Abstract
In a recent work, we introduced four variants of diagnosability (FA, IA, FF, IF) in (finite) probabilistic systems (pLTS) depending whether one considers (1) finite or infinite runs and (2) faulty or all runs. We studied their relationship and established that the corresponding decision problems are PSPACE-complete. A key ingredient of the decision procedures was a characterisation of diagnosability by the fact that a random run almost surely lies in an open set whose specification only depends on the qualitative behaviour of the pLTS. Here we investigate similar issues for infinite pLTS. We first show that this characterisation still holds for FF-diagnosability but with a $G_δ$ set instead of an open set and also for IF- and IA-diagnosability when pLTS are finitely branching. We also prove that surprisingly FA-diagnosability cannot be characterised in this way even in the finitely branching case. Then we apply our characterisations for a partially observable probabilistic extension of visibly pushdown automata (POpVPA), yielding EXPSPACE procedures for solving diagnosability problems. In addition, we establish some computational lower bounds and show that slight extensions of POpVPA lead to undecidability.

1 Introduction

Diagnosis. Monitoring (hardware and/or software) systems prone to faults involves several critical tasks: controlling the system to prevent faults as much as possible, deducing the cause of the faults, etc. Most of these tasks assume that an observer has the capability to assess the status of the current run based on the outputs of the system: providing information about the possible occurrence of faults. Such an observer is called a diagnoser and its associated task is called diagnosis. This framework leads to interesting decision and synthesis problems: “Does there exist a diagnoser?” and in the positive case “How to build such a diagnoser?”, “Which kind of diagnoser is sufficient?”, etc. The decision problem, on which we focus here, is called diagnosability [14].

Diagnosis of discrete event systems. In order to formally reason about diagnosability, the systems were first modelled by finite labelled transition systems (LTS). Then the specification of a diagnoser is defined by two requirements: correctness, meaning that the information provided by the diagnoser is accurate, and reactivity, ensuring that a fault will eventually be detected. Within the framework of finite LTS, the decision problem was shown to be solvable in PTIME [9] and it is in fact NLOGSPACE-complete.

Diagnosis of probabilistic systems. A natural way of modelling partially observable systems consists in introducing probabilities (e.g. when the design is not fully known or the effects of the interaction with the environment is not predictable). Thus the notion of diagnosability was later extended to Markov chains with labels on transitions, also called probabilistic labelled transition systems (pLTS) [15]. In this context, the reactivity requirement now asks that faults will be almost surely eventually detected. Regarding correctness, two specifications have been proposed: either one sticks to the original definition
and requires that the provided information is accurate, defining $A$-diagnosability; or one weakens the correctness by admitting errors in the provided information that should, however, have an arbitrary small probability defining $AA$-diagnosability. From a computational viewpoint, we recently proved that $A$-diagnosability is $\text{PSPACE}$-complete [3] and that $AA$-diagnosability can be solved in $\text{PTIME}$ [4].

In case a system is not diagnosable, one may be able to control it, by forbidding some controllable actions, so that it becomes diagnosable. This property of active diagnosability has been studied for discrete-event systems [13, 8], and for probabilistic systems [2]. Interestingly, the diagnosability notion in the latter work slightly differs from the original one in [15]. Building on this variation, in [3] semantical issues have been investigated and four relevant notions of diagnosability ($FA$, $IA$, $FF$, $IF$) have been defined depending on (1) whether one considers finite or infinite runs and (2) faulty or all runs. In finite pLTS, it was shown that all these notions can be characterized by the fact that a random run almost surely lies in an open set, whose specification only depends on the qualitative behaviour of the pLTS.

**Diagnosis of infinite-state systems.** Diagnosability in infinite-state systems has been studied, on the one hand for restricted Petri nets [5], for which an accurate diagnoser can be designed, and on the other hand for visibly pushdown automata (VPA) [11], for which diagnosability can be decided via the determinisation procedure of [1]. However to the best of our knowledge diagnosis of probabilistic infinite-state systems has not yet been studied.

**Contributions.** The characterisations of diagnosability established in [3] strongly relied on the finiteness of the models. Our first aim is thus to establish characterisations in the infinite-state case. $FF$-diagnosability (the original notion of diagnosability) states that almost surely a faulty run will be detected in finite time. We establish that $FF$-diagnosability can be characterised by the fact that a random run almost surely lies in a $G_\delta$ set, only depending on the qualitative behaviour of the system. This characterisation also applies to $IF$-diagnosability for finitely-branching systems, since then the two notions coincide. An ambiguous infinite correct (resp. faulty) run is a run indistinguishable from a faulty (resp. correct) run. $IA$-diagnosability states that almost surely a run is unambiguous. The set of ambiguous runs is an analytic set (so a priori not known to be a Borel set). However in the finitely-branching case, we establish that the set of unambiguous runs is a $G_\delta$ set, yielding a characterisation of $IA$-diagnosability. $FA$-diagnosability states that the probability that a finite run is unambiguous goes to 1 when its length goes to infinity. Surprisingly, despite the fact that $IA$-diagnosability and $FA$-diagnosability are very close, we prove that $FA$-diagnosability cannot be characterised by the fact that a random run almost surely lies in a $G_\delta$ set. Furthermore we strenghten this result by another inexpressivess result also related to $FA$-diagnosability.

We then introduce partially observable probabilistic visibly pushdown automata (POpVPA), a model generating infinite-state probabilistic systems. We show how to exploit the above characterisations to design a decision procedure for diagnosability in POpVPA. More precisely we show that we can “encode” our characterisations in an enlarged probabilistic VPA and then exploit the decision procedures of [7] leading to an $\text{EXPSPACE}$ algorithm. Since our characterisations are not regular, this requires some tricky machinery. Finally we complete this work by exhibiting an $\text{EXPTIME}$ lower-bound and showing that slight extensions of POpVPA lead to undecidability of the diagnosability problem.

**Organisation.** In Section 2, we successively introduce probabilistic infinite-state systems, equip them with partial observation and faults, and define diagnosability notions. In Section 3, we establish characterisations of the diagnosability notions and inexpressiveness results. We exploit the characterisations to design decision procedures for POpVPA in Section 4, also
proving hardness and undecidability results. We conclude and give some perspectives in Section 5. All the proofs are given in Appendix.

2 Diagnosis specifications of infinite-state probabilistic systems

2.1 Probabilistic labelled transition systems

Probabilistic labelled transition systems (pLTS) are labelled transition systems equipped with probability distributions on transitions outgoing from a state.

> **Definition 1.** A pLTS is a tuple \( M = (Q, q_0, \Sigma, T, P) \) where:

- \( Q \) is a finite or countable set of states with \( q_0 \in Q \) the initial state;
- \( \Sigma \) is a finite set of events;
- \( T \subseteq Q \times \Sigma \times Q \) is a set of transitions;
- \( P : T \to Q_{\geq 0} \) is the transition probability fulfilling: \( \forall q \in Q, \sum_{(q,a,q') \in T} P[q,a,q'] = 1 \).

Given a pLTS \( M \), the transition relation of the underlying LTS \( \mathcal{L} \) is defined by \( q \xrightarrow{a} q' \) for \( (q,a,q') \in T \); this transition is then said to be enabled in \( q \). In order to emphasise the relation between the pLTS and the LTS, we sometimes write \( M = (\mathcal{L}, P) \). Note that since we assume the state space to be at most countable, a pLTS is by definition at most countably branching: from every state \( q \), there are at most countably many transitions enabled in \( q \).

> **Example 2.** The pLTS of Figure 1 represents a server that accepts jobs (event \( \text{in} \)) until it randomly decides to serve the jobs (event \( \text{serve} \)). When a job is done the result is delivered (event \( \text{out} \)). When all jobs are done, the server waits for a new batch of jobs. However randomly, the server may trigger a fault (event \( f \)) and then abort all remaining jobs (event \( \text{abort} \)). Afterwards, the server is reset (event \( \text{reset} \)). In the figure, the label of a transition \((q,a,q')\) is depicted as \( P[q,a,q'] \cdot a \).

![Figure 1 An infinite-state pLTS.](image)

Let us now introduce some important notions and notations that will be used throughout the paper. A run \( \rho \) of a pLTS \( M \) is a (finite or infinite) sequence \( \rho = q_0a_0q_1 \ldots \) such that for all \( i, q_i \in Q, a_i \in \Sigma \) and when \( q_{i+1} \) is defined, \( q_i \xrightarrow{a_i} q_{i+1} \). The notion of run can be generalised, starting from an arbitrary state \( q_0 \). We write \( \Omega \) for the set of all infinite runs of \( M \) starting from \( q_0 \), assuming the pLTS is clear from context. When it is finite, \( \rho \) ends in a state \( q \) and its length, denoted \(|\rho|\), is the number of events occurring in it. Given a finite run \( \rho = q_0a_0q_1 \ldots q_n \) and a (finite or infinite) run \( \rho' = q_n a_n q_{n+1} \ldots \), we call concatenation of \( \rho \) and \( \rho' \) and we write \( \rho \rho' \) the run \( qa_0q_1 \ldots q_n a_n q_{n+1} \ldots \); the run \( \rho \) is then a prefix of \( \rho \rho' \), which we denote \( \rho \preceq \rho \rho' \). The cylinder defined by a finite run \( \rho \) is the set of all infinite runs that extend \( \rho: C(\rho) = \{ \rho' \in \Omega \mid \rho \preceq \rho' \} \). Cylinders are a basis of open sets for the standard topology on the set of runs (which can be viewed as an infinite tree). One equips a pLTS
with a probability measure on $\Omega$ with $\sigma$-algebra being $\mathcal{B}$, the set of Borel sets, and which is uniquely defined by Caratheodory’s extension theorem from the probabilities of the cylinders:

$$P(C(\sigma_0q_0q_1\ldots q_n)) = P[q_0, q_1, \ldots, q_n] .$$

We will sometimes omit the $\Sigma$ words inductively:

We consider this measure in the sequel.

The sequence associated with $\rho = q_0q_0q_1\ldots$ is the word $\sigma_\rho = q_0q_1\ldots$, and we write indifferently $q \xrightarrow{\rho} q'$ or $q \xrightarrow{\sigma_\rho} q'$ (resp. $q \xrightarrow{\rho^*} q'$ or $q \xrightarrow{\sigma_\rho^*} q'$) for an infinite (resp. finite) run $\rho$. A state $q$ is reachable from $q_0$ if there exists a run such that $q_0 \xrightarrow{\rho} q'$, which we alternatively write $q_0 \xrightarrow{\sigma_\rho} q'$. The (infinite) language of pLTS $\mathcal{M}$ consists of all infinite strings that label runs of $\mathcal{M}$ and is formally defined as $L^\omega(\mathcal{M}) = \{ \sigma \in \Sigma^\omega | q_0 \xrightarrow{\sigma^*} \}$.

### 2.2 Partial observation and faults

The observation of a pLTS is given by a mask function. This function projects every event to its observation. This observation is partial as an event can have no observation or shares its observation with another event, but it is deterministic.

- **Definition 3.** A partially observable pLTS (POpLTS) is a tuple $\mathcal{N} = \langle \mathcal{M}, \Sigma_0, \mathcal{P} \rangle$ consisting of a pLTS $\mathcal{M}$ equipped with a mapping $\mathcal{P} : \Sigma \rightarrow \Sigma_0 \cup \{ \varepsilon \}$ where $\Sigma_0$ is the set of observations.

Note that our setting generalizes most existing frameworks of fault diagnosis by considering a mask function $\mathcal{P}$ onto a possibly different alphabet rather than a partition of the event alphabet into observable and unobservable events. An event $a \in \Sigma$ is said unobservable if $\mathcal{P}(a) = \varepsilon$, fully observable if $\mathcal{P}(a) \neq \varepsilon$ and $\mathcal{P}^{-1}(\{ \mathcal{P}(a) \}) = \{ a \}$ and partially observable if $\mathcal{P}(a) \neq \varepsilon$ and $|\mathcal{P}^{-1}(\{ \mathcal{P}(a) \})| > 1$. The set of unobservable events is denoted $\Sigma_u$.

Let $\sigma \in \Sigma^*$ be a finite word; its length is denoted $|\sigma|$. The mapping $\mathcal{P}$ is extended to finite words inductively: $\mathcal{P}(\varepsilon) = \varepsilon$ and $\mathcal{P}(\sigma a) = \mathcal{P}(\sigma)\mathcal{P}(a)$. We say that $\mathcal{P}(\sigma)$ is the mask of $\sigma$. Write $|\mathcal{P}(\sigma)|$. When $\sigma$ is an infinite word, its mask is the limit of the masks of its finite prefixes. This mask function is applicable to runs via their associated sequence; it can be either finite or infinite. As usual the mask function is extended to languages. With respect to $\mathcal{P}$, a POpLTS $\mathcal{N}$ is convergent if there is no infinite sequence of unobservable events from any reachable state: $L^\omega(\mathcal{M}) \cap \Sigma^* \Sigma_u^\omega = \emptyset$. When $\mathcal{N}$ is convergent, for every $\sigma \in L^\omega(\mathcal{M})$, $\mathcal{P}(\sigma) \in \Sigma_0^\omega$. In the rest of the paper we assume that POpLTS are convergent. $\mathcal{P}$ can also be viewed as a mapping from runs to $\Sigma_0^\omega$ by defining $\mathcal{P}(q_0a_0q_1a_1\ldots) = \mathcal{P}(a_0a_1\ldots)$. Remark that this mapping is continuous. We will refer to a sequence for a finite or infinite word over $\Sigma$, and an observed sequence for a finite or infinite sequence over $\Sigma_0$. Clearly, the application of the mask function onto $\Sigma_0$ of a sequence yields an observed sequence.

The observable length of a run $\rho$ denoted $|\rho|_o \in \mathbb{N} \cup \{\infty\}$, is the number of observable events that occur in it: $|\rho|_o = |\sigma|_o$. A signalling run is a finite run whose last event is observable. Signalling runs are precisely the relevant runs w.r.t. partial observation issues since each observable event provides an additional information about the execution to an external observer. Given states $q, q'$ and an observed sequence $\sigma \in \Sigma_0^\omega$, we write $q \xrightarrow{\sigma} q'$ if there is a signalling run from $q$ to $q'$ with observed sequence $\sigma$.

In the sequel starting from the initial state $q_0$, $\text{SR}$ denotes the set of signalling runs, and $\text{SR}_n$ the set of signalling runs of observable length $n$. Since we assume that the POpLTS are convergent, for all $n > 0$, $\text{SR}_n$ is equipped with a probability distribution defined by assigning measure $P(\rho)$ to each $\rho \in \text{SR}_n$. Given $\rho$ a finite or infinite run, and $n \leq |\rho|_o$, $\rho_{1n}$ denotes the
signalling subrun of $\rho$ of observable length $n$. For convenience, we consider the empty run $q_0$ to be the single signalling run, of null length.

### 2.3 Fault diagnosis for POpLTS

To model the problem of fault diagnosis in POpLTS, we assume the event alphabet $\Sigma$ contains a special event $f \in \Sigma$ called the fault. A run $\rho$ is then said to be faulty if its associated sequence of events contains a fault, i.e. $\sigma_\rho \in \Sigma^*f\Sigma^*$; otherwise it is correct. The set of faulty (resp. correct) runs is denoted $F$ (resp. C). For $n \in \mathbb{N}$, we write $F_n$ for the set of runs $\rho$ such that $\rho_{\leq n}$ is faulty and $C_n$ for the set of runs $\rho$ such that $\rho_{\leq n}$ is correct. By definition, for all $n$, $\Omega = F_n \cup C_n$, $F = \bigcup_{n \in \mathbb{N}} F_n$ and $C = \bigcap_{n \in \mathbb{N}} C_n$.

In order to reason about faults we partition sequences of observations into three subsets: an observed sequence $\sigma \in \Sigma^*$ is surely correct if $P^{-1}(\sigma) \cap L^\omega(M) \subseteq (\Sigma \setminus f)^\omega$; it is surely faulty if $P^{-1}(\sigma) \cap L^\omega(M) \subseteq \Sigma^*f\Sigma^\omega$; otherwise, it is ambiguous. For finite sequences, we need to rely on signalling runs: a finite observed sequence $\sigma \in \Sigma^*$ is surely faulty (resp. surely correct) if for every signalling run $\rho$ with $P(\sigma_\rho) = \sigma$, $\rho$ is faulty (resp. correct); otherwise it is ambiguous. A (finite signalling or infinite) run $\rho$ is surely faulty (resp. surely correct, ambiguous) if $P(\rho)$ is surely faulty (resp. surely correct, ambiguous).

In order to specify various requirements for diagnosability we need to refine the notion of ambiguity. Let $N$ be a POpLTS and $n \in \mathbb{N}$ with $n \geq 1$. Then:

- $F_{\text{Amb}}(\text{infty})$ (resp. $C_{\text{Amb}}(\text{infty})$) is the set of infinite faulty (resp. correct) ambiguous runs of $N$;
- $F_{\text{Amb}}(n)$ (resp. $C_{\text{Amb}}(n)$) is the set of infinite runs of $N$ whose signalling subrun of observable length $n$ is faulty (resp. correct) and ambiguous;

At this point it is interesting to look at the status of the different subsets of runs we have introduced with respect to the Borel hierarchy. The complementary sets $F_n$ and $C_n$ are unions of cylinders; so they are open (and by complementation) closed sets. The set of faulty (resp. correct) runs $F$ (resp. $C$) is an open (resp. closed) set as a union (resp. intersection) of open (resp. closed) sets. The sets $F_{\text{Amb}}(n)$ and $C_{\text{Amb}}(n)$ are unions of cylinders; so they are open. The sets $F_{\text{Amb}}(\text{infty})$ and $C_{\text{Amb}}(\text{infty})$ may be defined as follows. Consider $(\Sigma^2)^\omega$ and $\Omega^2$ both equipped with the product topology. $\text{SameObs} = \{(\sigma, \sigma') \mid P(\rho) = P(\rho')\}$ is the inverse image by a continuous mapping of the closed set $\{(\sigma, \sigma) \mid \sigma \in \Sigma^\omega\}$. Therefore $\text{SameObs}$ is closed. Thus $C \times F \cap \text{SameObs}$ is a Borel set. The first and second projections are exactly $C_{\text{Amb}}(\text{infty})$ and $F_{\text{Amb}}(\text{infty})$ which establishes that these sets are analytic sets (i.e. continuous images of Borel sets). The set of analytic sets is a strict superset of Borel sets but every analytic set is still measurable w.r.t. the complete measure [12, 2H8 p.83].

In the context of finite POpLTS, we introduced four possible specifications of diagnosability [3]. There are two discriminating criteria: whether the non ambiguity requirement holds for faulty runs only or for all runs, and whether ambiguity is defined at the infinite run level or for longer and longer finite signalling subruns. Let $N$ be a POpLTS. Then:

- $N$ is $\text{IF-diagnosable}$ if $P(F_{\text{Amb}}(\text{infty})) = 0$.
- $N$ is $\text{IA-diagnosable}$ if $P(F_{\text{Amb}}(\text{infty}) \cup C_{\text{Amb}}(\text{infty})) = 0$.
- $N$ is $\text{FF-diagnosable}$ if $\limsup_{n \to \infty} P(F_{\text{Amb}}(n)) = 0$.
- $N$ is $\text{FA-diagnosable}$ if $\limsup_{n \to \infty} P(F_{\text{Amb}}(n) \cup C_{\text{Amb}}(n)) = 0$.

We recall in the next theorem all the implications that hold between these definitions. Missing implications do not hold, already for finite-state POpLTS.

> **Theorem 4** ([3]). Let $N$ be a POpLTS. Then

- $N$ $\text{FA-diagnosable} \Rightarrow N$ $\text{IA-diagnosable}$ and $\text{FF-diagnosable}$;
- $N$ $\text{IA-diagnosable}$ or $\text{FF-diagnosable} \Rightarrow N$ $\text{IF-diagnosable}$;
If \( \mathcal{N} \) is finitely branching, then \( \mathcal{N} \) is IF-diagnosable iff \( \mathcal{N} \) is FF-diagnosable.

In order to illustrate the different kinds of diagnosability, we describe below some discriminating examples.

Consider the POPLTS \( \mathcal{N} \) on the left of Figure 2 where \( \{u, f\} \) is the set of unobservable events (represented by dashed arrows) and \( \mathcal{P} \) is the identity over the other events. A faulty run will almost surely produce a \( b \)-event that cannot be mimicked by the single correct run. Thus this POPLTS is IF-diagnosable. The unique correct run \( \rho = q_0q_1a_q \ldots \) has probability \( \frac{1}{2} \) and its corresponding observed sequence \( a^\omega \) is ambiguous. Thus the POPLTS is not IA-diagnosable. This simple example shows that, already for finite-state POPLTS, IF-diagnosability does not imply IA-diagnosability.

Similarly, let us look at the POPLTS on the right of Figure 2 where \( \{u, f\} \) is the set of unobservable events and \( \mathcal{P} \) is the identity over the other events. Any infinite faulty run will contain a \( b \)-event, and cannot be mimicked by a correct run, therefore \( FA_{\text{Amb}} = \emptyset \). The two infinite correct runs have \( a^\omega \) as observed sequence, and cannot be mimicked by a faulty run, thus \( CA_{\text{Amb}} = \emptyset \). As a consequence, this POPLTS is IA-diagnosable. Consider now the infinite correct run \( \rho = q_0q_1a_q \ldots \). It has probability \( \frac{1}{2} \), and all its finite signalling subruns are ambiguous since their observed sequence is \( a^n \), for some \( n \in \mathbb{N} \). Thus for all \( n \geq 1 \), \( P(CA_{\text{Amb}}) \geq \frac{1}{2} \), so that this POPLTS is not FA-diagnosable.

3 Characterisation of diagnosability

The aim of this section is to establish “simple” characterisations of the diagnosability notions for a POPLTS \( \mathcal{N} = (\mathbb{L}, \mathcal{P}, \Sigma_o, \mathcal{P}) \) and more precisely to study whether one can express it as a Borel set \( B \in \mathcal{B} \) only depending on the underlying LTS \( \mathbb{L} \) and the mask function \( \mathcal{P} \), such that almost surely a random run belongs to \( B \) if and only if \( \mathcal{N} \) is diagnosable. Furthermore if possible, one looks for a set \( B \) belonging to a lower level of the Borel hierarchy. Observe that for all notions, this requires some machinery since the finite runs-based notions FF and FA are expressed by a family of Borel sets and the infinite runs-based notions IF and IA are expressed by a set which is not a priori a Borel set.

Pursuing this goal, we introduce a language \textbf{pathL} for specifying Borel sets of runs. It is based on \textit{path formulae}. A path formula \( \alpha \) is a predicate over finite prefixes of runs. The (pseudo-)syntax of a formula of \textbf{pathL} is:

\[
\phi ::= \alpha \mid \neg \phi \mid \phi_1 \land \phi_2 \mid \diamond \phi
\]

where \( \alpha \) is a path formula. In the sequel we use the standard shortcut \( \Box \phi \equiv \neg \diamond \neg \phi \).

A formula is evaluated at some position \( k \) of a run \( \rho = q_0a_0q_1 \ldots \). The semantics of \textbf{pathL} is inductively defined by:

\begin{itemize}
  \item \( \rho, k \Vdash \alpha \) if and only if \( \alpha(\rho[0, k]) \);
  \item \( \rho, k \Vdash \neg \phi \) if and only if \( \rho, k \not\Vdash \phi \);
\end{itemize}
\( \rho, k = \phi_1 \land \phi_2 \) if and only if \( \rho, k = \phi_1 \) and \( \rho, k = \phi_2 \);

\( \rho, k = \Diamond \phi \) if and only if there exists \( k' \geq k \) such that \( \rho, k' = \phi \).

Finally \( \rho = \phi \) if and only if \( \rho, 0 = \phi \). Due to the presence of path formulae (with no restriction) this language subsumes LTL and more generally any \( \omega \)-regular specification language. In order to reason about the probabilistic behaviour of a POpLTS, we introduce qualitative probabilistic formulae \( \mathbb{P}^{wp}(\phi) \) with \( \ast \in \{<, >, =\} \), \( p \in \{0, 1\} \) and \( \phi \in \text{pathL} \). The semantics is obvious: \( N = \mathbb{P}^{wp}(\phi) \) if and only if \( \mathbb{P}^{\mathcal{N}}(\{ \rho \in \Omega \mid \rho = \phi \}) = p \). Since \( \text{pathL} \) is closed by complementation the probabilistic formulae can be restricted to \( \mathbb{P}^{\text{a}=0}(\phi) \) and \( \mathbb{P}^{\text{a}=0}(\phi) \).

Let us give some examples of path formulae. Given a finite run \( \rho = q_0a_0q_1 \ldots q_k \), let \( \mathbf{f} \) be defined by \( \mathbf{f}(\rho) = \text{true} \) if \( a_i = \mathbf{f} \) for some index \( i \). This path formula characterises the faulty finite runs. Let \( \Omega \) be defined by \( \Omega(\rho) = \text{true} \) if there exists a correct signalling run \( \rho' \) with \( \mathcal{P}(\rho) = \mathcal{P}(\rho') \). Using the path formulae \( \mathbf{f} \) and \( \Omega \), we exhibit a formula of \( \text{pathL} \) that characterises FF-diagnosability.

\[ \text{Proposition 5.} \quad \text{Let } N \text{ be a POpLTS. Then } N \text{ is FF-diagnosable iff } N = \mathbb{P}^{\text{a}=0}(\Diamond \square (\mathbf{f} \land \Omega)) \]

Due to Theorem 4, in finitely-branching POpLTS the above characterisation also holds for IF-diagnosability. We also need the finitely-branching assumption in order to characterise IA-diagnosability. To this goal, let us introduce a more intricate path formula. For \( \sigma \in \Sigma^* \), we define \( \text{firstf}(\sigma) \) by \( \text{firstf}(\sigma) = \min(\{k \mid \exists \rho \text{ signalling run } \mathcal{P}(\rho) = \sigma \land \rho_k \text{ is faulty}\}) \) with the convention that \( \text{min}(\emptyset) = \infty \). Then the path formula \( \mathbf{m} \) is defined by: \( \mathbf{m}(\varepsilon) = \text{false} \) and \( \mathbf{m}(q_0a_0 \ldots q_{n+1}) = \text{true} \) if \( \text{firstf}(\mathcal{P}(q_0a_0 \ldots q_{n+1})) = \text{firstf}(\mathcal{P}(q_0a_0 \ldots q_n)) < \infty \).

\[ \text{Proposition 6.} \quad \text{Let } N \text{ be a finitely branching POpLTS. Then } N \text{ is IA-diagnosable iff } N = \mathbb{P}^{\text{a}=0}(\Diamond \square (\Omega \land \mathbf{m})) \]

An infinitely-branching IA-diagnosable POpLTS.

The POpLTS of Figure 3 illustrates the necessity of the finitely-branching requirement in Proposition 6. \( \{u, \mathbf{f}\} \) is the set of unobservable events and \( \mathcal{P} \) is the identity over the other events. Observation \( b \) occurs in every infinite correct run, while the observed sequence of the single infinite faulty run is \( a^\omega \). This POpLTS is thus IA-diagnosable. However, it does not satisfy \( \mathbb{P}^{\text{a}=0}(\Diamond \square (\Omega \land \mathbf{m})) \) since the unique infinite faulty run has probability \( \frac{1}{2} \) and satisfies \( \square \Omega \). Indeed for every \( n \in \mathbb{N} \), there is a correct signalling run with observed sequence \( a^n \).

Observe that the sets of runs specified by the characterisations of FF-diagnosability \( \Diamond \square (\mathbf{f} \land \Omega) \) and IA-diagnosability \( \Diamond \square (\Omega \land \mathbf{m}) \) are \( F^*_\sigma \) sets, i.e. countable unions of closed sets. Surprisingly, we show that such a characterisation is impossible for FA-diagnosability.

\[ \text{Proposition 7.} \quad \text{There exists a finitely-branching LTS } \mathcal{L} \text{ and a mask function } \mathcal{P} \text{ such that for every } F^*_\sigma \text{ set } E \text{ of runs, there exists a POpLTS } N = ((\mathcal{L}, \mathcal{P}), \Sigma_0, \mathcal{P}) \text{ such that:} \]

\( \text{either } N \text{ is FA-diagnosable and } \mathbb{P}_N(E) > 0; \)

\( \text{or } N \text{ is not FA-diagnosable and } \mathbb{P}_N(E) = 0. \)
We conjecture that the previous impossibility result also holds for all Borel sets. The next proposition shows that a positive probability condition (instead of a null condition) may not exist whatever the Borel set.

**Proposition 8.** There exists a finitely-branching LTS \( \mathcal{L} \) and a mask function \( \mathcal{P} \) such that for every Borel set \( E \) of runs, there exists a POpLTS \( \mathcal{N} = ((\mathcal{L}, \mathcal{P}), \Sigma_0, \mathcal{P}) \) such that:

- either \( \mathcal{N} \) is FA-diagnosable and \( \mathbb{P}_{\mathcal{N}}(E) = 0; \)
- or \( \mathcal{N} \) is not FA-diagnosable and \( \mathbb{P}_{\mathcal{N}}(E) > 0. \)

### 4 Diagnosis for probabilistic pushdown automata

We now turn to a concrete model for infinite-state POPLTS, namely the ones generated by probabilistic pushdown automata. Among probabilistic infinite-state systems the ones generated by probabilistic pushdown automata (POpVPA). To do so, we face the difficulty that the Borel sets that characterise IF-, IA- and IF-diagnosability are not a priori regular, even in the finite branching case. Yet, for POpVPA, we circumvent this problem, and manage to specify these sets by pLTL formula on a determinisation of the model, tagged with the needed atomic propositions. The decidability of the qualitative model checking for recursive probabilistic systems [7] then yields the decidability of the above three diagnosability notions for POpVPA.

#### 4.1 Probabilistic visibly pushdown automata

Among probabilistic infinite-state systems the ones generated by probabilistic pushdown automata [10, 7] support relevant decision procedures. Already in the non-probabilistic case, the subclass of visibly pushdown automata (VPA) [1] is more tractable than the general model. In VPA, the type of events determines whether the operation on the stack is a push, a pop, or possibly changes the top stack symbol, so that the languages defined by VPA enjoy most of the desirable properties regular languages have.

**Definition 9.** A probabilistic visibly pushdown automaton (pVPA) is a tuple \( A = (Q, \Sigma, \Gamma, \delta, \mathcal{P}) \) where:

- \( Q \) is a finite set of control states with \( q_0 \) the initial state;
- \( \Sigma \) is a finite alphabet of events, partitioned into local, push and pop events \( \Sigma = \Sigma_1 \cup \Sigma_2 \cup \Sigma_3 \).
- \( \Gamma \) is a finite alphabet of stack symbols including a set of bottom stack symbols \( \Gamma_\bot \) with initial symbol \( \bot_0 \in \Gamma_\bot; \)
- \( \delta \subseteq Q \times \Gamma \times \Sigma \times Q \times \Gamma^* \) is the set of transitions such that for every \( (q, \gamma, a, q', w) \in \delta, |w| \leq 2, \)
  \( \gamma \in \Gamma_\bot \) implies \( w \in \Gamma_\bot (\Gamma \setminus \Gamma_\bot)^* \) and \( \gamma \notin \Gamma_\bot \) implies \( w \in (\Gamma \setminus \Gamma_\bot)^* \);
- \( \mathcal{P} \) is the transition probability function fulfilling for every \( q \in Q \) and \( \gamma \in \Gamma: \)
  \( \sum_{(q, \gamma, a, q', w) \in \delta} \mathcal{P}[(q, \gamma, a, q', w)] = 1. \)

A transition \( t = (q, \gamma, a, q', w) \in \delta \) is said to be a local (resp. push, pop) transition if \( |w| = 1 \) (resp. \( |w| = 2, |w| = 0 \)). We require that for every transition \( t = (q, \gamma, a, q', w) \in \delta, t \) is a local (resp. push, pop) transition iff \( a \) is a local (resp. push, pop) event.

The semantics of a pVPA is an infinite-state pLTS whose states are pairs \( (q, z) \) consisting of a control state and a stack contents.

**Definition 10.** A pVPA \( \mathcal{V} = (Q, \Sigma, \Gamma, \delta, \mathcal{P}) \) defines a pLTS \( \mathcal{M}_\mathcal{V} = (Q_\mathcal{V}, (q_0, \bot_0), \Sigma, T_\mathcal{V}, \mathcal{P}_\mathcal{V}) \) where:

- \( Q_\mathcal{V} = \{(q, z) \mid q \in Q \land z \in \Gamma_\bot (\Gamma \setminus \Gamma_\bot)^* \}; \)
To obtain an algorithm for the diagnosability of POpVPA, we follow the finite-state case.

**Example 11.** Figure 4 gives an example of a pVPA. The event alphabet is composed of local events \(\{serve, empty, reset\}\), a push event \(in\) and pop events \(\{out, f, abort\}\). A transition \(t = (q, \gamma, a, q', w)\) is represented by an edge from state \(q\) to state \(q'\) and labelled by \(P[t] \cdot \gamma, a, w\). The semantics of this pVPA is precisely the pLTS from Figure 1. Indeed, the stack alphabet consists of two letters \(\Gamma = \{\gamma, 1_0\}\) where the set of bottom stack symbol is \(\Gamma_B = \{1_0\}\). Thus one can encode the stack using a counter that gives the number of \(\gamma\) in the stack. For instance, in the pLTS from Figure 1 the configuration \((q_1, 1_0, \gamma^n)\) of the pVPA corresponds to the state \(q_{1n}\).

\[\begin{array}{c}
q_0\xrightarrow{\gamma, in, 1_0}\gamma q_0
\xrightarrow{\gamma, serve, 1_0}\gamma q_1
\xrightarrow{\gamma, out, 1_0}\gamma q_1
\xrightarrow{\gamma, abort, 1_0}\gamma q_1
\end{array}\]

**Figure 4** A pVPA generating the pLTS from Figure 1 with two finite runs.

To define partially observable pVPA, we equip a pVPA with a mask function and require that only local events may be unobservable, and that pushes and pops can still be distinguished. Thus, the observed sequence of a signalling run of a POpVPA still provides the information about the height of the stack since it is equal to the difference of pushes and pops, plus one.

**Definition 12.** A partially observable pVPA (POpVPA) is a tuple \(\langle \mathcal{V}, \Sigma_o, P \rangle\) consisting of a pVPA \(\mathcal{V}\) equipped with a mapping \(P : \Sigma \rightarrow \Sigma_o \cup \{\varepsilon\}\) such that:

- \(\Sigma_o = \Sigma_{o,b} \cup \Sigma_{o,f} \cup \Sigma_{o,\varepsilon}\) is the set of observations;
- \(P(\Sigma_f) \subseteq \Sigma_{o,b} \cup \{\varepsilon\}\), \(P(\Sigma_g) \subseteq \Sigma_{o,f}\) and \(P(\Sigma_i) \subseteq \Sigma_{o,\varepsilon}\).

In the sequel, we may identify a POpVPA with the POpLTS it generates. In particular, the various concepts of diagnosability are lifted from POpLTS to POpVPA.

### 4.2 Complexity of diagnosability for POpVPA

To obtain an algorithm for the diagnosability of POpVPA, we follow the finite-state case approach [3]. First, we determinise POpVPA \(\mathcal{V}\) into \(\mathcal{A}(\mathcal{V})\), with the diagnosis objective in mind, building on the deterministic automaton recognising unambiguous sequences from [8]. We therefore introduce tags that reflect the category of runs (faulty or correct) given an observed sequence with a distinction between “old” and “young” faulty runs. It then suffices to check whether the characterisations hold on the synchronised product \(\mathcal{V} \times \mathcal{A}(\mathcal{V})\) where \(\mathcal{V}\) enlarges \(\mathcal{V}\) by keeping track of a fault occurrence. To reduce to a decidable model checking question, we specify the Borel sets from Section 3 by LTL formulae.
Diagnosis-oriented determinisation. The determinisation of $\mathcal{V}$ (where probabilities are irrelevant for this transformation) into $\mathcal{A}(\mathcal{V})$ exploits some ideas of the original determinisation by Alur and Madhusudan [1], yet, it is customised to diagnosis. In particular, it uses tags that were first defined to construct a deterministic Büchi automaton recognising the unambiguous sequences of a finite LTS [8]. The complete definition of $\mathcal{A}(\mathcal{V})$ is postponed to Appendix B.1. We emphasise here some aspects of the construction and illustrate them on an example.

$$a_0^X = \left\{ \frac{X_{q_0}}{X \in 1} \right\}, a_1^X = \left\{ \frac{X_{q_1}}{X \in 1} \right\}, a_0^X = \left\{ \frac{X_{q_0}}{X \in 1} \right\}, b_1^X = \left\{ \frac{X_{q_1}}{X \in 1} \right\}, b_0^X = \left\{ \frac{X_{q_0}}{X \in 1} \right\}$$

$$X_0 = \left\{ \frac{X_{q_0}}{X \in 1} \right\}, \gamma, X_1 = \left\{ \frac{X_{q_1}}{X \in 1} \right\}$$

$\mathcal{V} \times \mathcal{A}(\mathcal{V})$. The POpVPA $\mathcal{V}$ of Figure 4 with two runs.

\begin{align*}
\text{(run, } \{U_{q_0}, W_{f_1} \} \text{ }) & \overset{\text{in}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) \overset{\text{in}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) \overset{\text{serve}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) \\
\text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) & \overset{\text{pop}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) \overset{\text{empty}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ }) \overset{\text{reset}}{\rightarrow} \text{(run, } \left\{ \frac{U_{q_0}}{\gamma}, \frac{W_{f_1}}{\gamma} \right\} \text{ })
\end{align*}

**Figure 5** The VPA $\mathcal{A}(\mathcal{V})$ associated with the POpVPA $\mathcal{V}$ of Figure 4 with two runs.

States and stack symbols. The VPA $\mathcal{A}(\mathcal{V})$ tracks all runs with same observation in parallel memorising their status w.r.t. faults. More precisely to the current set of runs corresponds the symbol on the top of the stack which is a set of tuples where each tuple is written as a fraction $X_{q^*}$. Let us describe the meaning of this tuple:

- $q$ is the current state of the run and $\gamma$ is the symbol on the top of its stack;
- $X \in \text{Tg} = \{ U, V, W \}$ is the status of the run: $U$ for a correct run, $V$ for a young faulty run and $W$ for an old faulty run;
- The denominator $(\gamma^-, X^-, q^-)$, is related to the configuration just after the last push event of the run: $\gamma^-$ is the stack symbol under the top symbol, while $X^-$ is the status of the run reaching this configuration and $q^-$ the state of this configuration.

A priori, a single state $\text{run}$ would be enough. However the simulation of a pop event in the original VPA is performed in two steps requiring some additional states that we explain later.
Illustration. The initial configuration of the VPA $A(V)$ of Figure 5 (run, $\{\frac{1}{2}U, q_0]\}$) corresponds to the empty run represented by a singleton. The denominator of bottom stack symbols is by convention $(t_0, U, q_0)$ and is irrelevant for specifying the transitions of $A(V)$.

Tag updates. Let us explain how the tag $X$ of an item $\frac{X}{\gamma^2 \cdot q^2}$ of the current stack symbol is determined. If this item corresponds to a correct run then $X = U$. When, in a current state, after a transition of $A(V)$ a (tracked) correct run becomes faulty in the next state, there are two cases. Either there was no tag $W$ in (the numerators of items of) the top stack symbol of the current state then the run is tagged by $W$. Otherwise it is tagged by $V$ meaning that it is a young faulty run. The tag $V$ (young) becomes $W$ (old) when, in the previous state, there was no tag $W$ in the top stack symbol. A tag $W$ is unchanged along the run.

Push transitions. Given an observed push event $o \in \Sigma_{o,1}$, from the control state run with top stack symbol $bel$, there is a looping push transition (run, $\{\frac{1}{2}, U, q_0\}$, $o$, run, $\{\frac{1}{2}, U, q_0\}$) in $A(V)$ that encodes the possible signalling runs with observation $o$ in $\mathcal{V}$. More precisely for every transition sequence $(q, \alpha) \rightarrow (r, \beta)$ in $\mathcal{V}$ (i.e. a sequence of unobservable local events ended by an event $e$ with $\mathcal{P}(e) = 0$ and $\frac{\alpha X q}{\gamma^2 \cdot q}$ $\in$ bel one inserts $\frac{\beta Y r}{\alpha X q}$ in $bel'$). The value of $\mathcal{Y}$ follows the rules of tag updates.

Illustration. In Figure 5 several transitions correspond to the transition $(q_0, 1, o, in, q_0, 1)$ of $\mathcal{V}$, including (run, $\{\frac{1}{2}, U, q_0\}$, in, run, $\{\frac{1}{2}, U, q_0\}$) and several transitions correspond to the transition $(q_0, \gamma, in, q_0, \gamma)$ of $\mathcal{V}$, including (run, $\{\gamma, U, q_0\}$, in, run, $\{\gamma, U, q_0\}$). Here, the specification of the tag updates is straightforward since it does not involve faulty runs. The runs represented in Figure 5 use these two transitions from the initial state.

Local transitions. Given an observed local event $o \in \Sigma_{o,1}$, from the control state run with top stack symbol $bel$, there is a looping local transitions (run, $\{\frac{1}{2}, U, q_0\}$, $o$, run, $\{\frac{1}{2}, U, q_0\}$) in $A(V)$ that encodes the possible signalling runs with observation $o$ in $\mathcal{V}$. More precisely for every transition sequence $(q, \alpha) \rightarrow (r, \beta)$ in $\mathcal{V}$ (i.e. a sequence of unobservable local events ended by an event $e$ with $\mathcal{P}(e) = 0$ and $\frac{\alpha X q}{\gamma^2 \cdot q}$ $\in$ bel one inserts $\frac{\beta Y r}{\alpha X q}$ in $bel'$). The value of $\mathcal{Y}$ follows the rules of tag updates.

Illustration. In the VPA $A(V)$ of Figure 5 there are several transitions corresponding to transition $(q_0, \gamma, serve, q_1, \gamma)$ of $\mathcal{V}$ including (run, $\{\gamma, U, q_0\}$, serve, run, $\{\gamma, U, q_0\}$). The runs represented in Figure 5 use this transition.

Pop transitions. Given an observed local event $o \in \Sigma_{o,1}$, from the control state run with top stack symbol $bel$, the “pop operation” is performed by a sequence of two transitions: a pop transition labelled by $o$ that keeps in the next state all the information needed by the next (local) transition labelled by $\varepsilon$ to move back to state run with a consistent stack symbol. Given an intermediate stack symbol, there is exactly one possible such transition. Thus despite these transitions, $A(V)$ is still deterministic. The first transition (run, $\{\frac{1}{2}, bel, o, \ell, \varepsilon\}$) in $A(V)$ is specified as follows. The next state $\ell$ is a set of items of the following shape $\frac{X o}{\gamma^2 \cdot q}$. More precisely for every transition sequence $(q, o) \rightarrow (r, \varepsilon)$ in $\mathcal{V}$ (i.e. a sequence of unobservable local events ended by an event $e$ with $\mathcal{P}(e) = 0$ and $\frac{\alpha X q}{\gamma^2 \cdot q}$ $\in$ bel one inserts $\frac{\beta Y r}{\alpha X q}$ in $\ell$). The value of $\mathcal{Y}$ follows the rules of tag updates. A transition $(\ell, bel, \varepsilon, \text{run, bel'})$ is specified as follows. For every $\frac{X' o}{\gamma^2 \cdot q}$ in $\ell$ and $\frac{X o}{\gamma^2 \cdot q}$ in $bel$ (i.e. the denominator of the first fraction and the numerator of the second fraction match), one inserts $\frac{X' o}{\gamma^2 \cdot q}$ in $bel'$.

Illustration. Let us describe how the pop event is performed by two transitions in the runs of the VPA of Figure 5 from the state reached after event serve. From $q_1$ with $\gamma$ as top of the stack there are two transitions whose observation is pop: $(q_1, \gamma, out, q_1, \varepsilon)$ and $(q_1, \gamma, \ell, f_1, \varepsilon)$. Thus starting from run with top stack symbol $\{\gamma, U, q_0\}$, one reaches state $\ell = \{\gamma, U, q_0\}$, $W_{f_1}$. The faulty run is tagged with $W$ as there was no tag $W$ in the former top stack symbol. In
Diagnosis in Infinite-State Probabilistic Systems (long version)

the next configuration, the top stack symbol is \( \{ \frac{\gamma U q_0}{1_0 U q_0}, \frac{\gamma W f_0}{1_0 U q_0} \} \). So the transition labelled by \( \varepsilon \) moves back to state \( run \) with updated top stack symbol \( \{ \frac{\gamma U q_0}{1_0 U q_0}, \frac{\gamma W f_0}{1_0 U q_0} \} \).

**Product VPA.** We first define \( \hat{\mathcal{V}} \) whose set of states \( \hat{Q} \) is a duplication of \( Q \) in correct states \( Q_c \) and faulty states \( Q_f \). Given a transition of \( \mathcal{V} \) starting from \( q \) leading to \( q' \), there is in \( \hat{\mathcal{V}} \) a transition starting from \( q_f \) leading to \( q'_f \) and a transition starting from \( q_c \) leading either to \( q'_c \) if the event is not \( f \) or to \( q'_f \) otherwise. We then construct \( \mathcal{V}_{A(V)} = \hat{\mathcal{V}} \times A(V) \) the product automaton of \( \hat{\mathcal{V}} \) and \( A(V) \) synchronised on the alphabet of observed events \( \Sigma_o \).

The transitions of \( \hat{\mathcal{V}} \) labelled by unobservable events do not change the second component of the state and the transitions of \( A(V) \) labelled by \( \varepsilon \) do not change the first component of the state. Due to the determinism of \( A(V) \), \( \mathcal{V}_{A(V)} \) has the same probabilistic behaviour as the one of \( V \) except that it memorises additional information along the run. More precisely, let \( \rho \) be a run of \( V \), then \( \hat{\rho} \), a run of \( \mathcal{V}_{A(V)} \), is obtained from \( \rho \) by following the same transitions and adding the single \( \oplus \) transition firable after any pop transition. One immediately gets \( \mathbb{P}_{\mathcal{V}_{A(V)}}(\hat{\rho}) = \mathbb{P}_V(\rho) \).

Let us explain how to transform the paths formulae \( f, \mathcal{U} \) and \( \mathcal{W} \) into atomic propositions on the pairs \((q, run(\gamma, bel))\) consisting of a control state of \( \mathcal{V}_{A(V)} \) together with a top stack contents. For path formula \( f \), we define the corresponding atomic proposition \( \nu_f \) by \( \nu_f(q, run(\gamma, bel)) = \text{true} \) if and only if \( q \in Q_f \). Let \( bel \subseteq (\Gamma \times \Sigma \times Q)^2 \), we say that \( X \) occurs in \( bel \) if there exists \( \frac{\gamma X_0 q_0}{1_0 X_0 q_0} \in bel \). We define atomic propositions \( \nu_u \) and \( \nu_w \) by: \( \nu_u(q, run(\gamma, bel)) = \text{true} \) if and only if \( U \) occurs in \( bel \); and \( \nu_w(q, run(\gamma, bel)) = \text{true} \) if and only if \( W \) occurs in \( bel \).

Given a run \( \rho \) of \( \mathcal{V}_{A(V)} \), we write \( \text{last}(\rho) \) for the pair formed of the control state and top stack symbol in \( \mathcal{V}_{A(V)} \) after \( \rho \). The atomic propositions \( \nu_f \) and \( \nu_u \) perfectly reflect the paths formula \( f \) and \( U \), and \( \nu_w \) is eventually forever true if and only if \( W \) is.

**Proposition 13.** Let \( \rho \) be an infinite run of \( V \). Then:

- For all \( k \in \mathbb{N} \), \( f(\rho_{ik}) \Leftrightarrow \nu_f(\text{last}(\hat{\rho}_{ik})) \) and \( \mathcal{U}(\rho_{ik}) \Leftrightarrow \nu_u(\text{last}(\hat{\rho}_{ik})) \);
- \( \rho = \bigdiamond \mathcal{W} \Leftrightarrow \exists K \forall k \geq K. \nu_w(\text{last}(\hat{\rho}_{ik})) = \text{true} \).

Thanks to the relationships between the paths formulae, and the atomic propositions, and using the characterisations from Section 3, we manage to reduce the FF-, IF- and IA-diagnosis to the model checking of a pLTL formula on the product VPA \( \mathcal{V}_{A(V)} \). Model checking qualitative pLTL for probabilistic pushdown automata is doable in polynomial space in the size of the model [7]. In our case, \( \mathcal{V}_{A(V)} \) is exponential in the size of \( V \). We thus obtain the decidability and a complexity upper-bound for the diagnosability problems for POpVPA.

**Theorem 14.** FF-diagnosability, IF-diagnosability and IA-diagnosability are decidable in EXPSPACE for POpVPA.

Reducing the universality problem for VPA, which is known to be EXPTIME-complete [1], we obtain the EXPTIME-hardness of all diagnosability variants for POpVPA.

**Theorem 15.** Diagnosability is EXPTIME-hard for POpVPA.

The restriction to visibly pushdown automata is motivates by the unfeasibility of diagnosis for general probabilistic pushdown automata. The undecidability can be obtained by adapting the proof for diagnosis of non-probabilistic pushdown automata [11]. However, in order to show how robust the result is, we rather reduce from the Post Correspondence Problem and prove the undecidability of diagnosability for restricted classes of partially observable probabilistic pushdown automata, see Theorems 23 and 24 in Appendix B.4.
5 Conclusion

We studied the diagnosability problem for infinite-state probabilistic systems, both from a semantical perspective, and from an algorithmic one when considering probabilistic visibly pushdown automata. A natural research aim is to reduce the complexity gap for the diagnosability of POpVPA (currently EXPTIME-hard and in EXPSPACE). We could also investigate the diagnosability problem for other probabilistic extensions infinite state systems, such as lossy channel systems or VASS. Another research direction would be to consider the fault diagnosis problem for continuous-time probabilistic models, starting with CTMC.

References

A Proofs for Section 3

Proposition 5. Let \( \mathcal{N} \) be a POpLTS. Then \( \mathcal{N} \) is FF-diagnosable iff \( \mathcal{N} \models \forall \rho. (\rho \sqcap (f \sqcup \Omega)) \).

Proof. Consider the set of fault-triggering runs:
\[
\mathcal{R} = \{ \rho \in \Omega \mid \rho \sqcap (f \sqcup \Omega) \}.
\]
Write \( E = \{ \rho \in \Omega \mid \rho \sqcap (f \sqcup \Omega) \} \) for the set of runs we are interested in. We further define, for every \( \rho \in \mathcal{R} \), \( E_\rho = \{ \rho' \in \Omega \mid \rho' \sqcap \rho = \sqcap n \Omega \} \) and for every \( n \in \mathbb{N} \), \( E^n_\rho = \{ \rho' \in \Omega \mid \rho' \sqcap \rho = \sqcap n \Omega \} \) where \( \rho = \sqcap n \phi \) if for every \( k \leq n \), \( \rho, k = \phi \). Observe that \( E = \bigcup_{\rho \in \mathcal{R}} E_\rho \) and that \( E_\rho = \cap_{n \in \mathbb{N}} E^n_\rho \). Thus \( \mathbb{P}(E) = \sum_{\rho \in \mathcal{R}} \mathbb{P}(E_\rho) \) and \( \lim_{n \to \infty} \mathbb{P}(E^n_\rho) = \mathbb{P}(E_\rho) \).

- Assume first that \( \mathbb{P}(E) > 0 \). Then, there exists \( \rho \in \mathcal{R} \) such that \( \mathbb{P}(E_\rho) > 0 \). By definition, for every \( n > |\rho|_o \), \( \mathbb{P}(F \text{Amb}_n) \geq \mathbb{P}(E_\rho) \). Thus, \( \mathcal{N} \) is not FF-diagnosable.

- Assume now that \( \mathbb{P}(E) = 0 \). So, for every \( \rho \in \mathcal{R} \), \( \mathbb{P}(E_\rho) = 0 \). Let us pick some \( \epsilon > 0 \). Since \( F = \bigcup_{n \in \mathbb{N}} F_n \), there exists \( n_0 \) such that for every \( n \geq n_0 \), \( \mathbb{P}(F \cap F_n) \leq \frac{\epsilon}{5} \). Let \( \mathcal{R}' = \{ \rho \in \mathcal{R} \mid |\rho|_o \leq n_0 \} \). Pick a finite subset \( \mathcal{R}' \) of \( \mathcal{R} \) such that \( \sum_{\rho \in \mathcal{R}' \setminus \mathcal{R}_o} \mathbb{P}(\rho) \leq \frac{\epsilon}{5} \). Define \( K = |\mathcal{R}'| \). Let \( n_1 \) be such that for every \( n \geq n_1 \) and every \( \rho \in \mathcal{R}' \), \( \mathbb{P}(E^n_\rho) \leq \frac{\epsilon}{5} \). Observe now that for every \( n \geq n_1 \), \( \mathbb{P}(F \text{Amb}_n) \leq \frac{\epsilon}{5} + \frac{\epsilon}{5} + K \frac{\epsilon}{5} = \epsilon \). Since \( \epsilon \) is arbitrary, \( \mathcal{N} \) is FF-diagnosable.

Proposition 6. Let \( \mathcal{N} \) be a finitely branching POpLTS. Then \( \mathcal{N} \) is IA-diagnosable iff \( \mathcal{N} \models \forall \rho. (\rho \sqcap (f \sqcup \Omega \sqcap \Omega)) \).

Proof. It is enough to show that \( \rho \in \Omega \) is ambiguous if and only if \( \rho \models \forall \rho. (\rho \sqcap (f \sqcup \Omega \sqcap \Omega)) \). We focus below on correct runs; the case of faulty runs is similar and even simpler.

- Let \( \rho \in \text{CAmb}_\infty \). Since \( \rho \) is ambiguous, there exists a faulty run \( \rho' \) such that \( \mathbb{P}(\rho') = \mathbb{P}(\rho) \).

Let \( k_0 \) be such that \( \rho|_{k_0} \) is faulty. Thus for all \( k \geq k_0 \), \( \text{first}(\mathbb{P}(\rho|_{k})) < k \) and in addition it is non decreasing. So there exists some \( k_1 \geq k_0 \) such that for all \( k \geq k_1 \), \( \text{first}(\mathbb{P}(\rho|_{k})) \) is constant. We thus obtain \( \rho \models \forall \rho. (f \sqcup \Omega \sqcap \Omega) \). Moreover, since \( \rho \models \forall \rho. (f \sqcup \Omega) \), we conclude that \( \rho \models \forall \rho. (f \sqcup \Omega \sqcap \Omega) \).

- Let \( \rho \) be a correct run such that \( \rho \models \forall \rho. (f \sqcup \Omega \sqcap \Omega) \). Thus there is a position \( k_0 \) such that for all \( k \geq k_0 \), \( \rho, k \in \Omega \). In particular, by definition of \( \Omega \), for all \( k \geq k_0 \), there is a finite signalling run \( \rho(k) \) such that \( \mathbb{P}(\rho(k)) = \mathbb{P}(\rho|_{k_0}) \) and \( \rho|_{k_0} \) is faulty. Consider the tree of these runs \( \rho(k) \) by merging the common prefixes. This tree is finitely branching and infinite. By Kőnig’s lemma, it must admit an infinite branch, corresponding to a run \( \rho' \) with \( \mathbb{P}(\rho') = \mathbb{P}(\rho) \) and \( \rho|_{k_0} \) faulty. We deduce that \( \rho \) is ambiguous.

Let us recall some standard facts about Borel sets and measures. A set \( F \) is closed if and only if \( F = \cap_{n \in \mathbb{N}} O_n \) where \( O_n \) is a union of cylinders defined by \( O_n = \{ C(\rho) \mid |\rho| = n \land 3\rho' \in F, \rho \leq \rho' \} \). Thus an \( F_\sigma \) set \( F \) can be written as \( F = \bigcup_{n \in \mathbb{N}} \cap_{n \in \mathbb{N}} O_{m,n} \) where \( O_{m,n} \) is a union of cylinders whose associated paths have length \( n \). Without loss of generality, the sequence of closed sets may be chosen as a non decreasing sequence. The measures we have defined in the core of the paper are regular. In particular, for every measurable set \( E \) such that \( \mathbb{P}(E) > 0 \), there exists a closed set \( F \subseteq E \) such that \( \mathbb{P}(F) > 0 \).

Proposition 7. There exists a finitely-branching LTS \( \mathcal{L} \) and a mask function \( \mathcal{P} \) such that for every \( F_\sigma \) set \( E \) of runs, there exists a POpLTS \( \mathcal{N} = (\mathcal{L}, \mathcal{P}, \Sigma, \rho) \) such that:

- \( \mathcal{N} \) is FA-diagnosable and \( \mathbb{P}_\mathcal{N}(E) > 0 \);

or \( \mathcal{N} \) is not FA-diagnosable and \( \mathbb{P}_\mathcal{N}(E) = 0 \).

Proof. Consider the LTS \( \mathcal{L} = (Q, \rho_0, \Sigma, T) \) defined as follows and let the mask function be defined by: \( \mathcal{P}(u) = \mathcal{P}(f) = \varepsilon \) and \( \mathcal{P} \) is the identity over the other events.
We consider a family of POpLTS, represented in Figure 6, with underlying LTS \( \Sigma, P \). By definition of \( P \), we observe that for all \( i, j \in \mathbb{N} \), such that \( \frac{1}{2} \cdot b, \frac{1}{2} \cdot a \), \( \frac{1}{2} \cdot f \), \( \frac{1}{2} \cdot u \), \( 1 - p_1 \cdot a \), \( 1 - p_2 \cdot a \), \( p_1 \cdot b \), \( p_2 \cdot b \), \( (1 - p_1) \cdot a \), \( (1 - p_2) \cdot a \), \( q_0 \), \( q_1 \), \( q_2 \), \( \cdots \)

\[ Q = \{ q_i, q_f \} \cup \{ q_i \mid i \in \mathbb{N} \}; \]

\[ \Sigma = \{ a, b, c, u, f \}; \]

\[ T = \{(q_0, u, q_f), (q_0, u, q_1), (q_f, a, q_f), (q_f, b, q_f), (q_f, f, f_1), (f_1, b, f_1), (f_1, c, f_1)\} \cup \{(q_i, a, q_{i+1}), (q_i, b, q_{i+1})\}_{i \geq 1}. \]

\[ \frac{1}{2} \cdot b \quad \frac{1}{2} \cdot a \quad \frac{1}{2} \cdot f \quad \frac{1}{2} \cdot u \quad \frac{1}{2} \cdot u \quad q_0 \quad q_1 \quad q_2 \quad \cdots \]

\( \frac{1}{2} \cdot c \quad \frac{1}{2} \cdot b \]

**Figure 6** A family of POpLTS whose underlying LTS has no appropriate characterisation of FA-diagnostics.

We consider a family of POpLTS, represented in Figure 6, with underlying LTS \( \mathcal{L} \). For \( p = (p_n)_{n \geq 1} \) a sequence of probabilities, we define the POpLTS \( \mathcal{N}_p = (\mathcal{L}, P_p, \Sigma_0, \mathcal{P}) \) in which for every \( n \geq 1 \) the probability that \( b \) occurs from state \( q_n \) is \( P_p(q_n, b, q_{n+1}) = p_n \), and all other probabilities are independent of \( p \): \( P_p(q_0, u, q_f) = P_p(q_0, u, q_1) = P_p(f_1, b, f_1) = P_p(f_1, c, f_1) = \frac{1}{2} \), \( P_p(q_f, a, q_f) = P_p(q_f, b, q_f) = P_p(q_f, f, f_1) = \frac{1}{3} \). Observe that \( \lim_{n \to \infty} P(FAmb_n) = 0 \) and \( P(CAmb_{n-1}) = p_n + \frac{2^{n-1}}{3^{n-1}} \). Therefore, \( \mathcal{N}_p \) is FA-diagnosable iff \( \lim_{n \to \infty} p_n = 0 \).

Let \( E \) be an arbitrary FA set. Pick some FA-diagnosable \( \mathcal{N}_p \) i.e. with \( \lim_{n \to \infty} p_n = 0 \). If \( P_p(E) > 0 \) where \( P_p \) is the probability measure of this POpLTS, we are done. Assume thus that \( P_p(E) = 0 \). In order to define a second POpLTS, via \( p' \), consider an infinite increasing sequence \( \{n_j\}_{j \geq 1} \) and let for \( n \not\in \{n_j\}_{j \geq 1} \), \( p'_n = p_n \) and for \( n \in \{n_j\}_{j \geq 1} \), \( p'_n = \frac{1}{2} \). Due to the sub-sequence \( p'_{n_j} = \frac{1}{2}, \mathcal{N}_{p'} \) is not FA-diagnosable. The sequence \( \{n_j\}_{j \geq 1} \) depends on \( P_p \) and will be defined after some preliminary observations.

Let \( F = \{ p \mid q_0 u q_f \leq p \} \). Denoting \( P'_{p'} \) the probability measure of the second POpLTS, observe that \( P'_{p'}(E \cap F) = P_p(E \cap F) = 0 \). Using the above discussion, the \( F \) set \( E \cap F = \bigcup_{m,n} \bigcap_{m,n} O_{m,n} \) where for all \( m, n, O_{m,n} \) is a disjoint union of cylinders \( C(p) \) with \( |p| = n \), \( O_{m,n} \subseteq O_{m,n} \) and \( O_{m,n} \subseteq O_{m+1,n} \). Denote \( F_m = \bigcap_{n \in \mathbb{N}} O_{m,n} \). For all \( m \), \( \lim_{n \to \infty} P_p(O_{m,n}) = P'_p(E \cap F_m) \leq P_p(E \cap F) = 0 \).

- \( n_1 \) is chosen such that for all \( n \geq n_1, p_n \leq \frac{1}{2} \). Observe now that for all \( n_j \),

\[ p'_{n_j} = \frac{1}{2} \cdot \frac{1}{2^{p_{n_j}}} - 1 \cdot p_{n_j} = \frac{1}{2} \leq 1 - p_{n_j} \leq \frac{1}{2^{p_{n_j}}} (1 - p_{n_j}) \]

By definition of \( P'_p \), since \( O_{m,n} \) is a disjoint union of cylinders \( C(p) \) with \( |p| = n \), applying inductively the previous inequalities, for all \( n \) such that \( n_k < n \leq n_{k+1} \) (denoting \( n_0 = 0 \)):

\[ P'_p(O_{m,n}) \leq \frac{P_p(O_{m,n})}{2^k \prod_{1 \leq j < k} p_{n_j}}. \tag{1} \]

- Assume that we have chosen \( n_1, \ldots, n_k \). Since \( \lim_{n \to \infty} P_p(O_{k,n}) = 0 \), there exists \( n_{k+1} > n_k \) such that \( P_p(O_{k,n_{k+1}}) \leq \prod_{1 \leq j < k} p_{n_j} \). We choose such an index.

Equation 1 now implies that for all \( m \leq k \), \( P_p(O_{m,n_{k+1}}) \leq P'_p(O_{k,n_{k+1}}) \leq \frac{1}{2^k} \). Thus for all \( m, P_p(F_m) = \lim_{k \to \infty} P'_p(O_{m,n_{k+1}}) = 0 \). Since \( E \cap F = \bigcup_{m \in \mathbb{N}} F_m, P_p(E \cap F) = 0 \) and so \( P'_p(E) = 0 \).
Proposition 8. There exists a finitely-branching LTS $L$ and a mask function $P$ such that for every Borel set $E$ of runs, there exists a POP LTS $N = ((L, P), \Sigma, P)$ such that:

- either $N$ is FA-diagnosable and $P_N(E) = 0$;
- or $N$ is not FA-diagnosable and $P_N(E) > 0$.

Proof. Consider the LTS $L = (Q, q_0, \Sigma, T)$ defined as follows, and let the mask function be defined by: $P(u) = P(f) = \epsilon$ and $P$ is the identity over the other events.

- $Q = \{f_1, q_f, q_0\} \cup \{q_w \mid w \in (a + b)^*\}$;
- $\Sigma = \{a, b, c, u, f\}$;
- $T = \{(q_0, a, q_f), (q_0, u, q_1), (q_f, a, q_f), (q_f, f, f_1), (f_1, b, f_1), (f_1, c, f_1)\} \cup \{(q_w, a, q_wa), (q_w, b, q_wb)\}_{w \in (a + b)^*}$.

Figure 7 Another family of POP LTS whose underlying LTS has no appropriate characterisation of FA-diagnosability.

We consider a family of POP LTS, represented in Figure 7, with underlying LTS $L$, parameterised by a mapping $p: (a + b)^* \rightarrow (0, 1)$. Let $N_p = ((L, P_p), \Sigma, P)$ be the POP LTS such that the probability that $b$ occurs from state $q_w$ is $P(q_w, b, q_wb) = p(w)$, and all other probabilities are independent from $p$: $P_p(q_0, u, q_f) = P_p(q_0, u, q_1) = P_p(f_1, b, f_1) = P_p(f_1, c, f_1) = \frac{1}{2}$, $P_p(q_f, a, q_f) = P_p(q_f, b, q_f) = P_p(q_f, f, f_1) = \frac{1}{2}$. In the sequel, for convenience, we also write $p(w, b)$ for $P_p(w)$, and define $p(w, a) = 1 - p(w)$, so that $P(q_w, a, q_wa) = p(w, a)$.

Word $w$ can be decomposed into letters $w = w[1] \ldots w[n]$, and we give notations for factors: $w[1, k] = w[1] \ldots w[k]$ with the convention that $w[1, 0] = \epsilon$. Finally we define $p_0(w) = \prod_{1 \leq k \leq n} p(w[1, k - 1], w[k])$, as the probability to read $w$ from $q_c$. Since $\lim_{n \rightarrow \infty} P(FA)_{\text{amb}n} = 0$ and $P(FA)_{\text{amb}n} = \sum_{|w|=n-1} p(w, b) + \frac{2^{n-1}}{3}$, we deduce that $N_p$ is FA-diagnosable iff $\lim_{n \rightarrow \infty} \text{P}(w,b) = 0$.

Let $E$ be an arbitrary measurable set. Pick some POP LTS $N_p$ which is FA-diagnosable, i.e. with $\lim_{n \rightarrow \infty} \sum_{|w|=n} p(w, b) = 0$. If $P(E) = 0$ where $P_p$ is the probability of this POP LTS, we are done. Assume therefore that $P(E) > 0$. Let $F = \{\rho \mid q_0uq_c \in \rho\}$ be the set of runs starting with a $u$-transition to $q_c$. Denoting $P_p'$ the probability measure of any other POP LTS $N_p'$, observe that $P_p(E \setminus F) = P_p(F \setminus F)$. So, if $P_p(E \setminus F) > 0$, then by picking any non FA-diagnosable $(L, p_p)$, we are done. So assume $P_p(E \setminus F) = 0$ which implies $P_p(E \cap F) > 0$. Using our recalls, there exists a closed set $G \subseteq E \cap F$ with $P_p(G) > 0$.

If $G = F$ then $P_{p'}(G) = P_p(G) = \frac{1}{2}$. In this case, we can therefore conclude by picking any non FA-diagnosable POP LTS $N_p'$.

Assuming $G \not\subseteq F$, since $G$ is closed, there is some cylinder $C(\rho)$ with $\rho = q_0uq_c \ldots q_w$ such that $G \cap C(\rho) = \emptyset$. Then we define the POP LTS $N_p'$ as the POP LTS $N_p$ except that for every $w \leq w'$ and every $x \in \{a, b\}$, $P'(w', x) = \frac{1}{2}$. Thus for every $n \geq |w|$, $\sum_{|w'|=n} P'(w', b) \geq \frac{P_p(G)}{2}$. So $N_p'$ is not FA-diagnosable. On the other hand, $P_p(F \cap E) \geq P_p'(G) = P_p(G) > 0$. \hfill \blacksquare
Details and proofs for Section 4

B.1 Formal definitions

Here we give formal definitions omitted in the core of the paper due to space constraints. More precisely given a POPVPA \( \mathcal{V} \), we define its estimate VPA \( \mathcal{A}(\mathcal{V}) \), its enlarged VPA \( \tilde{\mathcal{A}} \) and their synchronised product.

Let \( \mu \in \{ g, c, f \} \) we write \( (q, \gamma) \overset{\sigma}{\Rightarrow}_\mu (q', w) \) with \( o \in \Sigma_o \) if when \( \mu = g \) (resp. \( c, f \) ), there exists a general (resp. correct, faulty) run of transitions starting from \( (q, \gamma) \) to \( (q', w) \) such that all transitions are unobservable except the last one labelled by \( e \) with \( \mathcal{P}(e) = o \). Let \( \rho \) be such a run then we also write \( (q, \gamma) \overset{\rho}{\Rightarrow} (q', w) \) All transitions of such runs are local except the last one whose type depends on the type of \( o \).

**Definition 16.** Given \( (\mathcal{V}, \mathcal{P}, \Sigma_o) \) a POPVPA with \( \mathcal{V} = (Q, \Sigma, \Gamma, \delta, \mathcal{P}) \), its *estimate VPA* is the deterministic VPA \( \mathcal{A}(\mathcal{V}) = (Q', \Sigma_o, \Gamma', \delta') \) defined by:

1. \( Q' = \{ \text{run} \} \cup (2^{(\Gamma \times \Sigma_o) \setminus \emptyset}) \) is the set of states with initial state \( q_0' = \text{run} \);
2. \( \Gamma' = 2^{(\Gamma \times \Sigma_o)} \times \emptyset \) is the stack alphabet with set of bottom stack symbols \( \Gamma'_0 = 2^{\text{Init}} \times \emptyset \)

where \( \text{Init} = \{ (\alpha, q) \mid (X, q) \in T_g \times Q \} \) and initial stack symbol \( \Gamma'_0 = \{ \alpha \} \);

3. The transition relation \( \delta' \) is defined as follows.

**Local transitions** \( \text{run}, \text{bel}, o, \text{run}, \text{bel}' \) \( \in \delta' \) if:

- \( \beta_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{U}r} \in \text{bel} \text{ and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta) \).
- \( \text{If } W \text{ occurs in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{W}r} \in \text{bel} \text{ and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta) \).
- \( \text{If } W \text{ does not occur in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{W}r} \in \text{bel} \text{ and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta) \).

**Push transitions** \( \text{run}, \text{bel}, o, \text{run}, \text{bel}' \) \( \in \delta' \) if:

- \( \beta_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \in \text{bel}' \text{ and } \beta_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \text{bel and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta, \beta) \).
- \( \text{If } W \text{ occurs in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ and } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \text{bel and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta, \beta) \).
- \( \text{If } W \text{ does not occur in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ and } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \text{bel}' \text{ iff there exists } \alpha_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \text{bel and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \beta, \beta) \).

**Pop transitions** \( \text{run}, \text{bel}, o, \ell, \varepsilon \) \( \in \delta' \) with \( \varepsilon \in Q' \setminus \{ \text{run} \} \) if:

- \( \beta_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \in \ell \text{ iff } \alpha_{\text{U}r} \quad \overset{\alpha_{\text{U}r}}{\Rightarrow} \quad \in \text{bel} \text{ and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \varepsilon) \).
- \( \text{If } W \text{ occurs in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \ell \text{ iff there exists } \alpha_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \text{bel and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \varepsilon) \).
- \( \text{If } W \text{ does not occur in } \beta_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \in \ell \text{ iff there exists } \alpha_{\text{W}r} \quad \overset{\alpha_{\text{W}r}}{\Rightarrow} \quad \text{bel and } (q, \alpha) \overset{\sigma}{\Rightarrow} (r, \varepsilon) \).
Illustration. Let us look at the run given in the example of Figure 5. It starts in the initial configuration $(q_0, γ, a, q_0)$. The estimate VPA manages information in order to evaluate whether the run entered by reading $\nu$ is correct or faulty. Conversely a configuration is incorrect if its associated state is run.

While $A(V)$ contains $ε$-transitions it is deterministic: from any configuration, either a single $ε$-transition is enabled or for all event $o$, there is at most one $o$-transition enabled. We say that a configuration is stable if its associated state is run.

Definition 17. Let $V = (Q, \Sigma, Γ, δ, P)$ be a pVPA. Then the pVPA $V̄ = (Q̄, Σ, Γ, ̄δ, ̄P)$ is defined by:

- $Q̄ = Q_v \cup Q_f$ where $Q_v = \{q_v \mid q \in Q\}$ and $Q_f = \{q_f \mid q \in Q\}$ with initial state $q_{0_v}$;
- For all $(q, γ, a, q', w) \in ̄δ$ with $a \neq f$ and all $g \in \{ε, f\}$, $(gq, γ, a, q', w) \in ̄δ$;
- For all $(q, γ, f, q', w) \in ̄δ$ and all $g \in \{ε, f\}$, $(gq, γ, f, q', w) \in ̄δ$;
- For all $(q, γ, a, q', w) \in ̄δ$, $̄P(q, γ, a, q', w) = P(q, γ, a, q', w)$.
We now define the product \( \mathcal{V}_A(V) \) between \( \mathcal{V} \) and \( A(V) \) that keeps all the information we need along a run.

**Definition 18.** Given \((V, \mathcal{P}, \Sigma_o)\) a POPOVPA with \( \mathcal{V} = (Q, \Sigma, \Gamma, \delta, \mathcal{P}) \) and \( A(V) = (Q^e, \text{run}, \Sigma_o, \Gamma^e, \delta^e) \), their synchronised product is the pVPA \( \mathcal{V}_A(V) = (Q^A, \Sigma \cup \{\emptyset\}, \Gamma^A, \delta^A, \mathcal{P}^A) \) where:

- \( Q^A = Q \times Q^e \) is the set of control states with initial state \( q^A_0 = (q^0_o, \text{run}) \);
- \( \Gamma^A = \Gamma \times \Gamma^e \) is the stack alphabet with \( \Gamma^A \) the set of bottom stack symbols and \( \Gamma^A_0 = (1, \bot, \bot) \) the initial symbol;
- The transition relation \( \delta^A \) consists of:

**local transitions.**

- For all \((q, q', a, q', \gamma') \in Q^A \) with \( a \) unobservable and \( \text{bel} \in \Gamma^e \),
  \((q, q', a, q', \gamma')) \in \delta^A;\)
- For all \((q, q', a, q', \gamma') \in Q^A \) and \((\text{run}, a, q, \text{run}) \) \( \in \delta^e \) with \( P(a) = \emptyset \),
  \((q, q') \in \delta^A;\)
- For all \((q, q', a, q', \gamma') \in Q^A \) and \((\text{run}, a, q, \text{run}) \) \( \in \delta^e \) with \( P(a) = \emptyset \),
  \((q, q') \in \delta^A;\)

**push transitions.**

- For all \((q, q', a, q', \gamma') \in Q^A \) and \((\text{run}, a, q, \text{run}) \) \( \in \delta^e \) with \( P(a) = \emptyset \),
  \((q, q') \in \delta^A;\)

**pop transitions.**

- For all \((q, q', a, q', \gamma') \in Q^A \) and \((\text{run}, a, q, \text{run}) \) \( \in \delta^e \) with \( P(a) = \emptyset \),
  \((q, q') \in \delta^A;\)

The transition probability function \( \mathcal{P}^A \) is defined by:

- \( \mathcal{P}^A(q, \text{run}, (\gamma, \text{bel}), a, (q', \text{run}), (\gamma', \text{bel}')) = \mathcal{P}(q, a, q', \gamma');\)
- \( \mathcal{P}^A((q, \text{run}), (\gamma, \text{bel}), a, (q', \text{run}), (\gamma', \text{bel}')(\gamma'', \text{bel}'')) = \mathcal{P}(q, a, q', \gamma', \gamma'');\)
- \( \mathcal{P}^A((q, \text{run}), (\gamma, \text{bel}), a, (q', \text{run}), (\gamma', \text{bel}', \emptyset, (q, \text{run}), (\gamma, \text{bel}')) = 1.\)

**Illustration.** The product POPOVPA contains the current run of the POPOVPA, information on the correctness of the run and the information given by the estimate POPOVPA. If we look at the faulty run given in the example of Figure 4, after reading \( in \), we are in state \((q_0, c, \text{run}) \) meaning our real state is \( q_0 \), it was reached by a correct run and our estimate VPA is in state \( \text{run} \), the head of stack is \((\gamma, \gamma_1, \cdots, \gamma_n) \), meaning our real head is \( \gamma \) and the rest is the head of the estimate VPA. If we follow the faulty run until after the first pop, we reach the state \((f_1, f, (\gamma_1, \cdots, \gamma_n, \gamma_1, \cdots, \gamma_n)) \), we are thus in \( f_1 \) with a faulty run and the estimate VPA is in one of the temporary states. In order to leave this state, we read a \( \emptyset \) which leads to the state \((f_1, f, \text{run}) \). \( \emptyset \) is an event affecting only the part of the POPOVPA corresponding to the estimate VPA, making it realises the \( \varepsilon \) transition.

Given a finite run \( \rho \) of \( V \), we inductively define the run \( \tilde{\rho} \) of \( \mathcal{V}_A(V) \) as follows. First \((q_0^A, 1^A) = (q^0_o, 1^0) \). Let \( \rho \) of length \( n \geq 1 \), \( a \in \Sigma \) and \( q \in Q \) and \( \gamma_1, \cdots, \gamma_n \in \Gamma \) such that \( \rho = \rho'(a(q, \gamma_1, \cdots, \gamma_n)) \). If \( a \notin \Sigma \), then \( \rho = \rho'(a(q, \gamma_1, \cdots, \gamma_n)) \).

If \( a \in \Sigma \), then \( \rho = \rho'(a(q, \gamma_1, \cdots, \gamma_n)) \) is the configuration reached by \( P(\rho) \) in \( A(V) \).
If \( a \in \Sigma \) and \( \rho = \rho'(a(q, \gamma_1, \cdots, \gamma_n)) \) is the configuration reached by \( P(\rho) \) in \( A(V) \),

As previously observed, \( P(\rho) = P(\tilde{\rho}) \).
B.2 Decidability of diagnosability for POpVPA

In order to prove decidability of diagnosability for a POpVPA $\mathcal{V}$, one wants to check whether the formulae characterising diagnosability hold on $\mathcal{V}$. To do so, we transform the pathL formulae of Section 3 into pLTL properties that are checked on $\mathcal{V}_A(\mathcal{V})$. These pathL formulae use three paths formulae $\mathcal{f}$, $\mathcal{U}$ and $\mathcal{W}$. In the core of the paper, we explained how to define alternative pLTL formulae, relying on atomic propositions $\nu_f$, $\nu_u$ and $\nu_w$ that only depend on the current control state and top of stack symbol of $\mathcal{V}_A(\mathcal{V})$. Proposition 19 links runs of $\mathcal{V}$ and observed sequences of $\mathcal{A}(\mathcal{V})$ and Proposition 13 establishes the correctness of the $\nu$'s with respect to the paths formulae $\mathcal{f}$, $\mathcal{U}$ and $\mathcal{W}$.

> **Proposition 19.** Let $\sigma$ be an observed sequence of $\mathcal{A}(\mathcal{V})$ and $\rho'$ be its corresponding finite run with successive stable configurations $(run, w_0) \ldots (run, w_n)$. Let $w_n = bel_1 \ldots bel_h$ and for $i < n$, $bel(i)$ be the top stack symbol of $w_i$. Then:

- For all $\gamma_i \in bel_h$, there exists a sequence $(\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi})_{0 \leq h}$ such that for all $i$, $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_i$ and a signalling run $\rho$ of $\mathcal{V}$ such that $P(\rho) = \sigma$ that reaches configuration $(\gamma_i, \gamma_1 \ldots \gamma_h)$. In addition:
  - if $X_h = U$ then $\rho$ may be chosen correct;
  - if $X_h = W$ then $\rho$ may be chosen faulty;
  - if $X_h = W$ then there exists $0 < k \leq n$, such that $\rho_{ik}$ is faulty and $W$ does not occur in $bel(k-1)$.

- Conversely, let $\rho$ be a signalling run of $\mathcal{V}$ such that $P(\rho) = \sigma$ reaching configuration $(\gamma_i, \gamma_1 \ldots \gamma_h)$, there exists a sequence $(\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi})_{0 \leq h}$ such that for all $i$, $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_i$. In addition:
  - if $\rho$ is correct then $X_h = U$;
  - if $\rho$ is faulty then $X_h = W$;
  - if there exists $0 < k \leq n$, such that $\rho_{ik}$ is faulty and $W$ does not occur in $bel(k-1)$ then $X_h = W$.

**Proof.** We prove it by induction on $|\sigma|$. The basis case is straightforward. For the inductive step, we only detail the most involved case: $\sigma[n] \in \Sigma_{\alpha^3}$. For the properties related to tags, we only detail the ones related to $W$. Denote $\sigma' = \sigma[1] \ldots \sigma[n-1]$ and $w_{n-1} = bel_1 \ldots bel_h bel_{h+1}$.

- Let $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_h$. By construction, there exists $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_{h+1}$ with $\gamma_h = \gamma_i$, a signalling run $(\gamma_{h+1}, \gamma_i) \Rightarrow (q_h, \varepsilon)$ with $proj(\rho'') = \sigma[n]$, $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_h$ where $(\gamma_1, \gamma_{h+1}) = (\gamma_{h+1}, \gamma_1, \gamma_{h+1})$ and $X_h$ is obtained by updating $X_{h+1}$ w.r.t. $bel_{h+1}$ and $\rho''$. In particular if $X_h = W$ then
  1. $X_h = W$, or
  2. $X_h = W$ does not occur in $bel_{h+1}$ and (a) $X_h = V$ or (b) $X_h = U$ and $\rho''$ is faulty.

By inductive hypothesis, there exists a sequence $(\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi})_{0 \leq i}$ such that for all $i$, $\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi} \in bel_h$ and a signalling run $\rho$ of $\mathcal{V}$ such that $P(\rho') = \sigma'$ reaching configuration $(\gamma_{h+1}, \gamma_1 \ldots \gamma_h)$. Consider the signalling run $\rho = \rho', \rho''$; it reaches configuration $(q_h, \gamma_1 \ldots \gamma_h)$. Since for all $i < h$, $bel_i = bel_i$, the sequence $(\frac{\gamma_i, X, \varphi}{\gamma_i, X, \varphi})_{0 \leq i}$ and the run $\rho$ are appropriate. The three additional properties follow from the rules of tag updates. In particular, if $X_h = W$, then
  - the assertion (1) holds and then the property comes from the inductive hypothesis, or
  - the assertion (2) holds which implies that $W$ does not occur in $bel_{h+1}$ and $\rho$ is faulty.

- Let $\rho$ be a signalling run of $\mathcal{V}$ such that $P(\rho) = \sigma$ which reaches configuration $(q_h, \gamma_1 \ldots \gamma_h)$. Let us write $\rho = \rho_{in-1} \rho''$ with $(\gamma_{h+1}, \gamma_i) \Rightarrow (q_h, \varepsilon)$. By the inductive hypothesis, there
exists a sequence \((x_{i+1}', x_i')\) such that for all \(i\), \(x_{i+1}', x_i' \in bel'_h\) and for all \(i \leq h\), \(\gamma'_i = \gamma_i\). By construction, \(x_{i+1}', x_i' \in bel_h\) for some \(\rho, K\). Since \(bel_i = bel'_i\) for all \(i < h\), we obtain the required sequence of items.

The three additional properties follow from the rules of tag updates. In particular, assume there exists \(0 < k \leq n\), such that \(\rho_{i_k}\) is faulty and \(W\) does not occur in \(bel^{k-1}\).

- If \(\rho_{i_{n-1}}\) is correct then, as \(\rho\) is faulty, \(\rho''\) is faulty and \(W\) does not occur in \(bel^{n-1} = bel'_{h+1}\). So by construction \(X_h = W\).
- If \(\rho_{i_{n-1}}\) is faulty then
  - either \(X'_{h+1} = W\) and by construction \(X_h = W\),
  - or \(X'_{h+1} = V\). By induction hypothesis there does not exist \(0 < k \leq n - 1\), such that \(\rho_{i_k}\) is faulty and \(W\) does not occur in \(bel^{k-1}\). So \(W\) does not occur in \(bel^{n-1} = bel'_{h+1}\). Therefore \(X_h = W\).

\(*\) Proposition 13. Let \(\rho\) be an infinite run of \(V\). Then:
- For all \(k \in \mathbb{N}\), \(\rho(f(\rho_{i_k})) \leftrightarrow \nu_f(last(\rho_{i_k}))\) and \(U(\rho_{i_k}) \leftrightarrow \nu_u(last(\rho_{i_k}))\);
- \(\rho = \bigcirc \left( W \right) \iff \exists K' \forall k \geq K. \nu_u(last(\rho_{i_k})) = \text{true}\).

Proof. First, remark that \(f\) and \(\nu_f\) obviously coincide: they both express that a fault occurred.

To prove the second item, about \(U\) and \(\nu_u\), we use the link from between observed sequences and the tag \(U\) in \(\mathcal{A}(V)\). Let \(\sigma\) be an observed sequence triggered by a run of \(V\). Then \(bel\) is the top stack symbol of the stable configuration in \(\mathcal{A}(V)\) reached by the run accepting \(\sigma\) (so ending by an \(\varepsilon\)-transition if the last event is a pop event). Due to Proposition 19, \(U\) occurs in \(bel\) iff there is a correct signalling run of \(V\) with observed sequence \(\sigma\). According to the definition of \(\nu_u\), we thus deduce that for any finite signalling run \(\rho\) of \(V\), \(\nu_u(last(\rho)) = \text{true}\) iff \(U(\rho) = \text{true}\).

We now establish the link between \(W\) and \(\nu_W\). To show the left-to-right implication, let \(\rho \in \Omega\) and \(K_0 \in \mathbb{N}\) be such that \(\rho, K_0 = \bigcirc W\). By definition of \(W\), \(first(\mathcal{A}(V)) = \text{constant and bounded by } K_0\) for \(k \geq K_0\). For all \(k \in \mathbb{N}\), let \(bel_k\) be the top stack symbol reached in \(\mathcal{A}(V)\) after reading the observed sequence \(\mathcal{A}(V) = \text{if \(\rho\)}\). If for all \(k \geq K_0\), \(W\) occurs in \(bel_k\), then for all \(k \geq K_0\), \(\nu_u(last(\rho_{i_k})) = \text{true}\). Otherwise there exists \(K_1 \geq K_0\) such that \(W\) does not occur in \(bel_{K_1}\). Let \(k > K_1\), as \(first(\mathcal{A}(V)) \leq K_0\), there exists a faulty run \(\rho'\) of \(\mathcal{A}(V)\) such that \(\mathcal{A}(\rho') = \mathcal{A}(\rho_{i_k})\) and \(\rho_{i_{K_0}}\) is faulty. \(W\) does not occur in \(bel_{K_1}\) and \(\rho_{i_{K_0}}\) is faulty. Thus by Proposition 19, \(W\) occurs in \(bel_k\). Therefore for all \(n \geq K_1\), \(\nu_u(last(\rho_{i_k})) = \text{true}\).

Let us show the right-to-left implication. Let \(\rho \in \Omega\) and \(K \in \mathbb{N}\) be such that for all \(k \geq K\), \(\nu_u(last(\rho_{i_k})) = \text{true}\). By definition of \(\nu_u\) for all \(k \geq K\), \(W\) occurs in \(bel_k\) (defined as above). Let \(k \geq K\), by Proposition 19, there exists a run \(\rho'\) of \(\mathcal{A}(V)\) such that \(\mathcal{A}(\rho') = \mathcal{A}(\rho_{i_k})\) and there exists \(n \leq k\) such that \(\rho_{i_n}\) is faulty and \(W\) does not occur in \(bel_{n-1}\). Thus \(n = k\). Therefore for all \(k \geq K\), \(first(\mathcal{A}(\rho_{i_k})) \leq K\). Since beyond \(K\) \(first\) is bounded, it is non decreasing and then eventually constant. Let \(K'\) such that for all \(k \geq K'\), \(first(\mathcal{A}(\rho_{i_k})) = first(\mathcal{A}(\rho_{i_{K-1}}))\). So \(\rho = \bigcirc W\) and thus \(\rho = \bigcirc W\).

We extend \(\nu_f, \nu_u, \nu_v\) over configurations \(cf = ((q, \ell), w)\) with \(\ell \neq \text{run}\) by \(\nu_f(cf) = \nu_u(cf) = \nu_v(cf) = \text{true}\).

\(*\) Theorem 14. FF-diagnosability, IF-diagnosability and IA-diagnosability are decidable in EXPSPACE for POpVPA.
Proof. The above lemmas allows us to derive pLTL characterisations of diagnosability for POpVPA. Namely, for $V$ a POpVPA, as $V$ and $V_{A(V)}$ have the same probabilistic behaviour,

- $V$ is FF-diagnosable iff $V_{A(V)} = P^0(\bigcirc (\nu_f \wedge \nu_u))$;
- $V$ is IA-diagnosable iff $V_{A(V)} = P^0(\bigcirc (\nu_0 \wedge \nu_w))$.

Moreover, since the POpLTS generated by POpPDA are finitely-branching, IA-diagnosability coincides with FF-diagnosability [3] (See also 4). The two above qualitative pLTL formulae can be checked on general probabilistic pushdown automata (beyond visibly pushdown ones) thanks to [6]. More precisely, one can transform $V_{A(V)}$ into a recursive Markov chain (the transformation is linear) [7]. Then, the model checking of qualitative pLTL on recursive Markov chains is doable in PSPACE in the size of the Recursive Markov Chain and $\text{EXPTIME}$ in the size of the formulae [6]. In our case, the product VPA $V_{A(V)}$ is exponential in the size of $V$ and the size of the formulae is constant. This yields an $\text{EXPSPACE}$ algorithm for checking diagnosability of POpVPA.

\section*{B.3 EXPTIME-hardness of the diagnosability for POpVPA}

We prove here Theorem 15, stating the EXPTIME-hardness of diagnosability for POpVPA. Let us restate it below more precisely.

\textbf{Theorem 20.} FF-diagnosability, FA-diagnosability and IA-diagnosability are EXPTIME-hard for POpVPA.

\textbf{Proof.} Let us start with FF-diagnosability. The proof is by reduction from the universality problem for VPA, which is known to be $\text{EXPTIME}$-hard [1].

From a VPA $V = (Q, \Sigma, \Gamma, \delta)$ and a subset of accepting control states $Q_f \subseteq Q$, we build a pVPA $V' = (Q', \Sigma', \Gamma', \delta', P')$ as follows:

1. $Q' = Q \cup \{f_0, f_1, q_0', q_1\}$ and $q_0'$ is the initial state;
2. $\Sigma' = \Sigma \cup \{f, u, b, h\}$;
3. $\Gamma' = \Gamma \cup \{B\}$ and $\Gamma_1' = \Gamma_1$;
4. Writing $\delta_1$, resp. $\delta_1$ and $\delta_b$ for the set of local resp. push and pop transitions of $V$, $\delta'$ consists of the following transitions:

   - local $\delta_1 \cup \{(q_0', l_0, u, l_0, q_0), (q_0', l_0, f, l_0, f_0), (f_0, \gamma, h, \gamma, f_1) | \gamma \in \Gamma \cup \{l_0\}\}$
   - $\cup \{(q, \gamma, h, \gamma, g_0) | q \in Q_f, \gamma \in \Gamma \cup \{l_0\}\}$
   - $\cup \{(f_0, a, \gamma, f_0) | a \in \Sigma, \gamma \in \{B, l_0\}\}$
   - $\cup \{(q_0', l_0, h, l_0, q_0), (f_1, l_0, h, l_0, f_0)\}$;

   - push $\delta_1 \cup \{(f_0, \gamma, a, \gamma, B, f_0) | a \in \Sigma, \gamma \in \{B, l_0\}\}$;

   - pop $\delta_1 \cup \{(f_0, B, a, \varepsilon, f_0) | a \in \Sigma, \gamma \in \{f_1, B, \gamma, f_1\}\}$;

5. $P'$ is such that for every $\gamma \in \Gamma$, $P'(f_0, \gamma, h, \gamma, f_1) = \frac{1}{2}$, and assigns arbitrary positive probabilities to the other transitions in $\delta'$.

We further consider the POpVPA $(V', \Sigma_0, \mathcal{P})$ with $\Sigma_0 = \Sigma \cup \{b, h\}$ and the masking function satisfies $P(a) = P(f) = \varepsilon$ and $P(x) = x$ for any other event $x \in \Sigma'$. This construction is illustrated in Figure 8. The figure uses the following shortcuts: $a_b \in \Sigma_b$, $a_t \in \Sigma_t$, $a_4 \in \Sigma_4$, $\gamma \in \Gamma$, $\gamma' \in \{B, l_0\}$ and $z \in \Gamma \setminus \{l_0\}$.

The correct observed sequences in $(V', \Sigma_0, \mathcal{P})$ are either of the form $w_1 h^k_1 h w_2 . . . h^{k_{n-1}} h w_n$ or of the form $w_1 h h w_2 . . . h w_{n-1} h^m$. In these decompositions, $w_i$, for $i < n$, is a sequence corresponding to a run of $V$ starting in $q_0$ and ending in some accepting state $Q_f$, $k_i$ is the number of elements in the stack after reading $w_i$ in $V$ and also in $V'$ (apart from the bottom stack symbol $\bot$), $w_n$ is the sequence associated to a run of $V$ starting in $q_0$, and $m$
is at most the number of elements in the stack after reading $w_{n-1}$ in $\mathcal{V}$. Note that $k_i$ only depends on $w_i$, and does not depend on the exact run over $w_i$, since $\mathcal{V}$ is a VPA.

Now, the faulty observed sequences in $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$ are either of the form $w_1\, \sharp\, k_1 \, w_2 \, \sharp\, k_2 \, w_3 \ldots$ or of the form $w_1 \, \sharp\, k_1 \, w_2 \ldots \, w_{n-1} \, \sharp\, k_m$. In these decompositions, $w_i \in \Sigma_\gamma$, $k_i$ is the size of the stack in $\mathcal{V}'$ (apart from the bottom stack symbol $\bot_0$) after reading $w_i$ and $m$ is at most the number of elements in the stack of $\mathcal{V}'$ after reading $w_{n-1}$.

Let us show that $\mathcal{V}$ is not universal if and only if $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$ is FF-diagnosable.

First assume that $\mathcal{V}$ is not universal. Then there exists a word $w \in \Sigma^*$ such that no run of $\mathcal{V}$ reading $w$ ends in an accepting state $q_f$. However, the observed sequence of any faulty run almost-surely contains the factor $\sharp\, w \, \sharp$. Indeed, faulty runs almost surely visit infinitely often the configuration $(f_i, 1_0)$, and from there, the probability $\lambda$ to read $\sharp\, w \, \sharp$ is positive. Let $\rho$ be an infinite faulty run. Its observed sequence is of the form $\mathcal{P}(\rho) = w_1 \, \sharp\, k_1 \, w_2 \, \sharp\, k_2 \, w_3 \ldots$ with $k_i \leq |w_i|$ for every $i$. If there exists $i \leq n$ such that $w_i = w$ then $\rho$ is surely faulty, since it has no corresponding correct run. The latter statement can be refined. For $n \geq |w|$, if, for every $i \leq n$, $|w_i| \leq n$ and there exists $i \leq n$ such that $w_i = w$ then $\rho(2n^2+n)$ is surely faulty. Indeed, $|w_i| \, \sharp\, k_i \leq 2n + 1$, $w$ occurs at the latest for $i = n$, and once it occurs the prefix is surely faulty. Let us therefore consider faulty runs that do not satisfy this property.

We let $\text{Avoid}_n = \{ \rho \in \mathcal{F} \mid \mathcal{P}(\rho) = w_1 \, \sharp\, k_1 \, w_2 \, \sharp\, k_2 \, w_3 \ldots \wedge (\forall i \leq n, w_i \neq w \lor \exists i \leq n, |w_i| > n) \}$. By construction, $\text{FAmb}_{2n^2+n} \subseteq \text{Avoid}_n$. Moreover, using standard union-sum inequalities, $\mathbb{P}(\text{Avoid}_n) \leq (1 - \lambda)^n + \frac{\lambda}{|\mathcal{F}|}$ (recall that $\lambda$ is the probability to read $\sharp\, w \, \sharp$ from $f_0, 1_0$). Thus $\lim_{n \to \infty} \mathbb{P}(\text{Avoid}_n) = 0$ and hence $\lim_{n \to \infty} \mathbb{P}(\text{FAmb}_n) = 0$ so that $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$ is FF-diagnosable. Assume now that $\mathcal{V}$ is universal. Let $\rho$ be an infinite surely faulty run of $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$. We write $\rho'$ for the greatest ambiguous prefix of $\rho$ and $a \in \Sigma_\omega \cup \{\bot, \sharp\}$ such that $\rho'a$ is again a prefix of $\rho$. Observe that $a$ cannot be $\bot$ since the number of $\top$’s between two $\bot$’s, whether on the left or right-hand-side of $\mathcal{V}'$, is entirely determined by the word of $\Sigma_\omega^*$ read before the first $\bot$. For the same reason, if $a = \bot$, $\mathcal{P}(\rho')$ ends with a word of $\Sigma_\gamma^*$ (i.e. the number of $\top$’s in $\mathcal{P}(\rho')$ is even). Let $w$ be the greatest suffix of $\mathcal{P}(\rho')$ contained in $\Sigma_\gamma^*$. If $a = \bot$, we deduce that there is no run starting in $q_0$ with observed sequence $w$ and ending in an accepting state of $\mathcal{V}$. Therefore, $\mathcal{V}$ is not universal. Similarly, if $a \in \Sigma_\omega$, then there is no run starting in $q_0$ and with observed sequence $w_0$. In that case also, $\mathcal{V}$ is not universal. Hence conclude that there is no infinite surely faulty run in $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$. As the probability to generate faulty runs is positive, this implies that $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$ is not FF-diagnosable. Now, FF-diagnosability is equivalent to FF-diagnosability for finitely branching POpLTS (see Theorem 4), and so $(\mathcal{V}', \Sigma_\omega, \mathcal{P})$ is not FF-diagnosable.

Let us now argue for the EXPTIME-hardness of FA-diagnosability and IA-diagnosability. From the VPA $\mathcal{V} = (Q, \Sigma, \Gamma, \delta)$ and pVPA $\mathcal{V}' = (Q', \Sigma', \Gamma', \delta')$ defined above, we construct a
We further consider the POpVPA $V'' = (Q'', \Sigma'', \Gamma'', \delta'', P'')$ such that

- $Q'' = Q' \cup \{q_0\}$ and $q_0'$ is the initial state;
- $\Sigma'' = \Sigma \cup \{f, u, C\}$;
- $\Gamma'' = \Gamma$;
- $\delta'' = \delta' \cup \{(q, \alpha, \gamma, q_0) \mid \gamma \in \Gamma \cup \{1_0\}, q \in Q \cup \{q_0\}\}$;
- $P''$ assigns arbitrary positive probabilities to transitions in $\delta''$.

We further consider the POpVPA $(V'', \Sigma_\circ, P)$ with $\Sigma_\circ = \Sigma'' \setminus \{f, u\}$, and the masking function satisfies $P(f) = P(u) = \varepsilon$ and $P(x) = x$ for any other event $x$. The construction is illustrated in Figure 9, where we use the shortcuts: $a_b \in \Sigma_3$, $a_d \in \Sigma_4$, $a_t \in \Sigma_4$, $\gamma \in \Gamma$, $\gamma' \in \{B, 1_0\}$ and $z \in \Gamma \setminus \{1_0\}$. 

![Figure 9](image-url) A POpVPA for EXPTIME-hardness of FA-diagnosability and IA-diagnosability.

$V''$ is a slight modification of $V':$ from any state of $V$ (accepting or not), reading the new letter $\alpha$ leads to the sink state $q_\circ$. As a consequence, for any correct run of $(V'', \Sigma_\circ, P)$, there is a positive probability at each step to perform event $\alpha$ and become surely correct. This implies $\lim_{n \to \infty} P(C_{Amb_n}) = 0$. Observe that the above proof for $V'$ also applies to $V'':$ $V$ is not universal if and only if $(V'', \Sigma_\circ, P)$ is FF-diagnosable. Now, since $\lim_{n \to \infty} P(C_{Amb_n}) = 0$, FF-diagnosability, FA-diagnosability and IA-diagnosability coincide for $(V'', \Sigma_\circ, P)$. We conclude that $V$ is not universal if and only if $(V'', \Sigma_\circ, P)$ is diagnosable (for any notion of diagnosability).

### B.4 Undecidability of diagnosability for POpPDA

As stated in the core of the paper, diagnosability is undecidable for partially observable probabilistic pushdown automata (POpPDA). Let us first give the definition of pPDA and POpPDA. Contrary to VPA, in PDA, the action does not determine the operation (push, pop, local) on the stack.

**Definition 21.** A probabilistic pushdown automaton (pPDA) is a tuple $A = (Q, \Sigma, \Gamma, \delta, P)$ where:

- $Q$ is a finite set of control states with $q_0$ the initial state;
- $\Sigma$ is a finite alphabet of events;
- $\Gamma$ is a finite alphabet of stack symbols including a set of bottom stack symbols $\Gamma_\bot$ with initial symbol $1_0 \in \Gamma_\bot$;
- $\delta \subseteq Q \times \Gamma \times \Sigma \times Q \times \Gamma^*$ is the set of transitions such that for every $(q, \gamma, a, q, w) \in \delta$, $|w| \leq 2$, $\gamma \in \Gamma_\bot$ implies $w \in \Gamma_\bot (\Gamma \setminus \Gamma_\bot)^*$ and $\gamma \notin \Gamma_\bot$ implies $w \in (\Gamma \setminus \Gamma_\bot)^*$;
\begin{itemize}
\item $P$ is the transition probability function fulfilling for every \( q \in Q \) and \( \gamma \in \Gamma \):
\[
\sum_{(q, \gamma, a, q', w) \in \delta} P[(q, \gamma, a, q', w)] = 1.
\]
\end{itemize}

\textbf{Definition 22.} A partially observable pPDA (POpPDA) is a tuple \((\mathcal{A}, \Sigma_o, P)\) consisting of a pPDA \(\mathcal{A}\) equipped with a mapping \(P: \Sigma \to \Sigma_o \cup \{\varepsilon\}\) where \(\Sigma_o\) is the set of observations.

The undecidability of diagnosability for POpPDA can be derived from the undecidability of diagnosability for non-probabilistic PDA \([11]\). However, to show how robust the result is, we refine the statement into Theorems 23 and 24: undecidability already holds for two (incomparable) subclasses of POpPDA with restriction on what is observable and on the number of phases of any run. A phase is a portion of run in which the stack either never decreases or never increases.

\textbf{Theorem 23.} The diagnosability problems are undecidable for POpPDA even when (1) the top of the stack is not updated, (2) every event labelling a push transition is fully observable and corresponds to the pushed symbol, and (3) every run consists of at most two phases.

\textbf{Proof.} The proof is by reduction from the Post correspondence problem (PCP). An instance of PCP is given by an integer \( n \in \mathbb{N} \) and two families of non-empty words \( \{v_i\}_{i \leq n} \) and \( \{w_i\}_{i \leq n} \) on the alphabet \( \{a, b\}\). The following question is undecidable: does there exist \( k > 0 \) and \( i_1, \ldots, i_k \in \{1, \ldots, n\} \) such that \( w_{i_1} \cdots w_{i_k} = v_1 \cdots v_k \)?

In this proof, we let \( \ell_i \) (resp. \( m_i \)) be the length of \( v_i \) (resp. \( w_i \)). Also, given a word \( w \) and \( k \leq |w| \) we use \( w[k] \) to denote the \( k^{th}\) letter of \( w \).

From an instance \((n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})\) of PCP, we build a pPDA \(\mathcal{A} = (Q, \Sigma, \Gamma, \delta, P)\) as follows:

\begin{itemize}
\item \( Q = \{q_0, q_c, q_0, f_s\} \cup \{q_i^k \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i\} \cup \{f_i^k \mid 1 \leq i \leq n, 1 \leq k \leq m_i\} \); \n\item \( \Sigma = \{1, \ldots, n, \bot, u, r, f, a, b\} \); \n\item \( \Gamma = \{1, \ldots, n, \bot_0\} \) with \( \Gamma_i = \{\bot_0\} \); \n\item \( \delta \) consists of the following transitions:
\[
\begin{align*}
&\{(q_0, \bot_0, x, \bot_0, q_0) \mid 1 \leq x \leq n\} \\
&\cup \{(q_c, x, y, x, y, q_c) \mid 1 \leq x, y \leq n\} \\
&\cup \{(q_i^k, z, v_i[k], \bot_0, q_i^k) \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i, z \in \{\bot_0, 1, \ldots, n\}\} \\
&\cup \{(f_i^k, z, w_i[k], \bot_0, f_i^k) \mid 1 \leq i \leq n, 1 \leq k \leq m_i, z \in \{\bot_0, 1, \ldots, n\}\} \\
&\cup \{(q_i^m, z, w_i[i], \bot_0, q_i^m) \mid 1 \leq i \leq n, z \in \{\bot_0, 1, \ldots, n\}\} \\
&\cup \{(q_i^m, x, r, \varepsilon, q_i^m) \mid 1 \leq i \leq n\} \\
&\cup \{f_s, x, r, \varepsilon, f_s \mid 1 \leq x \leq n\} \\
&\cup \{(q_c, x, u, x, q_c), (q_c, x, f, x, f_s) \mid 1 \leq x \leq n\} \\
&\cup \{(q, \bot_0, 1, \bot_0, q), (f_s, \bot_0, 1, \bot_0, f_s)\}.
\end{align*}
\end{itemize}

\( P \) assigns arbitrary positive probabilities to transitions in \( \delta \):

\[
P(q, \gamma, a, q', w) > 0 \iff (q, \gamma, a, q', w) \in \delta \text{ and } \sum_{(q, \gamma, a, q', w) \in \delta} P[(q, \gamma, a, q', w)] = 1.
\]

We further consider the POpPDA \((\mathcal{A}, \Sigma_o, P)\) with \(\Sigma_o = \Sigma \setminus \{r, u, f\}\), and the masking function satisfies \(P(u) = P(r) = P(f) = \varepsilon\) and \(P(x) = x\) for any other event \( x \). This POpPDA is represented in Figure 10.

Let us prove that the instance of the PCP is positive if and only if the POpPDA is I\(\mathcal{F}\)-, I\(\mathcal{A}\)- and FA-diagnosable.

Assume first that there exists a solution \( i_1, \ldots, i_k \) to the PCP instance \((n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})\). Consider in the POpPDA the faulty run:

\[
p_f = q_0(i_1j_1q_c)_{j \leq k}f_s^k(f_j^i w_{i_1}[p])_{p \leq m_{i_1}}(f_s k)^\omega,
\]
and the correct run:

$$\rho_c = q_0(i_j q_c)_{j \leq k} w^1 q_s r(q_{i_j}^p v_{i_j}[p])_{j \leq k} (q_k h)^w.$$ 

These two runs have the same observed sequence: $P(\rho_f) = P(\rho_c) = i_1 \ldots i_k w^1 h^w$ with $w = w_{i_1} \ldots w_{i_k} = v_{i_1} \ldots v_{i_k}$. Therefore, $\rho_f$ is an infinite ambiguous faulty run. Given that $P(\rho_f) > 0$, we deduce that the POpPDA $(A, \Sigma_0, P)$ is not FA-diagnosable. From Theorem 4, it is also neither IA-diagnosable nor FA-diagnosable.

Conversely, assume that the PCP instance $(n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})$ has no solution. Independently of that, observe that $h$ almost surely occurs in an infinite run of the pPDA $A$. Thus, for any $\varepsilon > 0$, there exists $N \in \mathbb{N}$ such that the measure of signalling runs with observable length $N$ that reach configurations $(q_s, l_0)$ or $(f_s, l_0)$ by an event $h$ is at least $1 - \varepsilon$. Consider a correct run $\rho_c$ with observable length $N$, ending in $(q_s, l_0)$ and containing at least an occurrence of $h$. Its observed sequence is of the form $P(\rho_c) = i_1 \ldots i_k v_{i_1} \ldots v_{i_k} h^m$ for some $i_1, \ldots, i_k, m$. Due to the fact that $(n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})$ has no solution, no faulty run can have the same observed sequence. Therefore, $\rho_c$ is surely correct. Symmetrically, any faulty run ending in $(f_s, l_0)$ after an occurrence of $h$ is surely faulty. We thus conclude that, for any $\varepsilon > 0$, there exists $N \in \mathbb{N}$ such that $P(FAmb_N \cup CAmb_N) \leq \varepsilon$. As a consequence, the POpPDA $(A, \Sigma_0, P)$ is FA-diagnosable. By Theorem 4 it is also IA-diagnosable and FA-diagnosable.

A similar undecidability result holds for a class of POpPDA in which pop events are fully observable, and the number of phases is constant:

**Theorem 24.** The diagnosability problems are undecidable for POpPDA even when (1) the top of the stack is not updated, (2) every event labelling a pop transition is fully observable and corresponds to the popped symbol, and (3) every run consists of at most two phases.
Proof. The proof follows the same line as the one for Theorem 23. From an instance \((n, \{(v_i)_s\}, (w_i)_s)\) of PCP, let us define a pPDA \(A = (Q, \Sigma, \Gamma, \delta, P)\) where:

- \(Q = \{q_0, q_1, f_s, q_e, f_e\} \cup \{q_i^k \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i\} \cup \{f_i^k \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i\}\);
- \(\Sigma = \{1, \ldots, n, \sharp, u, c, f, a, b\}\);
- \(\Gamma = \{1, \ldots, n, \bot\}\) with \(\Gamma_i = \{\bot\}\);
- \(\delta\) consists of the following transitions:
  \[
  \begin{align*}
  &\{(q_0, 1, u, 1, q_0), (q_0, 1, f, 1, f_s), (q_e, \bot, 1, q_e), (f_e, 1, \bot, 1, f_e)\} \\
  &\cup \{(q_i^k, z, v_i[k], z, q_{i+1}) \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i, z \in \{1, 1, \ldots, n\}\} \\
  &\cup \{(f_i^k, z, w_i[k], z, f_{i+1}) \mid 1 \leq i \leq n, 1 \leq k \leq \ell_i, z \in \{1, 1, \ldots, n\}\} \\
  &\cup \{(q_i^m, z, w_i[m], z, f_s) \mid 1 \leq i \leq n, z \in \{1, 1, \ldots, n\}\} \\
  &\cup \{(f_i^m, z, c, z, f_e) \mid z \in \{1, 1, \ldots, n\}, x \in \{1, 1, \ldots, n\}\} \\
  &\cup \{(q_s, x, x, \epsilon, q_s) \mid x \in \{1, \ldots, n\}\} \\
  &\cup \{(f_s, x, x, \epsilon, f_e) \mid x \in \{1, \ldots, n\}\} \\
  &\cup \{(q_e, x, x, \epsilon, q_e) \mid x \in \{1, \ldots, n\}\} \\
  &\cup \{(f_e, x, x, \epsilon, f_e) \mid x \in \{1, \ldots, n\}\}.
  \end{align*}
\]

- \(P\) assigns arbitrary positive probabilities to transitions in \(\delta\).

We further consider the PopPDA \(\langle A, \Sigma, P \rangle\) with \(\Sigma_o = \Sigma \setminus \{c, u, f\}\), and the masking function satisfies \(P(u) = P(c) = P(f) = \epsilon\) and \(P(x) = x\) for any other event \(x\). This PopPDA is represented in Figure 11.

Let us prove that the instance of the PCP is positive if and only if the PopPDA is IF-, IA- and FA-diagnosable.
Assume first that there exists a solution \( i_1, \ldots, i_k \) to the PCP instance \((n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})\). Consider the faulty run:

\[
\rho_f = q_0\beta_{i_1} (c(f_{i_1} \leq j)_{s_k} (i_{j} f_{e})_{j \leq k} (h \omega),
\]

and the correct run:

\[
\rho_c = q_0\alpha_{i_1} (c(q_{i_1} \leq j)_{s_k} (i_{j} q_{e})_{j \leq k} (h \omega).
\]

These two runs have the same observed sequence: \( \mathcal{P}(\rho_f) = \mathcal{P}(\rho_c) = wi_1 \ldots i_k \omega \) with \( w = w_1 \ldots w_k = v_1 \ldots v_k \). Therefore, \( \rho_f \) is an infinite ambiguous faulty run. Given that \( \mathbb{P}(\rho_f) > 0 \), we deduce that the POpPDA \( (A, \Sigma_o, \mathbb{P}) \) is not IF-diagnosable. From Theorem 4, it is also neither IA-diagnosable nor FA-diagnosable.

Conversely, assume that the PCP instance \((n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})\) has no solution. Independently of that, observe that \( h \) almost surely occurs in an infinite run of the pPDA \( A \). Thus, for any \( \varepsilon > 0 \), there exists \( N \in \mathbb{N} \) such that the measure of signalling runs with observable length \( N \) that reach configurations \((q_e, \bot_0)\) or \((f_e, \bot_0)\) by an event \( h \) is at least \( 1 - \varepsilon \). Consider a correct run \( \rho_c \) with observable length \( N \) ending in \((q_e, \bot_0)\) and with an occurrence of \( h \). Its observed sequence is of the form \( v_{i_1} \ldots v_{i_k} i_1 \ldots i_k \omega \) for some \( i_1, \ldots, i_k, m \). Due to the fact that \((n, \{v_i\}_{i \leq n}, \{w_i\}_{i \leq n})\) has no solution, no faulty run can have the same observed sequence. Therefore, \( \rho_c \) is surely correct. Symmetrically, any faulty run ending in \((f_e, \bot_0)\) by an occurrence of \( h \) is surely faulty. We thus conclude that, for any \( \varepsilon > 0 \), there exists \( N \in \mathbb{N} \) such that \( \mathbb{P}(\text{FAmb}_N \cup \text{Cam}_N) \leq \varepsilon \). As a consequence, the POpPDA \( (A, \Sigma_o, \mathbb{P}) \) is FA-diagnosable. By Theorem 4 it is also IA-diagnosable and IF-diagnosable. \( \Box \)
