name passing processes, closing an open issue in [28,30]. The work opens a door for event structure semantics for probabilistic $\lambda$-calculi and programming languages, using the probabilistic linear $\pi$-calculus as an intermediate formalism.

Due to the space limitation, the proofs are omitted and some non-probabilistic materials are left to [30,29].

## 2 Segala automata

To give an operational semantics to the probabilistic $\pi$-calculus we use *Segala automata*, a model that combines probability and nondeterminism. Segala automata can be seen as an extension both of Markov chains and of labelled transition systems. They were introduced by Segala and Lynch [26,25]. A recent presentation of Segala automata can be found in [27]. The name “Segala automata” appears first in [2].
2.1 Notation

A probability distribution over a finite or countable set \( X \) is a function \( \xi : X \to [0,1] \) such that \( \sum_{x \in X} \xi(x) = 1 \). The set of probability distributions over \( X \) is denoted by \( \mathcal{P}(X) \). By \( \mathcal{P}(X) \), we denote the powerset of \( X \). A Segala automaton over a set of labels \( A \) is given by a finite or countable set of states \( X \) together with a transition function \( t : X \rightarrow \mathcal{P}(V(A \times X)) \). This model represents a process that, when it is in a state \( x \), nondeterministically chooses a probability distribution \( \xi \) in \( t(x) \) and then performs action \( a \) and enters in state \( y \) with probability \( \xi(a,y) \).

The notation we use comes from \[14\]. Consider a transition function \( t \). Whenever a probability distribution \( \xi \) belongs to \( t(x) \) for a state \( x \in X \) we will write

\[
\xi \in t(x)
\]

where \( x_i \in X, i \neq j \implies (a_i,x_i) \neq (a_j,x_j), \) and \( \xi(a_i,x_i) = p_i \). Probability distributions in \( t(x) \) are also called transition groups of \( x \).

A good way of visualising probabilistic automata is by using alternating graphs \[13\]. In Figure \ref{fig:i}, black nodes represent states, hollow nodes represent transition groups.

2.2 Runs and schedulers

An initialised Segala automaton, is a Segala automaton together with an initial state \( x_0 \). A finite path of an initialised Segala automaton is an element in \((X \times V(X \times A) \times A)^*X\), written as \( x_0\xi_1a_1x_1\ldots\xi_na_nx_n \), such that \( \xi_{i+1} \in t(x_i) \). An infinite path is defined in a similar way as an element of \((X \times V(X \times A) \times A)^\omega\).

The probability of a finite path \( \tau := x_0\xi_1a_1x_1\ldots\xi_na_nx_n \) is defined as

\[
\Pi(\tau) = \prod_{1 \leq i \leq n} \xi_i(a_i,x_i).
\]

The last state of a finite path \( \tau \) is denoted by \( l(\tau) \). A path \( \tau \) is maximal if it is infinite or if \( t(l(\tau)) = \emptyset \).

A scheduler for a Segala automaton with transition function \( t \) is a partial function \( \mathcal{S} : (X \times V(X \times A) \times A)^*X \rightarrow V(X \times A) \) such that, if \( t(l(\tau)) \neq \emptyset \) then \( \mathcal{S}(\tau) \) is defined and \( \mathcal{S}(\tau) \in t(l(\tau)) \). A scheduler chooses the next probability distribution, knowing the history of the process. Using the representation with alternating graphs, we can say that, for every path ending in a black node, a scheduler chooses one of his hollow sons.

Given an (initial) state \( x_0 \in X \) and a scheduler \( \mathcal{S} \) for \( t \), we consider the set \( \mathcal{B}(t,x_0,\mathcal{S}) \)
of maximal paths, obtained from $t$ by the action of $\mathcal{S}$. Those are the paths $x_0\xi_1a_1x_1\ldots\xi_n\alpha_n\alpha_nx_n$ such that $\xi_{i+1} = \mathcal{S}(x_i\xi_1a_1x_1\ldots\xi_n\alpha_nx_n)$. The set of maximal paths is endowed with the $\sigma$-algebra $\mathcal{F}$ generated by the finite paths. A scheduler induces a probability measure on $\mathcal{F}$ as follows: for every finite path $\tau$, let $K(\tau)$ be the set of maximal paths extending $\tau$.

Define $\zeta_{\mathcal{S}}(K(\tau)) := \Pi(\tau)$, if $\tau \in \mathcal{B}(t, x_0, \mathcal{S})$, and 0 otherwise. It can be proved [25] that $\zeta_{\mathcal{S}}$ extends to a unique probability measure on $\mathcal{F}$.

Given a set of labels $B \subseteq A$ we define $\zeta_{\mathcal{S}}(B)$ to be $\zeta_{\mathcal{S}}(Z)$, where $Z$ is the set of all maximal paths containing some label from $B$.

### 3 A probabilistic $\pi$-calculus

#### 3.1 Syntax and Operational Semantics

We assume the reader is familiar with the basic definitions of the $\pi$-calculus [21]. We consider a restricted version of the $\pi$-calculus, where only bound names are passed in interaction. This variant is known as $\pi l$-calculus [24]. In the typed setting has the same expressiveness as the full calculus [34]. The labelled transition semantics of the $\pi l$-calculus is simpler than that of the full calculus and its labels more naturally corresponds to those of event structures. Syntactically we restrict an output to the form $(\nu \tilde{y})\tilde{x}(\tilde{y}).P$ (where names in $\tilde{y}$ are pairwise distinct), which we write $\pi(\tilde{y}).P$.

We extend this framework to a probabilistic version of the calculus, where the output is generative, while the input is reactive. Reactive input is similar to the “case” construct and selection is “injection” in the typed $\lambda$-calculi. The formal grammar of the calculus is defined below with $p_i \in [0, 1]$.

$$
P ::= x \&_{i \in I} \text{in}_i(\tilde{y}_i).P_i \mid \tilde{x} \bigoplus_{i \in I} p_i \text{in}_i(\tilde{y}_i).P_i \mid P \mid Q \mid (\nu x)P \mid \emptyset \mid !x(\tilde{y}).P
$$

$x \&_{i \in I} \text{in}_i(\tilde{y}_i).P_i$ is a reactive input, and no probability is attached to its events, $\tilde{x} \bigoplus_{i \in I} p_i \text{in}_i(\tilde{y}_i).P_i$ is a generative output, and the events are given probability denoted by the $p_i$, $P \mid Q$ is a parallel composition, $(\nu x)P$ is a restriction and $!x(\tilde{y}).P$ is a replicated input. When the input or output indexing set is a singleton we use the notation $x(\tilde{y}).P$ or $\pi(\tilde{y}).P$; when the indexing set finite, we can write $x(\text{in}_1(\tilde{y}_1).P_1 \& \ldots \& \text{in}_n(\tilde{y}_n).P_n)$ or $\pi(p_1\text{in}_1(\tilde{y}_1).P_1 \oplus p_n\text{in}_n(\tilde{y}_n).P_n)$. We omit the empty vector and $\emptyset$: for example, $\pi$ stands for $\pi()$. The bound/free names are defined as usual. We assume that names in a vector $\tilde{y}$ are pairwise distinct. We use $\equiv_\alpha$ and $\equiv$ for the standard $\alpha$ and structural equivalences [21,15].

The operational semantics is given in terms of Segala automata, using the notation defined in (1) in Section 2. The labels we use are of the following form:

$$
\alpha, \beta ::= x\text{in}_i(\tilde{y}) \mid \tilde{x}\text{in}_i(\tilde{y}) \mid x\text{pr}_i(\tilde{y}) \mid \tilde{x}\text{pr}_i(\tilde{y}) \mid \tau
$$

(branching) (selection) (offer) (request) (synchronisation)

With the notation above, we say that $x$ is the subject of the label $\beta$, denoted as $\text{subj}(\beta)$, while $\tilde{y} = y_1, \ldots, y_n$ are the object names, denoted as $\text{obj}(\beta)$. For branching/selection labels, the index $i$ is the branch of the label. The notation “in$^i$” comes from the injection of the typed $\lambda$-calculus.

The rules for deriving the transitions are presented in Figure 2. The partial operation $\cdot$ on labels is defined as follows: $x\text{in}_i(\tilde{y}_i) \cdot \tilde{x}\text{in}_i(\tilde{y}_i) = x\text{pr}_i(\tilde{y}) \cdot \tilde{x}\text{pr}_i(\tilde{y}) = \tau$, and
undefined otherwise. In particular, the generative output synchronises with the reactive input, and a synchronisation step takes place, with the probability chosen by the output process.

3.2 Linear types for the probabilistic $\pi$-calculus

This subsection outlines a basic idea of the linear types for a probabilistic $\pi$-calculus.

The linear type discipline \[3,35\] controls a composition of processes in two ways: first, for each linear name there are a unique branching input and a unique selecting output; and secondly, for each replicated name there is a unique stateless replicated input (offer, or server) with zero or more dual outputs (request, or client).

Let us consider the following example where branching and selection provide probabilistic behaviour, preserving linearity:

$$Q_1 \overset{\text{def}}{=} \pi.p.\text{in}_1.b \oplus (1 - p)\text{in}_2.c \mid a.\text{in}_1.d \& \text{in}_2.\overline{c}$$

$Q_1$ is typable, and we have either $Q \xrightarrow{\tau \downarrow p} (b \mid \overline{d})$ or $Q \xrightarrow{\tau \downarrow 1 - p} (c \mid \overline{c})$. The following process is also typable:

$$Q_2 \overset{\text{def}}{=} \overline{\pi}.(p.\text{in}_1.b \oplus (1 - p)\text{in}_2.b) \mid a.\text{in}_1.d \& \text{in}_2.\overline{c}$$

since whichever branch is selected, $b$ is used once. However $\overline{\pi}.b \mid \overline{\pi}.c \mid a$ is untypable as linear output $\overline{\pi}$ appears twice. As an example of the offer-request constraint, let us consider the following process:

$$Q_3 \overset{\text{def}}{=} !a(x).\pi.(p.\text{in}_1 \oplus (1 - p)\text{in}_2) \mid \overline{a}(x).\text{in}_1.d \& \text{in}_2.\overline{c} \mid \overline{a}(x).\text{in}_1.\overline{d} \& \text{in}_2.\overline{c}$$

$Q_3$ is typable since, while output at $a$ appears twice, a replicated input at $a$ appears only once. Note that $x$ under the replication preserves the linearity after each invocation at $a$. On the other hand, $!b.\overline{\pi} \mid !b.\overline{\pi}$ is untypable because $b$ is associated with two replicators.

In the context of deterministic processes, the typing system guarantees confluence, in the presence of nondeterminism it guarantees confusion freeness \[30\].

Channel types are inductively made up from type variables and action modes: the input modes $\downarrow$, $\downarrow$, and the dual output modes $\uparrow$, $\uparrow$. Then the syntax of types is given as follows:
\[ \tau ::= \&_{i \in I} (\tilde{\tau}_i) \downarrow \mid \bigoplus_{i \in I} (\tilde{\tau}_i) \uparrow \mid (\tilde{\tau})^? \mid (\tilde{\tau})^! \mid \downarrow \]

(branding) (selection) (offer) (request) (closed)

where \( \tilde{\tau} \) is a tuple of types.

Branching types represent the notion of “environmental choice”: several choices are available for the environment to choose. Selection types represent the notion of “process choice”: some choice is made by the process, possibly probabilistically. In both cases the choice is alternative: one excludes all the others. Offer types represent the notion of “available resource”: I offer to the environment something that is available regardless of whatever else happens. Request types represent the notion of “concurrent client”: I want to use an available resource. The closed type is used to represent a channel that cannot be composed further.

We write \( MD(\tau) \) for the outermost mode of \( \tau \). The dual of \( \tau \), written \( \overline{\tau} \), is the result of recursively dualising all action modes, with \( \downarrow \) being self-dual. A type environment \( \Gamma \) is a finite mapping from channels to channel types. Sometimes we will write \( x \in \Gamma \) to mean \( x \in \text{Dom}(\Gamma) \).

Types restrict the composability of processes: if \( P \) is typed under environment \( \Gamma_1 \), \( Q \) is typed under \( \Gamma_2 \) and if \( \Gamma_1, \Gamma_2 \) are “compatible”, then a new environment \( \Gamma_1 \odot \Gamma_2 \) is defined, such that \( P \parallel Q \) is typed under \( \Gamma_1 \odot \Gamma_2 \). If the environments are not compatible, \( \Gamma_1 \odot \Gamma_2 \) is not defined and the parallel composition cannot be typed. Formally, we introduce a partial commutative operation \( \odot \) on types, defined as follows:\(^2\):

(i) \( \&_{i \in I} (\tau_i) \downarrow \odot \bigoplus_{i \in I} (\overline{\tau}_i) \downarrow = \downarrow \)

(ii) \( (\tau)^? \odot (\tau)^! = (\tau)^! \)

(iii) \( (\tau)^? \odot (\tau)^? = (\tau)^? \)

Then, the environment \( \Gamma_1 \odot \Gamma_2 \) is defined homomorphically. Intuitively, the rule (i) says that once we compose input-output linear channels, the channel becomes uncomposable. The rule (ii) says that a server should be unique while rule (iii) says that an arbitrary number of clients can request interactions. Other compositions are undefined.

The rules defining typing judgments \( P \triangleright \Gamma \) (where \( \Gamma \) is an environment which maps a channel to a type) are identical to the affine \( \pi \)-calculus \(^3\) except a straightforward modification to deal with the generative output, which is defined by the same rule for confusion free processes in \(^30\), without any additional complexity due to the probability. The rules are presented in Figure 3. In (Par), \( \Gamma_1 \odot \Gamma_2 \) guarantees the consistent channel usage like linear inputs being only composed with linear outputs, etc. In (Res), we do not allow \( \uparrow \), \(? \) or \( \downarrow \)-channels to be restricted since they carry actions which expect their dual actions to exist in the environment. (WeakOut) and (WeakCl) weaken with \( ? \)-names or \( \downarrow \)-names, respectively, since these modes do not require further interaction. (Lin) and (LOut) ensure that \( x \) occurs precisely once. (RIn) is the same as (LIn) except that no free linear channels are suppressed. This is because a linear channel under replication could be used more than once. (ROut) is similar with (LOut). Note we need to apply (WeakOut) before the first application of (ROut).

We then obtain a typed version of the operational semantics by restricting the actions that are not allowed by the type environment. Informally an action is allowed by an envi-
$$P \triangleright \Gamma, a : \tau \quad a \not\in \Gamma \quad MD(\tau) = \top,$$

$$\tag{\nu a} P \triangleright \Gamma \quad \text{Res} \quad 0 \triangleright \emptyset \quad \text{Zero}$$

$$P \triangleright \Gamma, \tilde{y}_i : \tilde{\tau}_i \quad a \not\in \Gamma \quad \tag{\bigoplus_{i \in I} p_i \mathsf{in}_i(\tilde{y}_i).P_i \triangleright \Gamma, a : \bigoplus_{i \in I} (\tilde{\tau}_i)}$$

$$\tag{\mathsf{LOut}} P \triangleright \Gamma, x \not\in \Gamma \quad \text{WeakOut}$$

$$\tag{\bigoplus_{i \in I} p_i \mathsf{in}_i(\tilde{y}_i).P_i \triangleright \Gamma, a : \bigoplus_{i \in I} (\tilde{\tau}_i)}$$

$$\tag{\mathsf{LIn}} P \triangleright \Gamma, y : \tilde{\tau} \quad a \not\in \Gamma \quad \forall(x : \tau) \in \Gamma. MD(\tau) = ? \quad \tag{\mathsf{Lin}}$$

$$\top \triangleright \Gamma \quad \text{WeakIn}$$

$$\tag{\mathsf{RIn}} P \triangleright \Gamma, a : (\tilde{\tau})^\dagger \quad \tag{\mathsf{ROut}}$$

$$P \triangleright \Gamma, a : (\tilde{\tau})^\dagger \quad \mathsf{ROut}$$

Fig. 3. Linear Typing Rules

The nature of the typing system is such that for every transition group, either all actions are allowed, or all are not, and therefore the above semantics is well defined.

### 3.3 Example of a probabilistic process

We consider the model of traffic lights from [22]. Let $a$ be a driver, and let $\mathsf{in}_{\text{red}}, \mathsf{in}_{\text{yell}}, \mathsf{in}_{\text{green}}$ represent colours of the traffic light. The process $\mathsf{in}_{\text{red}}(y)$ represents the traffic light signalling to the driver it is red, at the same time communicating the name $y$ of the crossing. The behaviour of the driver at the crossing is either braking, staying still, or driving ($\mathsf{in}_{\text{brake}}, \mathsf{in}_{\text{still}}, \mathsf{in}_{\text{drive}}$).

A cautious driver is represented by the process:

$$D_c^a = a \& i \in \{\text{red, yell, green}\} \mathsf{in}_i(y).P_i \quad \text{with} \quad P_{\text{red}} = \mathcal{P}(0.2\mathsf{in}_{\text{brake}} \oplus 0.8\mathsf{in}_{\text{still}})$$

$$P_{\text{yell}} = \mathcal{P}(0.9\mathsf{in}_{\text{brake}} \oplus 0.1\mathsf{in}_{\text{drive}})$$

$$P_{\text{green}} = \mathcal{P}(\mathsf{in}_{\text{drive}})$$

A cautious driver watches what colour the light is and behaves accordingly. If it is red, she stays still, or finishes braking. If it is yellow, most likely she brakes. If it is green, she drives on.
A driver in a hurry is represented by the process

\[
D_h^a = a \& \iota \in \{\text{red,yell,green}\} \text{ in}_i(y).Q_i \quad \text{with} \quad Q_{\text{red}} = \overline{y}(0.3 \text{in\textsubscript{brake}} \oplus 0.6 \text{in\textsubscript{still}} \oplus 0.1 \text{in\textsubscript{drive}})
\]

\[
Q_{\text{yell}} = \overline{y}(0.1 \text{in\textsubscript{brake}} \oplus 0.9 \text{in\textsubscript{drive}})
\]

\[
Q_{\text{green}} = \overline{y}(\text{in\textsubscript{drive}})
\]

This is similar to the cautious driver, but he is more likely to drive on at red and yellow. In fact, both have the same type, they check the light, and they choose a behaviour:

\[
D_c^a, D_h^a \triangleright a : \& \iota \in \{\text{red,yell,green}\} \left(\bigoplus_{j \in \{\text{brake,still,drive}\}} (\iota^\uparrow)\right)^\downarrow
\]

where \& \iota \in \{\tau_i\} \downarrow is a branching type which inputs a value of type \tau_i and \bigoplus_{i \in I} (\iota^\uparrow) is a selection type which selects a branch i with a value of type \tau_i. Note that the type actually states that the driver chooses the behaviour after seeing the light. We can represent two independent drivers:

\[
D2 = (\nu a, a')((\pi \text{in\textsubscript{red}}(y).R | D_c^a | a' \text{in\textsubscript{green}}(y).R | D_h^a))
\]

where \ R = y \& \iota \in \{\text{brake,still,drive}\} \text{in}_i() \text{ represents the traffic light accepting the behaviour of the driver. We have that } D2 \text{ has two transition groups, corresponding to the two drivers. Note that linearity and confusion-freedom of } y \text{ guarantees that each driver can perform only one of three actions, i.e. either brake, still or drive at any one time.}

4 Probabilistic event structures

We now present the model of probabilistic event structures, that we use to give an alternative semantics to the probabilistic \pi-calculus. Probabilistic event structures were first introduced by Katoen [18], as an extension of the so called bundle event structure. A probabilistic version of prime event structures was introduced in [28]. Below we start from basic definitions without probability.

4.1 Basic definitions

An event structure is a triple \( E, \leq, \sim \) such that

- \( E \) is a countable set of events;
- \( (E, \leq) \) is a partial order, called the causal order;
- for every \( e \in E \), the set \( \{e' \mid e' < e\} \), called the enabling set of \( e \), is finite;
- \( \sim \) is an irreflexive and symmetric relation, called the conflict relation, satisfying the following: for every \( e_1, e_2, e_3 \in E \) if \( e_1 \leq e_2 \) and \( e_1 \sim e_3 \) then \( e_2 \sim e_3 \).

The reflexive closure of conflict is denoted by \( \bowtie \). We say that the conflict \( e_2 \bowtie e_3 \) is inherited from the conflict \( e_1 \bowtie e_3 \), when \( e_1 < e_2 \). If a conflict \( e_1 \bowtie e_2 \) is not inherited from any other conflict we say that it is immediate, denoted by \( e_1 \bowtie_{\mu} e_2 \). The reflexive closure of immediate conflict is denoted by \( \bowtie_{\mu} \). Causal dependence and conflict are mutually exclusive. If two events are not causally dependent nor in conflict they are said to be concurrent. A labelled event structure is an event structure \( E \) together with a labelling function \( \lambda : E \to L \), where \( L \) is a set of labels.
We introduce an interesting class of event structures where every choice is localised. To specify what “local” means that we need the notion of cell, a set of events that are pairwise in immediate conflict and have the same enabling sets.

**Definition 4.1** A partial cell is a set $c$ of events such that $e, e' \in c$ implies $e \succ_\mu e'$ and $[e] = [e']$. A maximal partial cell is called a cell. An event structure is confusion free if its cells are closed under immediate conflict.

Equivalently, in a confusion free event structure, the reflexive closure of immediate conflict is an equivalence with cells being its equivalence classes.

### 4.2 Probabilistic event structures

Once an event structure is confusion-free, we can associate a probability distribution with some cells. Intuitively it is as if, for every such cell, we have a die local to it, determining the probability with which the events at that cell occur.

We can think of the cells with a probability distribution as generative, while the other cells will be called reactive. Reactive cells are awaiting a synchronisation with a generative cell in order to be assigned a probability.

**Definition 4.2** Let $\mathcal{E} = \langle E, \leq, \succ \rangle$ be a confusion free event structure, let $G$ be a set of cells of $\mathcal{E}$ and let $G'$ be the set of events of the cells in $G$. The cells in $G$ are called generative. The cells not in $G$ are called reactive. A cell valuation on $(\mathcal{E}, G)$ is a function $p : G' \rightarrow [0, 1]$ such that for every $e \in G$, we have $\sum_{e \in c} p(e) = 1$. A partial probabilistic event structure is a confusion free event structure together with a cell valuation. It is called simply probabilistic event structure if $G' = E$.

This definition generalises the definition given in [28], where it is assumed that $G' = E$. Note also that a confusion free event structure can be seen as a probabilistic event structure where the set $G$ is empty.

### 4.3 Operators on event structures

Several operations can be defined on event structures.

- **prefixing** $a.\mathcal{E}$. This is obtained by adding a new minimum event, labelled by $a$. Conflict, order, and labels remain the same on the old events.

- **prefixed sum** $\sum_{i \in I} a_i.\mathcal{E}_i$. This is obtained by disjoint union of copies of the event structures $a_i.\mathcal{E}_i$, where the order relation is the disjoint union of the orders, the labelling function is the disjoint union of the labelling functions, and the conflict is the disjoint union of the conflicts extended by putting in conflict every two events in two different copies. It is a generalisation of prefixing, where we add an initial reactive cell, instead of an initial event.

- **probabilistic prefixed sum** $\sum_{i \in I} p_i a_i.\mathcal{E}_i$, where $\mathcal{E}_i$ are partial probabilistic event structures. This is obtained as above, but with the condition that the initial cell is generative, and that the probability of the new initial events are $p_i$.

- **restriction** $\mathcal{E} \setminus X$ where $X \subseteq A$ is a set of labels. This is obtained by removing from $E$ all events with label in $X$ and all events that are above one of those. On the remaining events, order, conflict and labelling are unchanged.
• relabelling $\delta[f]$. This is just composing the labelling function $\lambda$ with a function $f : L \rightarrow L$. The new event structure has thus labelling function $f \circ \lambda$.

• parallel composition The parallel composition of event structures is not so simple to define, due to the possibility of synchronisation among events. For lack of space we skip the details, that can be found in [33,29,30].

Intuitively, events in the parallel composition are the events of the two event structures, plus some new event representing synchronisation. For a labelled event structures with labels in $L$, the labels of the synchronisation events are obtained via a synchronisation algebra $S$, a partial binary operation $\bullet_S$ defined on $L$. If the labels of the two synchronising event are $l_1, l_2$, the synchronisation event will have label $l_1 \bullet_S l_2$, if defined, orelse it will be restricted away. The simplest synchronisation algebra is always undefined and represents the absence of synchronisation. In this case the parallel composition can be represented as the disjoint union of the sets of events, of the causal orders, and of the conflict. This can be also generalised to an arbitrary family of event structures $(E_i)_{i \in I}$. In such a case we denote the parallel composition as $\prod_{i \in I} E_i$.

All constructors above, except the parallel composition, preserve the class of partial probabilistic event structures. In the next section we present a typing system, which is designed to allow parallel composition to preserve that class.

4.4 Typed event structures

In this section we recall the notion of type for an event structure, which was defined in [29]. Types and type environments for event structures are inspired by those of the $\pi$-calculus, but they recursively keep track of the names communicated along the channels. They are generated by the following grammar:

$$\begin{align*}
\Gamma, \Delta & ::= y_1 : \sigma_1, \ldots, y_n : \sigma_n \\
\tau, \sigma & ::= \&_{i \in I} \Gamma_i \mid \bigoplus_{i \in I} \Gamma_i \mid \bigotimes_{i \in I} \Gamma_i \mid \biguplus_{i \in I} \Gamma_i \mid \uparrow \\
& \quad \text{(branching) (selection) (offer) (request) (closed type)}
\end{align*}$$

A type environment $\Gamma$ is well formed if any name appears at most once. Only well formed environments are considered for typing event structures. The intuition behind the types is similar to the $\pi$-calculus. The main difference is that offer is not restricted to a replicated server, but represents different concurrent resources.

Given a labelled confusion free event structure $E$ on $\pi$-calculus labels (defined in Section 3), we can define when $E$ is typed in the environment $\Gamma$, written as $E \triangleright \Gamma$. Informally, a confusion free event structure $E$ has type $\Gamma$ if cells are partitioned in branching, selection, request, offer and synchronisation cells, all the non-synchronisation events of $E$ are represented in $\Gamma$ and causality in $E$ refines the name causality implicit in $\Gamma$. This means that if name $y$ appears inside the type of a name $x$, any event whose subject is $y$ must be causally related with en event whose subject is $x$.

The types are designed so that the parallel composition of typed event structures will also be typed. To define the parallel composition, we use the following same synchronisation algebra used in Section 3: $xin_i(y_i) \bullet xpr_i(y) = xpr_i(y_i) \bullet xpr_i(y) = \tau$, and undefined otherwise. Moreover, the parallel composition of two typed event structures $E_1 \triangleright \Gamma_1$ and
\[ E_2 \triangleright \Gamma_2 \] is defined only when the environment \( \Gamma_1 \odot \Gamma_2 \) is defined, and in such a case the parallel composition has type \( \Gamma_1 \odot \Gamma_2 \). The formal definition of \( \odot \) is similar to the corresponding notion for the \( \pi \)-calculus, but it is recursively applied to the object names. It is designed to preserve the well formedness (linearity) of the environment. The details can be found in [29, 30].

To type a partial probabilistic event structure, we type it as a non probabilistic event structure. We also make sure that only the branching cells are reactive, as they are waiting to synchronise with a dual selection cell.

**Definition 4.3** Let \( \mathcal{E} = (E, \leq, \lambda, G, p) \) be a partial probabilistic event structure. We say that \( \mathcal{E} \triangleright \Gamma \), if the following conditions are satisfied:

- \( \mathcal{E} \triangleright \Gamma \) as for the non-probabilistic case;
- \( G \) includes all cells, except the branching ones.

From the fact that the parallel composition of typed event structures is typed, one can easily derive that the parallel composition of typed probabilistic event structures [29] is still a probabilistic event structure, and that it is typed.

### 4.5 Example of typed event structure

Figure 4 represents a typed (partial) probabilistic event structure \( \mathcal{E} \triangleright \Gamma \), where

\[
\Gamma = a : \&_{i \in \{1, 2\}} (x_i : \bigoplus_{k \in \{1, 2\}} ()), b : \&_{i \in \{1\}} (z_i : \bigcup_{k \in \{1\}} ())
\]

Immediate conflict is represented by curly lines, while causal order proceeds upwards along the straight lines. The selection cells \( x_1 \text{in}_1, x_2 \text{in}_2 \) and \( \pi_1 \text{in}_1, \pi_2 \text{in}_2 \) are generative. The branching cell \( a \text{in}_1(x_1), a \text{in}_2(x_2) \) is reactive. Every other cell is generative, and contains only one event, that has probability 1. We can see that the causality in \( \mathcal{E} \) refines the name causality in \( \Gamma \): for instance, \( \Gamma \) forces the labels with subject \( x_i \) to be above the label \( a \text{in}_i(x_i) \), but does not force the causal link between the events labelled by \( a \text{in}_i(x_i) \) and \( b(z_1) \). Note also that the synchronisation event is not represented in the type.

### 5 Event structure semantics of the probabilistic \( \pi \)-calculus

This section presents the event structure semantics of the \( \pi \)-calculus and its properties. As in [30], the semantics is given by a family of partial functions \([−]\), parametrised by a
“choice function” $\rho$, that take a judgment of the $\pi$-calculus and return an event structure. The “choice function” $\rho$ assigns to every bound name a set (possibly a singleton) of fresh distinct names. The parametrisation is necessary because $\pi$-calculus terms are identified up to $\alpha$-conversion, and so the identity of bound names is irrelevant, while in typed event structures, the identity of the object names is important. Also, since servers are interpreted as infinite parallel compositions, every bound name of a server must correspond to infinitely many names in the interpretation.

The semantics is defined as in the non probabilistic case [29]. As an example, we list the semantics of the selection:

$$ [\pi \bigoplus_{i \in I} p_i \text{in}_i(\tilde{y}_i).P_i \triangleright \Gamma, a : \bigoplus_{i \in I} p_i \text{in}_i(\tilde{\tau}_i).]\rho = \sum_{i \in I} p_i [\bigoplus_{i \in I} \tilde{y}_i.P_i[\tilde{\tau}_i/\tilde{y}_i] \triangleright \Gamma, \tilde{\tau}_i : \tilde{\tau}_i] \rho_i $$

where $\tilde{\tau}_i = \rho(\tilde{y}_i)$ and $\rho_i$ is $\rho$ restricted to to the bound names of $P_i$. We can see that syntactic prefix is modelled using the prefixing operator of event structures, while the parameter $\rho$ chooses an instantiation of the bound names.

The main property of the typed semantics is that all denoted event structures are typed.

**Theorem 5.1** Let $P$ be a process and $\Gamma$ an environment such that $P \triangleright \Gamma$. Suppose that $[P \triangleright \Gamma]^{\rho}$ is defined. Then there is a environment $\Delta$ such that $[P \triangleright \Gamma]^{\rho} \triangleright \Delta$.

This theorem means that all denoted event structures are indeed partial probabilistic event structures. Note that the set of generative cells includes all synchronisation cells. Therefore a closed process denotes a probabilistic event structure.

**Corollary 5.2** The event structure $[P \triangleright \emptyset]^{\rho}$ is a probabilistic event structure.

This implies that there exists a unique probability measure over the set of maximal runs [28]. In other words, for closed processes, the scheduler only influences the order of independent events, in accordance with the intuition that probabilistic choice are local and not influenced by the environment.

### 6 Event structures and Segala automata

In this section we show a formal correspondence between Segala automata and probabilistic event structures.

#### 6.1 From event structures to Segala automata

**Definition 6.1** Let $E = \langle E, \leq, \leadsto, \lambda \rangle$ be a labelled event structure and let $e$ be one of its minimal events. The event structure $E[e]$ is defined by: $E' = \{ e' \in E \mid e' \neq e \}, \leq' = \leq|_{E'}$, $\leadsto' = \leadsto|_{E'}$, and $\lambda' = \lambda_{E'}$.

Roughly speaking, $E[e]$ is $E$ minus the event $e$, and minus all events that are in conflict with $e$. We can then generate a Segala automata on event structures as follows:

$$ E \{ \underbrace{a_i}_{p_i} \} E \{ e_i \}_{i \in I} $$

if there exists a minimal generative cell $c = \{ e_i \mid i \in I \}$, such that $p(e_i) = p_i$ and $\lambda(e_i) = a_i$. We also put

$$ E \{ \underbrace{a}_{1} \} E \{ e \} $$

12
If there exists an event \( e \) belonging to a minimal reactive cell, such that \( \lambda(e) = a \). The initialised Segala automaton generated by an event structure \( \mathcal{E} \) is the above automation intialised at \( \mathcal{E} \).

A probabilistic event structure (where every cell is generative) generates a somewhat “deterministic” Segala automaton. The general formalisation of this property requires several technicalities (see [28], for instance). Here we state a simplified result. Consider a scheduler \( \mathcal{S} \) for a Segala automaton \( (t, x_0) \). We say that \( \mathcal{S} \) is fair if for every path \( \tau \in \mathcal{B}(t, x_0, \mathcal{S}) \), there does not exist a transition group \( \xi \) and an index \( j \), such that \( \xi \in \tau(x_i) \) for all \( i > j \), and \( \xi \) is never chosen by \( \mathcal{S} \).

**Theorem 6.2** Let \( \mathcal{E} \) be a probabilistic event structure, and consider the Segala automaton generated as above. For every set of labels \( B \), and for every fair schedulers \( \mathcal{S}, \mathcal{T} \), we have \( \zeta_{\mathcal{S}}(B) = \zeta_{\mathcal{T}}(B) \).

In a non-probabilistic confluent system, all (fair) resolutions of the nondeterministic choices give rise to the same set of events, possibly in different order. In this sense we can see Theorem 6.2 as expressing probabilistic confluence.

Figure 5 shows an example of a (partial) probabilistic event structure. The generative cells are \( \{\alpha', \alpha''\}, \{\beta'', \gamma''\} \) and the probability is indicated as superscript of the label. Figure 6 shows the Segala automaton corresponding to the event structure of Figure 5.

### 6.2 The adequacy theorem

There is a correspondence between the two semantics and of the \( \pi \)-calculus. It is formalised by the following theorem, which shows the correspondence between the Segala automata semantics defined in Section 3, and the Segala automaton derived from the event structure semantics, as described above.
Theorem 6.3 Let $\cong$ denote isomorphism of probabilistic event structures.

Suppose $P \triangleright \Gamma \{ \frac{\beta_i}{p_i} \}_{i \in I}$ in the $\pi$-calculus. Then there exists $\rho, \rho_i$ such that $[P \triangleright \Gamma]^{\rho}$ is defined and $[P \triangleright \Gamma]^{\rho} \{ \frac{\beta_i}{p_i} \cong [P_i \triangleright \Gamma_i]^{\rho_i} \}_{i \in I}$.

Conversely, suppose $[P \triangleright \Gamma]^{\rho} \{ \frac{\beta_i}{p_i} \cong \delta_i \}_{i \in I}$, for some $\rho$. Then there exist $P_i, \rho_i$ such that $P \triangleright \Gamma \{ \frac{\beta_i}{p_i} P_i \triangleright \Gamma \backslash \beta_i \}_{i \in I}$ and $[P_i \triangleright \Gamma \backslash \beta_i]^{\rho_i} \cong \delta_i$, for all $i \in I$.

The proof is analogous to the one for the non-probabilistic case [29] by induction on the operational rules, the difficult case being the parallel composition.

6.3 Example of probabilistic confluence

Theorem 6.3 and Theorem 6.2 together show that the linearly typed probabilistic $\pi$-calculus is “probabilistically confluent”.

To exemplify this, consider a process $P$ such that $P \triangleright a : \bigoplus_{i \in I}$. This is a process that emits only one visible action, whose subject is $a$. For every $j \in I$ we can define the probability $P$ emits $a \in_j$ as $p_{\mathcal{S}}(a \in_j)$ for some fair scheduler $\mathcal{S}$. By Theorem 6.2, we have that this probability is independent from the scheduler, so we can define it as $p(a \in_j)$.

This independence from the scheduling policy is what we call probabilistic confluence.

Note also that it can be shown that $\sum_{i \in I} p(a \in_i) \leq 1$. When the inequation is strict, the missing probability is the probability that the process does not terminate. This reasoning rely on the typing in that there exist untyped processes that are not probabilistically confluent. For instance consider

$$(\nu b)(b \mid b.\overline{\pi} \bigoplus_{i \in \{1, 2\}} p_i b_i \mid b.\overline{\pi} \bigoplus_{i \in \{1, 2\}} q_i b_i)$$

The above process also emits only one visible action, whose subject is $a$. The probability of $\overline{\pi} b_i$ is $p_1$, or $q_1$, depending on which synchronisation takes place, i.e. depending on the scheduler. Note, however, that this process is not typable.

7 Related and future work

7.1 Related work

This paper has provided an event structures semantics for a probabilistic version of the $\pi$-calculus. It is the first true concurrent semantics of a probabilistic $\pi$-calculus. Related work with true concurrency models for the $\pi$-calculus and (confusion-free) event structures are already discussed in [30,29]. There, the importance of confusion freeness and the use of types in event structures is also discussed in depth. Another recent event structure semantics of the $\pi$-calculus was presented in [5].

The natural comparison is with the probabilistic $\pi$-calculus by Hersonc and Palamidessi [14]. Their and our calculi both have a semantics in terms of Segala automata, while we also provide an event structure semantics. The key of our construction is the typing system, which allows us to stay within the class of probabilistic event structures.

Our typing system is designed to provide a “probabilistically confluent” calculus, and therefore their calculus is more expressive, as it allows non-confluent computations. At the core of their calculus, there is a renormalisation of probabilities, which is absent in our
setting, i.e. in our calculus, all probabilistic choices are local, and are not influenced by the environment.

A simpler calculus, without renormalisation, is presented in [6]. This version is very similar to ours, in that all choices are local; in fact, the protocol example presented in [6] (via an encoding into our calculus) is linearly typable. We believe we could apply a typing system similar to ours to the calculus in [6], prove the same results in this paper and identify a good class of probabilistic name-passing behaviours.

7.2 Future work

We have shown a correspondence between event structures and Segala automata. We would have liked to extend this correspondence to a categorical adjunction between two suitable categories, ideally extending the setting presented in [33]. It is possible to do so, by a simple definition of morphisms for Segala automata, and by extending the notion of probabilistic event structures. Unfortunately neither category has products, which are used in [33] to define parallel composition. The reason for this is nontrivial and it is has to do with the notion of stochastic correlation, a phenomenon already discussed in [28] in the context of true concurrent models. This issue needs to be investigated further.

The linearly typed \( \pi \)-calculus is the target of a sound and complete encodings of functional language [3,34]. Our traffic light example in Section 5 suggests that our calculus captures the core part of the expressiveness represented by the Stochastic Lambda Calculus [22]. We plan to perform similar encodings in the probabilistic version, notably the probabilistic functional language [22], probabilistic \( \lambda \)-calculus [10] and Probabilistic PCF [7]. Since the linear type structures are originated from game semantics [16], this line of study would lead to a precise expressive analysis between the probabilistic event structures, Segala automata, probabilistic programming languages and probabilistic game semantics [7], bridged by their representations of or encodings into probabilistic \( \pi \)-calculi. Finally, there are connections between event structures, concurrent game [20], and ludics [11,12] that should be investigated also in the presence of probabilities.
