Abstract

A new approach for the design of logic gates that do not involve chemical inputs is presented here. This concept is based on the polarization of a light-sensitive interface. AND and OR logic gates, working with cheap reactants, which locally triggered water splitting half reactions, were designed and operated.

The transfer of the fundamental concepts of microelectronics and integrated circuits to chemical and miniaturized fluidic systems is attracting a tremendous interest.¹⁻⁷ The design, fabrication and operation of components allowing the processing and computation of signals in these media are therefore becoming very active areas of research. There has been a growing interest on the fabrication of molecular,^{2-4,8} microfluidic,^{5,6,9-11} and electrochemical devices¹²⁻¹⁷ able to control signals or perform binary operations. In typical molecular logic gates, the operations are performed by molecules or proteins either in solution^{8,18-21} or immobilized on a surface^{4,22} that generate a detectable chemical output only in a presence of certain external input signals (e.g. optical or chemical). Besides, microfluidic-based logic operations are often based on fluids or bubbles inputs, generating optical outputs⁵ or specific patterns.¹⁰ Few examples of electrochemical logic gates have been reported, most of them involving redox-active molecules immobilized on an electrode and generating optical or electrical outputs.¹²⁻¹⁷ Other appealing examples of electrochemical Boolean operators were reported by Berggren et al. who used the conductivity change of a conducting

polymer,²³ Amatore et al. who designed “artificial neurons” based on paired-band microelectrode assemblies²⁴ and Crooks et al. who conceived a microfluidic device generating electrochemiluminescence (ECL).²⁵

In this context, we wish to report herein a novel approach towards logic gates operated by bipolar electrochemistry. Bipolar electrochemistry is a phenomenon that allows the generation of electrochemical reactions on the surface of conductive objects without the use of electrical wires.^{26,27} It is currently attracting considerable attention in the areas of analytical chemistry,²⁸⁻³² materials science,³³⁻⁴¹ motion generation⁴²⁻⁴⁵ and seawater desalination.⁴⁶ This phenomenon is particularly well suited for the implementation of miniaturized electrochemical systems in fluidic devices because of its inherent “wireless” nature.^{26,27} So far, the unique example of logic operators based on the use of bipolar electrochemistry was reported by the group of Crooks.⁴⁷ Their devices were operated by electrical inputs and involved the use of ruthenium-based luminescent complexes and an amine co-reactant for the generation of ECL as an output.⁴⁸ The bipolar electrochemical splitting of water was reported by Fleischmann et al.⁴⁹ and applied recently for steering conducting objects^{43,44} and for the synthesis of Janus particles.⁵⁰ So far, only little interest^{51,52} has been given to the use of semiconductor (SC) bipolar electrodes (BEs). It is worth noting that Ongaro et al. recently reported the electric field-assisted photoreduction of metal on TiO₂ nanofibers.⁵³

Fig 1. a) Scheme depicting the cell used for photoelectrochemical experiments performed with a p-SiH/Pt BE. b) Voltammetric curves showing the anodic behavior of Pt (grey) and the cathodic behavior of p-Si with (blue) and without (black) illumination. The curves were obtained at 50 mV.s⁻¹ in 50 mM H₂SO₄.

We introduce here a new concept for the design of bipolar photoelectrochemical logic gates using a SC surface as a reactive pole, which allows for the first time to use light as an input signal. The fabrication and operation of AND and OR logic gates are described, that operate with the bipolar photoelectrochemical splitting of water and do not require direct connections. These devices can be very easily implemented and function only with water and a low concentration of supporting electrolyte (in the mM range).

In a typical bipolar electrochemistry experiment, a conducting object is placed in an electrolytic solution between two feeder electrodes, as shown in Fig. 1a. This object can be a conductive surface (e.g. a metal wire) or junctions. The application of a potential E_{app} between the two feeder electrodes generates a potential drop in the solution and therefore leads to the generation of a polarization potential ΔV along the object surface, which is maximal between its two ends.^{26,27} The value of this maximum polarization potential, ΔV_{max} , is given by the following relation:

$$[\Delta V]_{max} = E_{app}/L \times l \times \theta \quad (1)$$

with L being the distance between the feeder electrodes (4.6 cm), l the characteristic length of the conducting surface and θ a dimensionless constant that depends on the potential losses of the cell.³⁴ If ΔV_{max} is sufficiently high, electrochemical reactions can be toposelectively triggered: oxidation at the anodic pole (the pole facing the feeder cathode) and reduction at the cathodic pole (the pole facing the feeder anode). The conducting surface is then behaving at the same time as an anode and a cathode, that is, a BE.^{26,27} An important aspect is that electron production and consumption must be equal at both sides of the BE in order to maintain charge neutrality. In the present work, the logic

gates were designed on the basis of the configuration shown in Fig. 1a, with a split-BE26 composed of an oxide-free, hydrogen-terminated p-type silicon (p-SiH) cathodic pole and a Pt anodic pole, electrically connected outside to the cell. This configuration allowed to easily measure the current I_{be} flowing through the BE with an ammeter. All the reported experiments were performed in 50 mM aq H₂SO₄ in the dark and under irradiation with a halogen lamp.

First, both materials used for the split-BE were investigated separately by voltammetry in a classical three-electrode electrochemical cell. The anodic response of Pt was independent of light and, as shown in Fig. 1b, displayed an anodic current starting at 1.1 V vs SCE, which corresponds to O₂ evolution:

Unlike metals, the electrical properties of SC electrodes can be dramatically changed by light. For instance, p-type Si requires the generation of minority carriers (i.e. electrons) to operate as a photocathode, therefore irradiation with a wavelength higher than the material band gap (1.1 eV) is necessary in order to promote electrochemical reduction reactions at its surface.⁵⁴ Consistent with that, no cathodic current was generated in the dark at p-SiH (black curve in Fig. 1b) while a significant photocurrent beginning at -0.6 V vs SCE was observed under illumination (blue curve), which corresponds to proton reduction:

These preliminary data suggest that reduction of water cannot occur at the cathodic pole (p-SiH) of the BE in the dark. Because the charge consumption must be equal at both sides of the BE,^{26,27} this blocking behavior should also prevent oxidation reaction to occur at the anodic pole and therefore no current should flow through the object. On the contrary, bipolar reactions should be possible under illumination, if the applied electric field is sufficiently high to generate a $\Delta V_{\text{max}} > 1.7 \text{ V}$ between the ends of the BE, corresponding to the thermodynamic value that must be overcome in order to trigger reactions (2) and (3), as determined by Fig. 1b. These conditions should lead to the generation of a faradaic current I_{be} flowing through the BE, as illustrated in Fig. 1a.

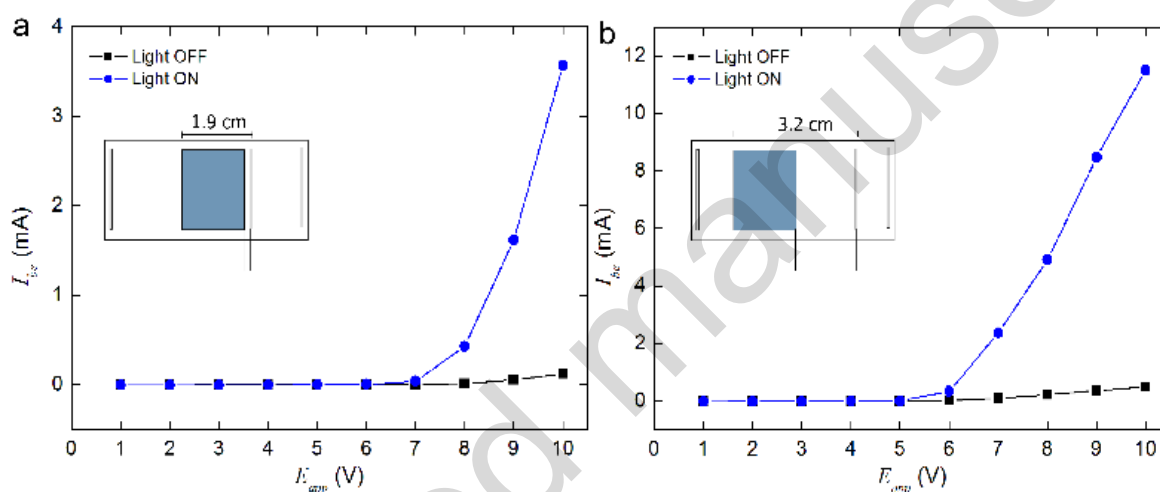

Fig 2. Curves showing the current flowing through the BE, I_{be} as a function of the potential applied between the feeder electrodes E_{app} in the dark (black curves) and under illumination (blue curves) for a) 1.9 cm-long and b) 3.2 cm-long BE. The insets are schemes representing the corresponding cells.

In order to assess thermodynamic and kinetic parameters directly on the BE, I_{be} measurements were performed while imposing different values of E_{app} , with and without illumination. Two characteristic BE lengths, $l_1 = 1.9 \text{ cm}$ and $l_2 = 3.2 \text{ cm}$, were used in this work. From the data shown in Fig. 2, it is obvious that a similar trend was obtained for both BEs. Under illumination, I_{be} was equal to zero until values $E_{\text{app}1} = 7 \text{ V}$ and $E_{\text{app}2} = 5 \text{ V}$ were respectively reached for l_1 and l_2 and then I_{be} increased with E_{app} . These threshold values correspond to the potentials to apply in order to

generate a ηV_{\max} of 1.7 V and locally trigger reactions (2) and (3). The highest value, E_{app1} was found for the smallest I value, which is well in line with eq. (1). This relation allowed us to calculate that $\sim 50\%$ of the applied electric field is effectively restituted to the BE (average $\eta = 0.54$), due to losses that may be attributed to field perturbation in the cell or potential drops at the solid/liquid or solid/solid interfaces. As expected, dark currents were found in both cases much lower than photocurrents (~ 25 times for $E_{app} = 10$ V, see Fig S1) thanks to the insulating behavior of p-SiH under these conditions. These data demonstrate that illumination and applied potential generate large current modifications in these BEs that can be easily measured. Therefore, such a configuration is very well-suited for the fabrication of two-input logic gates, which will be now described.

The two inputs can be defined as E_{app} ($In1$) and illumination ($In2$), whereas the current I_{be} can be considered as the output signal. Based on data of Fig. 2a, we decided to set $In1 = 0$ for $E_{app} = 7$ V and $In1 = 1$ for $E_{app} = 10$ V, in order to obtain a sufficiently high output signal when all the inputs will be equal to 1. The threshold output value was arbitrary set to 1.5 mA. The transient signals $In1$ and $In2$ and the resulting outputs for both systems are shown in Fig. 3a-d and summarized in the corresponding truth tables (Fig. 3f,g). The 1.9 cm-long BE (Fig. 3c) exhibited an output signal "1" ($I_{be} > 1.5$ mA) only when $In1 = In2 = 1$. All the other combinations yield an output signal of "0" ($I_{be} < 1.5$ mA). Therefore, this system acted as an AND gate. As shown in Fig. 3e, generation of H_2 and O_2 bubbles was observed at both reactive poles of the BE when Output = "1", confirming the triggering of reactions (2) and (3). The release of H_2 bubbles from the BE surface caused the current fluctuations that are visible in the output signal (Fig. 3c). In contrast, the 3.2 cm-long BE (Fig. 3d) was found to be always in its state "1" when illuminated, which is in good agreement with the data shown in Fig. 2b. Even if the latter configuration is not so beneficial in terms of Boolean logic (a YES gate, performing the operation Output = $In2$), it will be very useful in the following for the design of an OR logic gate.

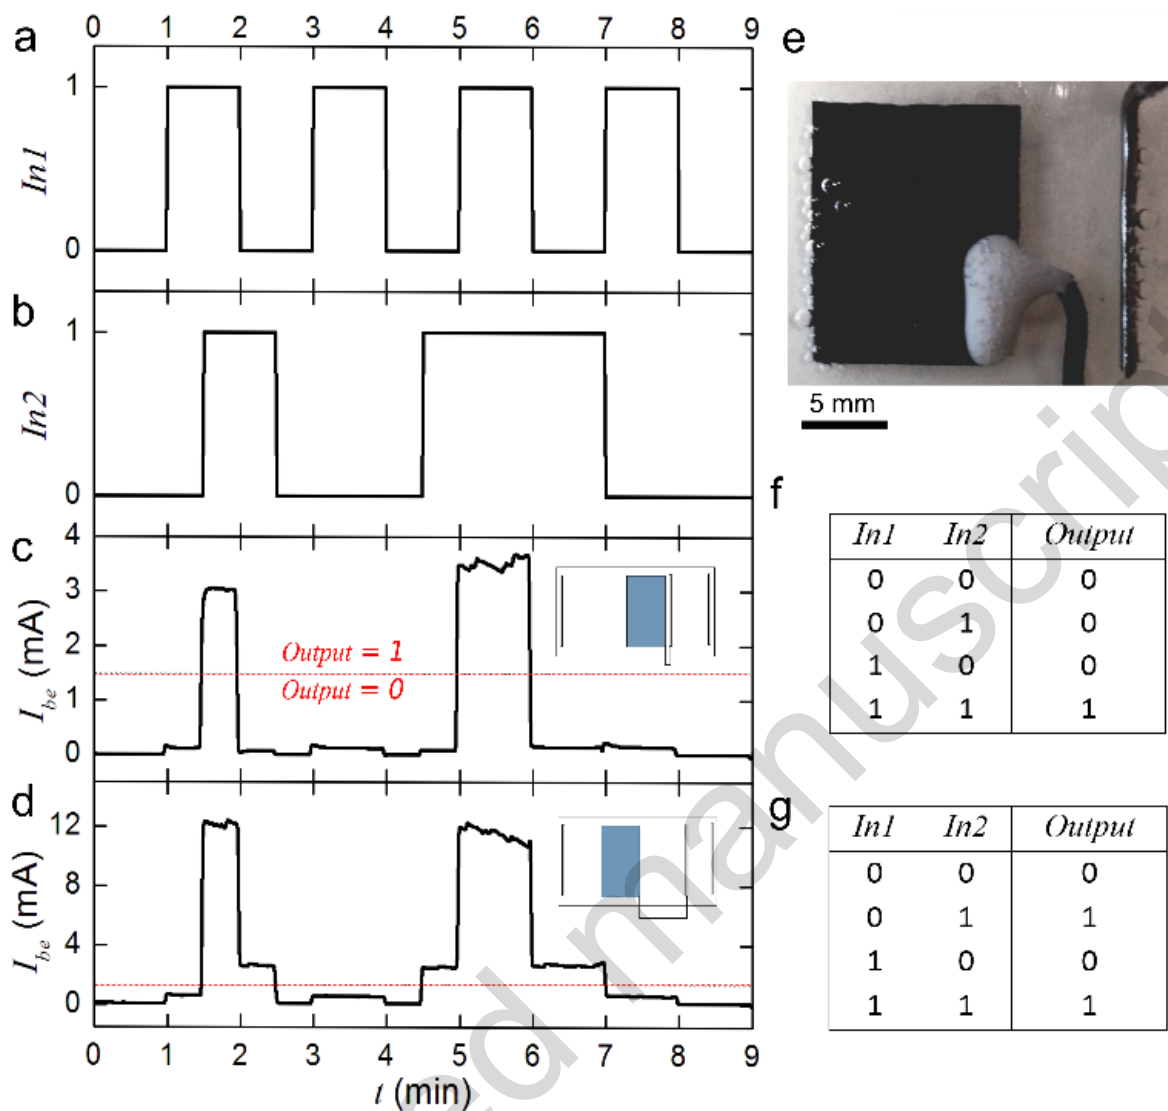

Fig. 3. Time-dependent profiles of the applied input signals a) $In1$ ($In1 = 0$ for $E_{app} = 7$ V and $In1 = 1$ for $E_{app} = 10$ V), b) $In2$ ($In2 = 0$ when the light is OFF and $In2 = 1$ when the light is ON) and the output I_{be} measured for c) a 1.9 cm-long BE acting as an AND gate and d) a 3.2 cm-long BE. Both BEs are composed of a p-SiH cathodic pole and a Pt anodic pole. The red line indicates the threshold current of 1.5 mA. e) Photograph of the split BE showing the evolution of H_2 and O_2 bubbles at the cathodic pole (left) and at the anodic pole (right), respectively. f,g) Truth tables summarizing the results obtained in f) Fig. 3c and g) Fig. 3d.

For comparison, split BEs only composed of Pt wires were also investigated and were found to perform the following operations: Output = "1" whatever the states of In1 and In2 for $l = 3.2$ cm (see Fig. S2 in the Supporting Information) and Output = In1 for $l = 1.9$ cm, as shown in Fig. 4c. These results were expected because the conductivity of metals like Pt is not sensitive to light, therefore the output was always independent of In2. The latter configuration was particularly attractive since it allowed to reach the combination that was missing in the truth table of Fig. 3g in order to get an OR gate, (i.e. Output = 1 when In1 = 1 and In2 = 0). An interesting strategy to combine the BE configurations of Fig. 3d and 4c was to use a hybrid BE made of a light-sensitive component as well as a component non-sensitive to light. The simplest design, depicted in Fig. 4e,f, consisted in the connection in parallel of a p-SiH surface with a Pt wire. The output signal of such a BE with the corresponding truth table are shown in Fig. 4d,h. As expected, this BE acted as an OR gate with the Pt wire being the cathodic pole when In1 = 1 and In2 = 0, and p-SiH being the cathodic pole when In1 = 0 and In2 = 1. These experiments demonstrate that AND and OR logic gates operated by bipolar photoelectrochemical water splitting can be designed and easily operated.

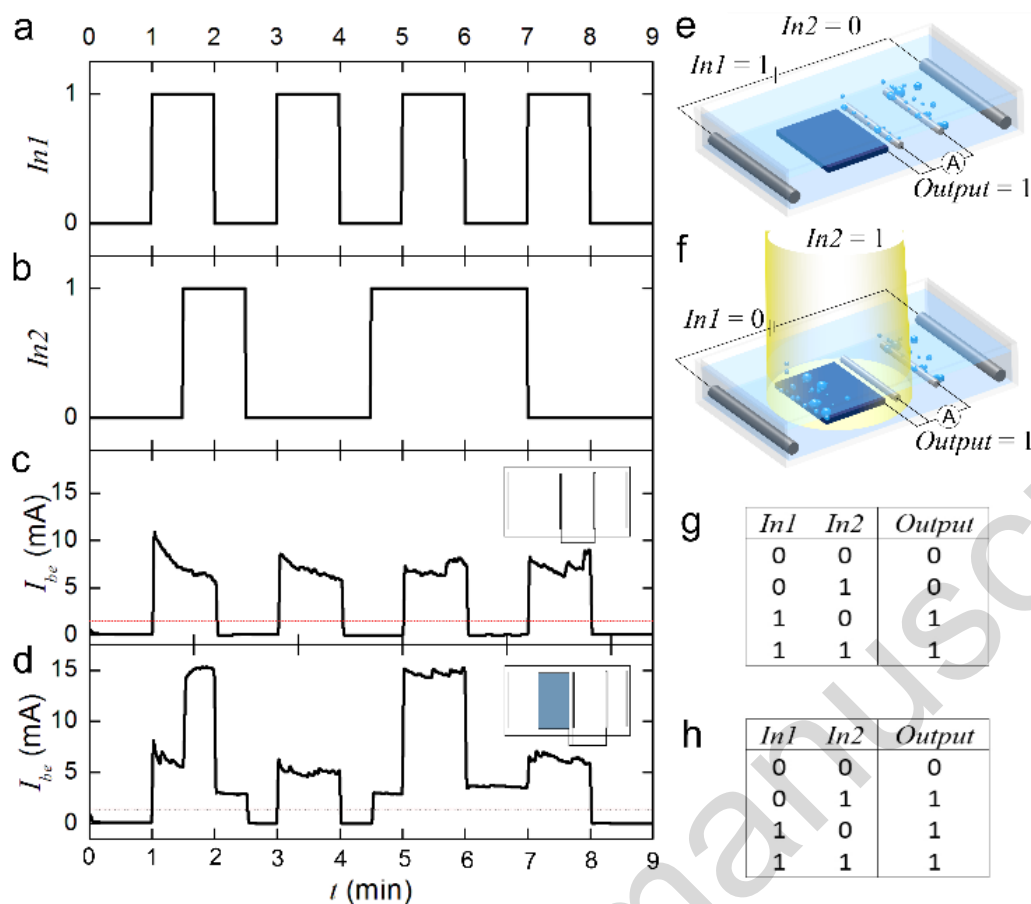

Fig. 4. Time-dependent profiles of the applied input signals a) In1 (In1 = 0 for $E_{app} = 7$ V and In1 = 1 for $E_{app} = 10$ V), b) In2 (In2 = 0 when the light is OFF and In2 = 1 when the light is ON) and the output I_{be} measured for c) a 1.9 cm-long BE with two Pt reactive poles and d) a 3.2 cm-long BE composed of a p-SiH/Pt cathodic pole and a Pt anodic pole acting as an OR gate. The red line indicates the threshold current of 1.5 mA. e, f) Cell schemes showing the OR gate operating when e) In1 = 1 and In2 = 0 and f) In1 = 0 and In2 = 1. g, h) Truth tables summarizing the results obtained in g) Fig. 4c and h) Fig. 4d.

The percentages of current flowing through the BEs were calculated for the AND and the OR logic gates and are reported in Table S1. Interestingly, they varied from values smaller than 0.4% when Output = "0" to values greater than 5% when Output = "1", with a maximum of 22% for the OR gate when In1 = In2 = 1. In order to assess the time stability of the involved surfaces, cycling tests were performed with the AND gate by imposing switching cycles to In1 while keeping In2 = 1. As shown in

Fig. 5, I_{be} was found to be constant over numerous switching cycles. Such a stability of the p-SiH-based BE is thus very promising for future integration of the logic gates in fluidic devices.

Fig. 5. Curve showing the time evolution of the output signal I_{be} for the AND gate when In 1 is switched ON and OFF. The red line indicates the threshold current 1.5 mA.

Conclusions

In this work, we have demonstrated a new strategy for the design of electrochemical logic gates working with optical and electrical inputs. Robust and stable AND and OR gates, operated with cheap reactants (i.e. acidic water) were fabricated. The inputs were mediated by electric and electromagnetic fields and the gates did not require direct connection. Thanks to their “wireless” implementation, these devices should be easily downscaled and therefore could be operated with LEDs in miniaturized devices such as micro-fluidic channels and lab-on-chips with suitable electric

fields (see eq. 1). It should be also possible to combine several gates in a single fluidic device and use the current flowing through the BE to perform additional logic operations or to supply integrated electronic devices.⁴⁴ Additionally, a signal other than the bipolar current (i.e. bubble production or the generation of an optically-active compound at a reactive pole) could be considered as output, in order to minimize the electrical connections. In this first report, SC/metal BEs were employed but it is evident that our approach can be extended to p-SC/n-SC BEs which will enlarge the panel of available operations and reduce the cost of the devices. Considering that a very large panel of materials and co-catalysts combinations can be used as BEs and that the electrolyte composition will have a direct effect on the output values, we believe that this work pave the way to a broad family of signal processing devices for chemical and fluidic systems.
