Abstract.- We present some general tools for measuring distances either between two
statistical models or between a parametric model (or signature) and a signal. These tools
are useful for solving a variety of Signal Processing problems such as detection,
segmentation, classification, recognition or coding.
After a section devoted to general distance measures between probability laws, we
investigate the question of spectral distances between processes. Then we describe
results concerning AR and ARMA models, for which we also mention the problems
related to the interaction between distances for parametric models and estimation of the
parameters of these models. We also recall (when necessary) some classical results
about error bounds in classification and feature selection for pattern recognition, which
are obtained with the aid of properties of distance measures.

DISTANCES EN TRAITEMENT DU SIGNAL ET RECONNAISSANCE
DES FORMES

Résumé.- On se propose de présenter quelques outils généraux pour mesurer des
distances soit entre deux modèles statistiques soit entre un modèle paramétrique et un
signal. Ces outils sont utiles pour résoudre de nombreux problèmes en Traitement du
Signal et notamment pour la détection, la segmentation, la classification, la
reconnaissance ou le codage.
Après un paragraphe consacré à des mesures générales de distances entre lois de
probabilité, on considère le problème des distances spectrales entre processus. Puis on
présente des résultats relatifs aux modèles AR ou ARMA, pour lesquels on mentionne
aussi les problèmes liés à l'interaction entre distances de modèles paramétriques et
estimation des paramètres de ces modèles. Sont également rappelés, lorsqu'il y a lieu,
les résultats classiques concernant les bornes d'erreur de classification ou la sélection de
traits caractéristiques pour la Reconnaissance des Formes, résultats obtenus à l'aide de
propriétés de distances précisément.

Running headline.- Distances for Signal Processing.

I - INTRODUCTION

Distance measures between statistical models or between a model and observations are widely used concepts in Signal Processing (and in Automatic Control) for solving various problems such as detection, automatic segmentation, classification, Pattern Recognition, coding, (model validation, choice of optimal input signals for system identification)...

Up to our knowledge, the studies concerning distance measures are basically of two types, apart from those of probabilists and statisticians. On one hand, there are general studies for the computation of error probabilities in classification problems (of any objects characterized by any measurements), without taking into account neither the nature of the parameters which characterize the probability laws nor the way by which they have been estimated. On the other hand, there are a lot of specific studies in the speech processing domain (coding, recognition), where refinements of Itakura or cepstral distance measures still emerge now.

The aim of this paper is to get together disseminated tools and results concerning distance measures, in view of application in Signal Processing, for detection and recognition in general. Especially, we shall address some typical issues in model based Signal Processing, namely choice of models, parametrizations and parametric estimation methods on one hand, and choice of distance measures between these models on the other one, without forgetting the possible interaction between these two choices.

However we do not claim that we exhaustively compiled all the litterature concerning distance measures. Nevertheless, we try to follow a presentation going from a general framework to particular cases.

In section II, we introduce general distance measures between probability laws and the relationships existing among them. Then, we present some general tools for measuring the distance between a model and a signal. Section III is devoted to spectral distance measures between processes. In section IV, we analyse the results related to AR or ARMA models and to the interaction parametrization/distance.

Let us emphasize that the word distance here means measure of how far away from each other the laws are, and is not used with the strict sense it has in metric spaces. Particularly, the measures which are mentioned are not all symmetrical and don't all satisfy the triangular inequality.
Furthermore, we shall use throughout the paper the following terminology and notations:

- $d(P_1, P_2)$ distance between the probability laws $P_1$ and $P_2$
- $d(A_1, A_2)$ distance between the parametric models $A_1$ and $A_2$
- $d(y_1, A_2)$ distance between a signal $(y_1)$ and a model $A_2$

- With such notations, if $\hat{A}_i$ represents an estimate of $A_i$ ($i = 1, 2$), then:

$$d(\hat{A}_1, \hat{A}_2) \text{ et } d(y_1, \hat{A}_2)$$

are distances between signals. The symbol $^\wedge$ will often be omitted for simplification.

**II - GENERAL DISTANCE MEASURES**

In this section, we introduce general classes of distance measures, or divergence coefficients, between probability distributions. In II.1, we start with the class related to Csiszar f-divergence (9) which contains many known distance measures which we also recall in the multidimensional case. But this class is not related to information measures, except for Kullback divergence. Then in II.2 we describe the so-called class of general mean distance introduced by Boeker and Van der Lubbe [6] for Pattern Recognition, which is directly related to information measures. In section II.3 we investigate a general contrast criterion which may be used as a distance and was introduced by Poor [41] for robust detection. Then we describe some general tools for measuring the distance between a model and observations: in section II.4, we recall the axiomatic derivation of the entropy principle due to Shore [42], and finally in section II.5 we present a general model validation tool to be used for segmentation or monitoring [4].

**II.1 - f-DIVERGENCE**
This general notion has been apparently introduced by Csiszar [9] [10] and independently by Ali et Silvey [1]. It is based upon the fact that it is intuitively "natural" to measure the remoteness of two probability distributions $p_1$ et $p_2$ with the aid of the "dispersion" - with respect to $p_1$ - of the likelihood ratio $\phi(x) = \frac{p_2(x)}{p_1(x)}$ : if $p_1$ and $p_2$ are two densities on $\mathbb{R}$, when they "move" away from each other, $\phi$ increases on a set of decreasing $p_1$-probability and decreases on a set of increasing $p_1$-probability. More generally, we get "reasonable" divergence coefficients by considering as a dispersion measure of $\phi$ the $p_1$-expectation of any increasing function $g$ of this $p_1$-expectation.

II.1.1 - Definition

More precisely, let $f$ a continuous convex real function on $\mathbb{R}_+$ (weaker conditions than continuity may be found in [9] [6]), and let $g$ be an increasing function on $\mathbb{R}$. Consider the following class of divergence coefficients between two probability laws $P_1$ et $P_2$ over the same space:

$$d (P_1, P_2) = g \left[ \mathbb{E}_1 \left[ f \left( \frac{dP_2}{dF_1} \right) \right] \right]$$

(1)

where

$$\frac{dP_2}{dP_1} \triangleq \phi$$

(2)

is the Radon-Nikodym derivative (possibly generalized in the case where $P_2$ has a singular component with respect to $P_1$ see [1]), and where $\mathbb{E}_1$ is the expectation with respect to $P_1$.

II.1.2. Properties

Then [1] $d$ has the following properties :

i) if $y = t(x)$ is a measurable transformation of $(\mathcal{X}, \mathcal{F})$ on $(\mathcal{Y}, \mathcal{G})$ then :

$$d (P_1, P_2) \geq d(P_1 t^{-1}, P_2 t^{-1})$$

(3)

where $P_1 t^{-1}$ is the measure image of $P_1$ by $t$. 

5
This implies that, when $t$ is the selection of coordinates of a process

$$(x_n)_{n \in \mathbb{N}},$$

we do not decrease the distinguishability between the two laws by increasing the number of observations, i.e.:

$$d(P_1^{(m)}, P_2^{(m)}) \leq d(P_1^{(n)}, P_2^{(n)})$$

for $m < n \quad (3')$$

where the $P_i^{(j)}$ are the marginal laws of $x_1, \ldots, x_j$.

ii) $d(P_1, P_2)$ is minimum when $P_1 = P_2$ and maximum when $P_1 \perp P_2$.

iii) if $(p_{\theta} ; \theta \in [a, b])$ is a family of densities on $\mathbb{R}$ with monotone likelihood ratio

(i.e if there exists a function $T$ such that for any $\theta_1 < \theta_2$, $\frac{p_{\theta_2}(x)}{p_{\theta_1}(x)}$ is an increasing function of $T(x)$; [33], p68; important condition for designing tests), then for $a < \theta_1 < \theta_2 < \theta_3 < b$, we have:

$$d(P_{\theta_1}, P_{\theta_2}) \leq d(P_{\theta_1}, P_{\theta_3}) \quad (4)$$

Let us notice that the convexity of $f$ is a necessary condition for i). Furthermore, for $g$ identity and $p_1, p_2$ two densities, we have [10]:

$$d(p_1, p_2) = \int_{\mathbb{R}} f \left( \frac{p_1(x)}{p_2(x)} \right) p_2(x) \, dx \geq f(1)$$

with equality if and only if $p_1 = p_2$ almost everywhere.

A key issue here is that there exist [1] other measures of the dispersion of $\phi$ which are not the expectation of a convex function of $\phi$. Thus it is possible to build divergence coefficients (or distance measures) based upon $\phi$ which do not have form (1), and of course coefficients which are not based upon $\phi$. However, we shall see that (1) contains many usual measures, and thus the comparison between many distance measures reduces to the comparison between convex functions [6]. Furthermore, the classification error probability $P_e$, for which the search for upper and lower bounds - see formulas (18) to (21) - gave rise to many studies about distance measures [6] [7] [13], can also be written as in (1) with $f(x) = \min(x, 1 - x)$. Thus the search for upper
and lower bounds for $P_e$ reduces to compare this function $f$ to other convex functions [5].

II.1.3. Examples

Let $\lambda$ be a measure on $(\mathfrak{X}, \mathcal{F})$ such that $P_1$ and $P_2$ are absolutely continuous with respect to $\lambda$, with densities $p_1$ and $p_2$ (ex: $\lambda = P_1 + P_2$ or Lebesgue measure).

- **Kolmogorov variational distance**

  \[ f(x) = |1 - x| ; \quad g(x) = \frac{x}{2} ; \]

  \[ d(P_1, P_2) = \frac{1}{2} \int_{\mathfrak{X}} |p_2 - p_1| \, d\lambda \triangleq V(P_1, P_2) \tag{5} \]

- **Hellinger distance**

  \[ f(x) = (\sqrt{x} - 1)^2 ; \quad g(x) = \frac{x}{2} ; \]

  \[ d(P_1, P_2) = \frac{1}{2} \int_{\mathfrak{X}} (\sqrt{p_2} - \sqrt{p_1})^2 \, d\lambda \triangleq H^2(P_1, P_2) \tag{6} \]

- **Kullback information**

  \[ f(x) = -\log x ; \quad g(x) = x ; \]

  \[ d(P_1, P_2) = \int_{\mathfrak{X}} p_1 \log \frac{p_1}{p_2} \, d\lambda \triangleq K(P_1, P_2) \tag{7} \]
• **Kullback divergence**

\[ f(x) = (x - 1) \log x \; ; \quad g(x) = x \; ; \]

\[ d(P_1, P_2) = \int \left( \frac{p_2}{p_1} - 1 \right) p_1 \log \frac{p_2}{p_1} \, d\lambda = J(P_1, P_2) \triangleq K(P_1, P_2) + K(P_2, P_1) \]

which is symmetrical.

• **Chernoff distance**

\[ 0 \leq r \leq 1 \; ; \quad f(x) = -x^{1-r} \; ; \quad g(x) = -\log(-x) \; ; \]

\[ d(P_1, P_2) = -\log C(P_1, P_2) \]

where \( C(P_1, P_2) = \int \frac{1}{p_1^{1-r}} p_2^{1-r} \, d\lambda \)

is called Chernoff coefficient.

• **Bhattacharyya distance** : previous case with \( r = \frac{1}{2} \)

ie \[ f(x) = -\sqrt{x} \; ; \quad g(x) = -\log(-x) \; ; \]

\[ d(P_1, P_2) = -\log \rho(P_1, P_2) \triangleq B(P_1, P_2) \]

where \( \rho(P_1, P_2) = \int \sqrt{p_1 p_2} \, d\lambda \triangleq 1 - H^2(P_1, P_2) \)

is called Bhattacharyya coefficient in the field of Pattern Recognition and affinity in theoretical Statistics. We refer to [28] for its formulation in the case of Markov chains and its use for detection.
• Generalized Matusita distance

\[ r \geq 1 \; ; \; f(x) = 1 - x^{1/r} \; ; \; g(x) = x^{1/r} \hydraspace ; \]

\[ d(P_1, P_2) = \sqrt{\int_{x} \left| p_1^{1/r} - p_2^{1/r} \right|^r \, d\lambda} \triangleq M_r(P_1, P_2) \quad (11) \]

Notice that, for \( r = 1 \), we get Kolmogorov distance and, for \( r = 2 \), the usual Matusita distance, which is equal to \( \sqrt{2} H(P_1, P_2) \).

• Error probability in classification

It is known that the error probability \( P_e \) of the optimal Bayes rule for the classification into 2 classes with a priori probabilities \( \pi \) et \( 1-\pi \) and where the corresponding densities of the observations are \( p_1 \) and \( p_2 \), is:

\[ P_e = \int_{x} \min \left[ \pi p_1, (1 - \pi) p_2 \right] \, d\lambda \quad (12) \]

It results that \( 1 - P_e \), which is a way to measure the distance between \( p_1 \) and \( p_2 \), is of the form (1) with \( f(x) = -\min (x, 1-x) \) and \( g(x) = x + 1 \).

• Notice that [31] Patrick and Fisher distance:

\[ d(P_1, P_2) = \sqrt{\int_{x} (p_1 - p_2)^2 \, d\lambda} \quad (13) \]

and Lissack and Fu distance

\[ (0 < \alpha) \; d(P_1, P_2) = \int_{x} \left| p_1 - p_2 \right|^{\alpha} \, d\lambda \quad (14) \]

are not of the form (1) (except for \( \alpha = 1 \) for the last one).

• We will see other examples of spectral distance measures in section III.

• Special case of gaussian multidimensional laws \( \mathcal{N}(\mu_i, \Sigma_i) \) (\( i = 1,2 \))

This case is investigated in many papers related to the field of Pattern Recognition. We then get [14] [31]:

9
* Bhattacharyya distance:

\[ B(P_1, P_2) = \frac{1}{4} (\mu_2 - \mu_1)^T (\Sigma_1 + \Sigma_2)^{-1} (\mu_2 - \mu_1) + \frac{1}{2} \log \frac{|\Sigma_1 + \Sigma_2|}{2\sqrt{\det(\Sigma_1 \Sigma_2)}} \]  

(15)

* Kullback divergence

\[ J(P_1, P_2) = \frac{1}{2} (\mu_2 - \mu_1)^T (\Sigma_1^{-1} + \Sigma_2^{-1}) (\mu_2 - \mu_1) + \frac{1}{2} \text{tr} (\Sigma_1^{-1} \Sigma_2 + \Sigma_2^{-1} \Sigma_1 - 2I) \]  

(16)

When the covariance matrices are identical \(\Sigma_1 = \Sigma_2 = \Sigma\), we get

* Mahalanobis distance:

\[ M(P_1, P_2) \triangleq J(P_1, P_2) = 8 B(P_1, P_2) = (\mu_2 - \mu_1)^T \Sigma^{-1} (\mu_2 - \mu_1) \]  

(17)

II.1.4 - Some inequalities

As we said before, the search for bounds of the classification error probability [7] [13] [5] [6], but also other goals such as feature selection for Pattern Recognition [7] [31] or signal selection [27] [37], led to various inequalities between \(P_e\) and many of the above mentioned distance measures or between these distances.

For example [27] [30]:

\[ \frac{1}{2} \left[ 1 - \sqrt{1 - 4 \pi (1 - \pi) \rho^2} \right] \leq P_e \leq \sqrt{\pi (1 - \pi)} \rho \]  

(18)

where \(\rho\) is defined in (10)

\[ \frac{1}{2} \min (\pi, 1 - \pi) e^{-J} \leq P_e \leq \sqrt{\pi (1 - \pi)} \left[ \frac{J}{4} \right]^{1/4} \]  

(19)

or [6]:

\[ P_e \leq \frac{1}{2} \cdot \frac{1}{2} V \]  

(20)

\[ P_e \leq \frac{1}{2} \cdot \frac{1}{2} M^r \]  

(21)
Other bounds for $P_e$ may be found in [13] [7], [6] where the case of several classes is also investigated and general bounds are given, and [5]. In [29] the author studies the case where the a priori probability laws are not precisely known.

Among the known theoretical inequalities[11], we have:

\[ H^2(2 - H^2) = 1 - \rho^2 \]  
(22)

\[ e^{-1/2 K \Phi_1, \Phi_2} \leq \rho (P_1, P_2) \]  
(23)

\[ H^2(P_1, P_2) \leq V(P_1, P_2) \leq H(P_1, P_2) \sqrt{2 - H^2(P_1, P_2)} \]  
(24)

\[ \frac{1}{4} e^{K \Phi_1, \Phi_2} \leq 1 - V(P_1, P_2) \leq \rho (P_1, P_2) \]  
(25)

II.2 - General mean distance for classification

For the m-classes classification problem, with a priori probabilities $\pi_i$, the error probability $P_e$ (12) becomes:

\[ P_e = 1 - \int_\infty \max_i \left[ \pi_i P(x | C_i) \right] dx \]

\[ = 1 - \int_\infty p(x) \left[ \max_i P(C_i | x) \right] dx \]

where $P(C_i | x)$ is the a posteriori probability of the class $C_i$ given the observation $x$,

and $p(x) = \sum_{i=1}^{m} \pi_i P(x | C_i)$.

A possible approximation is:

\[ P_e \leq \sum_{i=1}^{m-1} \sum_{j=i+1}^{m} P_e (C_i, C_j) \]

and for all the pairs $(C_i, C_j)$ the previously mentioned bounds may be used. Another way of getting bounds for $P_e$ was introduced by Van der Lubbe [6] who defines what he calls the "general mean distance" between the m classes $C_i$ by:
\[ G_{\alpha, \beta}(C) = \int_{\infty} p(x) \left[ \sum_{i=1}^{m} P(C_i | x)^\beta \right]^\alpha \, dx \] (26)

This "distance" is symmetric by definition.

This set of distances (26) also contains many known distance measures for Pattern Recognition, and is related to information measures such as Shannon entropy (also called equivocation) and the quadratic entropy, as can be seen from the following examples.

**Examples**

The following distance measures were introduced for the derivation of bounds for the error probability \( P_e \) which are tightest than Shannon entropy:

\[ \sum_i - P(C_i | x) \log P(C_i | x) \]

- **Devijver Bayesian distance[13]**
  - \( \beta = 2, \alpha = 1 \):
    \[ G_{1,2}(C | X) = \int_{\infty} p(x) \left[ \sum_{i=1}^{m} P(C_i | x)^2 \right] \, dx \]
  - \( A \equiv B(C | X) \)
    \[ = 1 - H_2(C | X) \]

where \( H_2 \) is the mean conditional quadratic entropy defined from the usual entropy by replacing \( -\log P(C_i | x) \) by \( 1 - P(C_i | x) \).

- \( \beta = 3, \alpha = 1 \)
  \[ G_{1,3}(C | X) = \int_{\infty} p(x) \left[ \sum_{i=1}^{m} P(C_i | x)^3 \right] \, dx \]

It can be shown that:

\[ G_{1,3}(C | X) = 1 - H_3(C | X) \] (28)
where $H_3$ is the mean conditional cubic entropy introduced by Chen [7] and defined from the usual entropy by replacing $\log P(C_i | x)$ by

$$P(C_i | x) - 1 + \frac{1}{2} \left[ P(C_i | x) - 1 \right]^2.$$  

* $\alpha = 1/\beta$ and $\beta > 1$:

$$G_{1/\beta, \beta}(C \mid X) = \int_X p(x) \left[ \sum_{i=1}^m P(C_i \mid x)^{\beta} \right]^{1/\beta} \, dx$$

is the distance $B_{S'}(C \mid X)$ proposed by Trouborst [50].

Many bounds for $P_e$ can be obtained from this class. Among others [6]:

* $\alpha > 0$, $\beta > 1$, $1 \leq \alpha \beta < 1 + \alpha$ $\Rightarrow$

$$1 - G_{\alpha, \beta}(C \mid X)^{1/\alpha \beta} \leq P_e \leq 1 - G_{\alpha, \beta}(C \mid X)^{1/\alpha (\beta - 1)}$$

$$\leq 1 - \frac{1}{m^\alpha} G_{\alpha, \beta}(C \mid X)$$

* $\alpha > 0$, $\beta > 1$, $\alpha \beta \leq 1$ $\Rightarrow$

$$1 - G_{\alpha, \beta}(C \mid X) \leq P_e \leq 1 - G_{\alpha, \beta}(C \mid X)^{1/\alpha (\beta - 1)}$$

$$\leq 1 - \frac{1}{m^{1/\beta}} G_{\alpha, \beta}(C \mid X)^{1/\alpha \beta}$$

* $\alpha > 0$, $\beta > 1$, $\alpha \beta \geq \alpha + 1$ $\Rightarrow$

$$1 - G_{\alpha, \beta}(C \mid X)^{1/\alpha \beta} \leq P_e \leq 1 - G_{\alpha, \beta}(C \mid X)$$

$$\leq 1 - \frac{1}{m^\alpha} G_{\alpha, \beta}(C \mid X)$$

$$\lim_{\beta \to \infty} (1 - G_{1/\beta, \beta}(C \mid X)) = P_e$$

These are generalizations of known bounds.
II.3 - CONTRAST TYPE DISTANCE MEASURES

Another type of distance between laws has been introduced by Poor [41] for robust detection. It is based upon a generalized version of the signal to noise ratio often called contrast.

Given a statistics \( h \) for deciding (by comparison to a threshold) between two laws \( P_1 \) and \( P_2 \), we call "distance between \( P_1 \) and \( P_2 \) through the statistics \( h \)":

\[
S_h(P_1, P_2) = \begin{cases} 
\frac{[E_2(h) - E_1(h)]^2}{\text{Var}_1(h)} & \text{if } \text{Var}_1(h) > 0 \\
0 & \text{if } \text{Var}_1(h) = 0 
\end{cases}
\] (29)

If \( P_1 \) and \( P_2 \) have densities \( p_1 \) et \( p_2 \), this distance may be written as:

\[
S_h(P_1, P_2) = \frac{\text{Cov}_1^2(h, \phi)}{\text{Var}_1(h)}
\] (30)

where \( \phi = \frac{p_2}{p_1} \). From Schwarz inequality, we have:

\[
S_h(P_1, P_2) \leq \text{Var}_1(\phi) = S_{\phi}(P_1, P_2)
\] (31)

Notice that \( S_{\phi} \) belongs to the class (1) with \( f(x) = (x - 1)^2 \), \( g(x) = x \) (32)

The interest of this generalized version of the signal to noise ratio for robust detection is as follows. The problem of designing robust detectors in terms of risk (in the usual sense of decision theory) reduces to the derivation of a least favorable pair in terms of risk - LMFR in abbreviated form - ; the risk robust detector is then the likelihood ratio of this LMFR pair. The problem is that the finding of this pair is not always a tractable task. It is thus of interest to search for sub-optimal detectors which are more easily obtainable. It can be shown [41] that, if we define a robustness notion in terms of the distance \( S \) (29), we keep the fact that the robust detector in terms of \( S \) - LMFS in abbreviated form - ; but we gain that such a LMFS pair is often more easily obtainable because it minimises \( S_{\phi}(P_1, P_2) \). Furthermore, this result is also true for the distance \( S' \) defined by:
\[ S_h(P_1, P_2) = \frac{(\mathbb{E}_2(h))^2}{\mathbb{E}_1(h^2)} \]  

(33)

also used for detection.

Poor also shows [41] that a LMFR pair is also a pair of closest laws with respect to any \( f \)-divergence of the class (1) for any convex continuous \( f \). Furthermore, a LMFR pair is also a LMFS one; but the converse is false.

Finally, referring to section II.5 for the local point of view, \( \text{Var}_1(\phi) = S_\phi(P_1, P_2) \) plays the same role as Fisher information \( I(p) = \int \frac{(p')^2}{p} \) when searching an optimal robust local test for a translation parameter. Indeed, when \( P_1 \) has density \( p(x) \) and \( P_2 \) has density \( p(x - \theta) \), where \( \theta \to 0 \), whence the local terminology, the optimum robust local test is built from the law \( p \) which minimizes \( I(p) \).

The remainder of this section II is devoted to distance measures not between laws but between a law (or a model) and data. This classification is somewhat arbitrary, because we would have dealt with this problem above by taking an a priori law as \( P_1 \) and an a posteriori or an empirical law as \( P_2 \). Nevertheless, we keep this distinction, mainly because of the initial motivations of the hereafter presented tools.

Paragraphs 4 and 5 are even less claimed to be exhaustive than the previous ones. The presented tools will be re-analysed in section IV devoted to parametric AR and ARMA models.

II.4 - ENTROPY

In this section, we give the axiomatic derivation of the maximum entropy and minimum cross-entropy (or divergence) principles due to Shore and Johnson [42], because it emphasizes the criteria which lead to these distance measures between models and data already introduced by Kullback [32].
Given a system with the following informations:

- an a priori density \( p \);
- constraints I on the "true" unknown density \( q^* \) of the form:

\[
\int q^*(x) \ a_k(x) \ dx = 0
\]

or

\[
\int q^*(x) \ c_k(x) \ dx \geq 0
\]

for known sets of bounded functions \( a_k \) and \( c_k \);

We investigate the problem of the choice of the best estimate \( q \) of \( q^* \) knowing the a priori \( p \) and the constraints I (34).

We define 4 axioms which are to be satisfied by the choice criterion and we show that any choice criterion satisfying these axioms is equivalent to the minimization of the cross-entropy (or "oriented" divergence or Kullback information (7)):

\[
K(q,p) = \int q(x) \ \log \frac{q(x)}{p(x)} \ dx
\]  

(35)

For this purpose, we introduce the following "information operator" 0:

\[
q = p \ 0 \ I
\]

which associates, to an a priori law \( p \) and a set of constraints I on \( q^* \), an a posteriori law \( q \) by minimization of a functional \( H \), ie:

\[
q = p \ 0 \ I \iff H(q,p) = \min_{q' \text{ satisfying } I} H(q', p)
\]

If there exists another functional \( H' \) such that

\[
H(q,p) = \min_{q'} H(q', p) \iff H'(q,p) = \min_{q'} H'(q', p)
\]

\( H' \) et \( H \) are said to be equivalent, and the operator 0 can be realized using either functional.
The axioms are as follows:

1) **uniqueness** for any \( p \) and any \( I, q = p \circ I \) is unique;

2) **invariance** by coordinate transformation: if \( \Gamma \) is a transformation from \( x \) to \( y \)
then:

\[
(\Gamma_p) \circ (\Gamma) = \Gamma(p \circ I)
\]

where \( \Gamma \) is the constraint satisfied by the transform of \( q^* \). This means that, if the
problem is solved in two different coordinates systems, the two resulting a posteriori
densities are related by the coordinate transformation.

3) **system independence**

If \( x_1 \) and \( x_2 \) are two spaces, with independent a priori densities \( p_1 \) and \( p_2 \), for which
we know the constraints \( I_1 \) and \( I_2 \), then:

\[
(p_1 p_2) \circ (I_1 \wedge I_2) = (p_1 \circ I_1) \circ (p_2 \circ I_2)
\]

(37)

where \( I_1 \wedge I_2 \) is the union of the constraints.

This means that the joint a posteriori is the product of the separated a posteriori.

4) **subset independence**

If \( x \) is an union of disjoint subspaces \( S_i \ (1 \leq i \leq n) \), let \( p \ast S_i \) be the conditional a priori
defined by:

\[
(p \ast S_i)(x) = \frac{p(x)}{\int_{S_i} p(x') \, dx'}
\]

and \( I_i \) the constraint on the conditional density \( q^* \ast S_i \). Then:

\[
(p \circ I) \ast S_i = (p \ast S_i) \circ I_i
\]

(38)

where \( I = I_1 \wedge \ldots \wedge I_n \).

(In fact, a stronger condition is imposed [42]).

In order to show that an operator \( 0 \) satisfying these 4 axioms can be realized only by the
cross-entropy \( K \) (35), the case of equality constraints in (34) is first investigated (and
finally \( K \) is shown to work also for inequality constraints). The first step consists in
showing that the axiom iv) (38) and a special case of the axiom ii) (36) lead to
restricted functionals of the form:

\[
H(q,p) = \int_{\infty} f(q(x), p(x)) \, dx
\]
Then, at the second step, the general case of ii) is shown to lead to the form:

\[ H(q,p) = \int_x q(x) f\left(\frac{q(x)}{p(x)}\right) \, dx \]  

(39)

(which strangely enough looks like the remark below (4)) !.

The third step uses axiom iii) and shows that, if \( H \) satisfies the 4 axioms, \( H \) is equivalent to the cross-entropy \( K \) (35). The last step shows that \( K \) actually satisfies the 4 axioms.

This cross-entropy minimization principle is successfully used for spectral analysis [43] including in the multidimensional case [26], classification for Pattern Recognition [44] and many other applications in various domains (see [42]).

II.5 - MODEL VALIDATION

We conclude this section with another tool for measuring the distance between a model and data, introduced for signal segmentation and systems monitoring [4]. An example of use of this measure will be presented in section IV devoted to the parametric models ARMA.

Let \( (Y_n) \) be a controlled Markovian process (or more generally a controlled semi-Markovian process) in \( \mathbb{R}^k \), the transition probability of which is parameterized by \( \theta_\ast \in \mathbb{R}^d \). Assume that this "true" parameter \( \theta_\ast \) is identifiable from the observations \( Y_n \), i.e. it exists a functional \( H \) such that the sequence \( (\theta_n) \) defined by:

\[ \theta_n = \theta_{n-1} + \gamma_n H(\theta_{n-1}, Y_n) \]  

(40)

converges to \( \theta_\ast \) (see [4] for precise conditions).
Let $\theta_0$ be a model fixed by the user, and let us investigate the problem of detecting small deviations (local approach as at the end of II.3) $\delta \theta$ with respect to $\theta_0$ using the vector field $H$ as the only statistics. One licit (based upon a central limit theorem) and possible solution consists in considering the random variables:

$$Z_k(\theta_0) \overset{\Delta}{=} H(\theta_0, Y_k)$$

as if they were independent, whatever the degree of dependency of the law of the $Y_k$ is, asymptotically gaussian distributed, and reflect the small deviation $\delta \theta$ by a change in their mean value. Thus we can use a $\chi^2$ test based upon these $Z_k$:

$$t = (\sum_k Z_k^T R^{-1} (\sum_k Z_k)$$

(42)

where

$$R(\theta_0) = \sum_{n \in Z} \text{cov} (H(\theta_0, Y_n), H(\theta_0, Y_\theta))$$

and where the dependency of $Z$ and $R$ in $\theta_0$ has been omitted for simplification.

In (42), we assume that, if:

$$h(\theta) \overset{\Delta}{=} \mathbb{E}_\theta (H(\theta, Y_n))$$

then $h(\theta)$ (ie the derivative of $h$) is invertible. If this is not the case, see [4].

(42) is clearly a way for measuring the agreement (or the deviation) between the model $\theta_0$ and the observations ($Y_n$).

This way is obviously not the unique possible one. Another one, more classical, consists in running the algorithm (40) and using a $\chi^2$ test of the form:

$$\left(\theta_n - \theta_0\right)^T \Sigma^{-1} (\theta_n - \theta_0) \geq \lambda$$

(43)

using the fact that $\theta_n - \theta_0$ is asymptotically gaussian distributed with zero mean. But it turns out that $\theta_n - \theta_0$ has a quite complex dynamics (Gaussian Markovian process of first order), and its temporal dependency structure, which is not taken into account in (43), is better reflected in (42) which is probably more efficient.
Finally, we refer to [45] for a special use of Kullback information (7) between conditional laws for multivariable input/output model validation.

Before entering the section devoted to spectral distance measures, let us notice the existence - and the huge theoretical importance - of a general distance between processes, called $\bar{D}$ Ornstein distance [18], which measures how two processes look like each other, namely how much one typical realization of one of the processes has to be modified in order to look like a typical realization of the other one. An example concerning gaussian processes will be seen in the paragraph III.3.5.

III - SPECTRAL DISTANCE MEASURES

In this section, we are interested in spectral distance measures, namely in distances between processes based upon their second order properties. Some of these distance measures have already been introduced in the previous section, but by far not all of them, and thus it is obviously interesting to present together all the possible distances. We recall that the formulation of these distances, when the spectra are represented by parametric AR or ARMA models, will be addressed in the next section, together with the questions related to parameter estimation.

The key references for this problem are without doubt the papers [16] [17] [36] [30], and also [18] and the book [40] which are less accessible.

III.1 - PRELIMINARY REMARKS

Following [17], we shall use the following notations. Let $s(\lambda)$ be a (energy or power) spectral density corresponding to a scalar signal. $\lambda$ varies from $-\pi$ to $\pi$, where we assume that $\pi$ is half of the sampling frequency of the signal. $s$ is a positive even function, the Fourier coefficients of which define an autocorrelation sequence:

$$s(\lambda) = \sum_{n \in \mathbb{Z}} r(n) e^{-j n \lambda}$$

$$r(n) = \int_{-\pi}^{\pi} s(\lambda) e^{jn\lambda} \frac{d\lambda}{2\pi}$$

(44)
For a wide sense stationary ergodic process \( (y_n)_{0 \leq n \leq N-1} \), the sequence \( r(n) \) defined by:

\[
\begin{align*}
  r(n) &= r_1^{(N)}(n) & \text{pour} \ |n| < N \\
  r(n) &= 0 & \text{pour} \ |n| \geq N
\end{align*}
\]

where

\[
r_1^{(N)}(n) \triangleq \sum_{k=0}^{N-|n|-1} y_k y_{k+|n|} \quad (0 \leq |n| \leq N - 1)
\]

corresponds to an energy spectral density.

If \( r(n) = r_2(n) \triangleq \mathbb{E}(y_k y_{k+n}) \), then (44) defines a power spectral density. Noting that for any \( n \):

\[
\lim_{N \to \infty} \frac{1}{N} r_1^{(N)}(n) = r_2(n) \quad \text{p.s.,}
\]

we conclude that the sequel will not depend upon the nature - energy or power - of the spectral density.

Following the terminology introduced in the introduction, for \( r = r_2 \) the following distance measures will be laws between processes, and for \( r = r_1 \) (empirical covariance) distances between signals.

Let \( R_N(s) \) be the Toeplitz \((N + 1) \times (N + 1)\) matrix, the \((k,j)\)th element of which is \( r(k-j) \) \((0 \leq k, j \leq N)\). We shall use several fundamental properties of \( R_N \) [19] [17].

\( |R_N| \) denotes the determinant of \( R_N \).
For each \( p \), there is associated with the spectral density \( s \) a Toeplitz form:

\[
T_p(a) \triangleq \int_{-\pi}^{\pi} \left| \sum_{k=0}^{p} a_k e^{jk\lambda} \right|^2 s(\lambda) \frac{d\lambda}{2\pi} = \sum_{k=0}^{p} \sum_{l=0}^{p} a_k a_l r(k-l)
\]

\[= a^T R_p(s) a\]

where \( a^T = (a_0, a_1, ..., a_p) \) is real.

A numerically convenient form is:

\[
T_p(a) = r(0) r_a(0) + 2 \sum_{k=1}^{p} r(k) r_a(k)
\]

(45')

where

\[
r_a(k) \triangleq \sum_{l=0}^{p-k} a_l a_{l+k} \quad (0 \leq k \leq p)
\]

We shall see later that this Toeplitz form directly appears in spectral distance measures, and especially in distances between a model \( a \) and a signal summarized in its covariances \( R_N \).

Let be:

\[
A(z) = \sum_{k=0}^{p} a_k z^{-k}
\]

Then:

\[
T_p(a) = \int_{-\pi}^{\pi} \left| A(e^{j\lambda}) \right|^2 s(\lambda) \frac{d\lambda}{2\pi}.
\]

Let be

\[
\sigma^2_s(p) = \min_{a} T_p(a) \quad \text{then}[19]:
\]

\[
(a_0 = 1)
\]
\[ \sigma_s^2(p) = \frac{|R_p(s)|}{|R_{p-1}(s)|}, \]

and the minimizing polynomial \( A(z) \) may be analytically expressed in terms of orthogonal polynomials (cf. Levinson algorithm). Let \( A_p(z) \) be the \( p \) th order polynomial with \( a_0=1 \) which minimizes (45).

This polynomial \( A_p(z) \) together with \( \sigma_s^2(p) \) may be used to model the spectral density \( s(\lambda) \). Actually, for any polynomial :

\[ G(z) = \sum_{k=0}^{n} g_k z^{-k}, \]

we can write:

\[
T_p(g) \triangleq \int_{-\pi}^{\pi} |G(e^{i\lambda})|^2 s(\lambda) \frac{d\lambda}{2\pi} \\
= \int_{-\pi}^{\pi} |G(e^{i\lambda})|^2 \frac{\sigma_s^2(p)}{|A_p(e^{i\lambda})|^2} \frac{d\lambda}{2\pi}
\]

Furthermore, let be [19]:

\[ \sigma_s^2 \triangleq \lim_{p \to \infty} \sigma_s^2(p) \]
\[ = \exp \left[ \int_{-\pi}^{\pi} \text{Log} \left( s(\lambda) \right) \frac{d\lambda}{2\pi} \right] \quad (47) \]

and let us consider the following spectral factorization:

\[ \frac{1}{s(\lambda)} = \frac{|A(e^{i\lambda})|^2}{\sigma_s^2} \quad (48) \]

where \( A(z) = \lim_{p \to \infty} A_p(z) \) has no zero on or outside the unit circle. We shall call \( \frac{\sigma_s^2}{A} \)

the (infinite) autoregressive model of \( s \), and \( \frac{1}{A} \) the normalized AR model.

Most of the spectral distance measures which we shall consider will be in terms of \( L_q \) norms, ie:

23
\[
\|s\|_q = \left( \int_{-\pi}^{\pi} |s(\lambda)|^q \frac{d\lambda}{2\pi} \right)^{1/q}
\]

which satisfies:

\[
\|s\|_{q_1} \leq \|s\|_{q_2} \quad \text{pour} \quad 0 < q_1 \leq q_2
\]

If \(s\) is continuous, \(\|s\|_{\infty}\) exists and is the maximum magnitude of \(s\).

### III.2 - SPECTRAL DISTANCE MEASURES AND EQUIVALENCES

Spectral distances between two spectral densities \(s_1\) et \(s_2\) may be measured with the aid of \(L_q\) norms of their difference, i.e.

\[
d(s_1, s_2) = \|s_1 - s_2\|_q
\]

These distances are "true" distances in the sense that they satisfy the symmetry property and the triangular inequality. We saw examples of such distance measures in section II.1. However, the spectral distances which will be used here are functions of the difference between the log-spectra, i.e., the ratio between the spectra:

\[
d(s_1, s_2) = d(1, \frac{s_2}{s_1}) = d(\frac{s_1}{s_2}, 1)
\]

for obvious requirements of invariance with respect to the measurement scale.

For a given distance \(d\), we shall use two types of scaling [17]. A **gain normalized distance measure** is defined by:

\[
d^*(s_1, s_2) = d\left[\frac{s_1}{\sigma_1^2}, \frac{s_2}{\sigma_2^2}\right]
\]

where \(\sigma_1\) and \(\sigma_2\) are defined in (47) and correspond to \(s_1\) and \(s_2\) respectively. This distance is useful for separating the effects of the normalized models and the gains.
A gain optimized distance measure is defined by:

\[ d'(s_1, s_2) \triangleq \min_{\alpha \geq 0} d(s_1, \alpha \cdot s_2) \quad (52) \]

By definition, \( d(s_1, s_2) \geq d'(s_1, s_2) \).

Notice that the usual spectral distance measures are easily defined in the spectral domain, but are most of the time numerically computed without reference to this domain.

As there exist numbers of spectral distance measures \( d \) (and \( d' \) and \( d^* \) defined above are ways to introduce variants!), it is important to know when they are equivalent. Intuitively, two distances are equivalent if the results obtained for a given application with either of them are qualitatively the same. More precisely, following again [17], we define two types of equivalence. The first one is the usual equivalence for metrics. The second one is a convenient equivalence for coding and classification problems (search of nearest neighbor).

A distance \( d_1 \) is said to be strong than a distance \( d_2 \), and we write:

\[ d_1 \Rightarrow d_2, \]

if a small distance \( d_1 \) implies a small distance \( d_2 \). \( d_1 \) and \( d_2 \) are said to be equivalent if each is stronger than the other.

Let us now consider the problem of finding a nearest neighbor (NN), i.e., of a representation \( \hat{s} \) of \( s \) in a particular set which minimizes a distance. \( d_1 \) and \( d_2 \) are NN-equivalent if the two corresponding functions \( s \mapsto \hat{s} \) are identical, whatever the representation set is. This equivalence can be very useful in practice because it allows to use the simplest NN-equivalent distance for the computations.

If two distances \( d_1 \) and \( d_2 \) are equivalent in both senses, they are said to be completely equivalent and we write:

\[ d_1 \equiv d_2. \]
From (51), (50), (52), we get :

$$d^* (s_1, s_2) \geq d' (s_1, s_2).$$

Thus \(d\) and \(d^*\) are stronger than \(d'\).

III.3 - MAIN SPECTRAL DISTANCE MEASURES

III.3.1 - Log spectral deviation

This measure is probably the oldest one in speech processing, and is defined by the \(L_q\) norm of the difference of the logarithms of the spectra :

$$d_q (s_1, s_2) = \| \log s_1 - \log s_2 \|_q$$

$$= \| \log \frac{s_1}{s_2} \|_q$$

(53)

The more common choices are :

* \(q = 1\) mean absolute distance
* \(q = 2\) mean quadratic distance (rms)
* \(q = \infty\) maximum deviation.

We have :

$$d_\infty \geq d_2 \geq d_1$$

These distances satisfy the symmetry property and the triangular inequality. They are directly related to decibel variations in the log spectral domain by the factor

$$\frac{10}{\log (10)} = 4.34.$$ The \(L_2\) norm is the most popular because the most easily computable. Approximations will be mentioned in the next section. Moreover, it turns out to be experimentally close to \(L_\infty\) [16], at least when the spectra are estimated via Fourier transform.
III.3.2 - Itakura-Saito distance [24]

It is defined by:

$$d_{IS}(s_1, s_2) = \| \frac{s_1}{s_2} - \log \frac{s_1}{s_2} - 1 \|_1$$  \hspace{1cm} (54)

and is also called "error matching measure".

As: $u - \log u - 1 \geq 0$, we also have:

$$d_{IS}(s_1, s_2) = \int_{-\pi}^{\pi} \frac{s_1 d\lambda}{s_2} \frac{1}{2\pi} \log \frac{\sigma_1^2}{\sigma_2^2}$$  \hspace{1cm} (55)

by the residual theorem.

Using the expansion:

$$u = \exp(\log u) = 1 + \log u + \frac{1}{2} (\log u)^2 + ...$$

it can be shown that $d_{IS}$ is an approximation for $\frac{1}{2} d_2^2$ for "small" distances.

On the other hand, by Jensen inequality, we have:

$$d_{IS}(s_1, s_2) \geq d_{IS}(\sigma_1^2, \sigma_2^2)$$

ie for given spectral gains, constant spectra give the smallest distortion.

For $s_2$ of the form:

$$s_2(\lambda) = \frac{\sigma_2^2}{1 \pm (e^{j\lambda})^2}$$

27
where $A_2$ is causal of order $p$ - namely if we want to solve the problem of linear prediction of $s_1$ - from (55) and (45) we conclude that:

$$d_{IS}(s_1, s_2) = \frac{1}{2} \frac{1}{\sigma_2^2} T_p^{(1)}(a_2) - \log \frac{\sigma_1^2}{\sigma_2^2} - 1$$  \hspace{1cm} (56)$$

We shall hark back to this expression in the next section.

Another form of the Itakura-Saito distance has actually already been mentioned in the last section. Consider the Kullback information (7) for gaussian processes [40]:

$$K_N(s_1, s_2) = \frac{1}{2} \log \frac{|R_N(s_1)|}{|R_N(s_2)|} + \frac{1}{2} \text{tr} \left[ R_N(s_1) R_N^{-1}(s_2) \right] - \frac{N}{2}$$  \hspace{1cm} (57)$$

It can be shown that [40]:

$$K(s_1, s_2) \Delta \lim_{N \to \infty} \frac{1}{N} K_N(s_1, s_2)$$

$$= \frac{1}{2} d_{IS}(s_1, s_2)$$  \hspace{1cm} (58)$$

In other words, Itakura-Saito distance is equal to two times the asymptotical Kullback information under gaussian hypothesis. This technique has been successfully tested for classifying non gaussian data for the purpose of recognition of EEG signals [15]. Furthermore, $d_{IS}$, even though non symmetrical, is well suited to quantification, classification, recognition, and detection problems, at least in the domain of speech processing [17]. This is also the case for classification [22] and recognition of EEG signals once more, for which in [21] Kullback distance, Kullback divergence and Bhattacharrya distance have been compared.

**III.3.3. Itakura distance**

$$d_I(s_1, s_2) \Delta d_{IS}(s_1, s_2)$$

$$= \min_{\alpha \geq 0} d_{IS}(s_1, \alpha s_2)$$  \hspace{1cm} (59)$$
From (55), we get:

\[ d_1(s_1, s_2) = \log \int_{-\pi}^{\pi} \frac{s_1/\sigma_1^2}{s_2/\sigma_2^2} \frac{d\lambda}{2\pi} \]  

(60)

and

\[ d_{14}(s_1, s_2) = \frac{\sigma_1^2}{\sigma_2^2} \exp \left[ d_1(s_1, s_2) \right] - \log \frac{\sigma_1^2}{\sigma_2^2} - 1 \]  

(61)

Using (48) as model for \( s_1 \) and \( s_2 \), we get:

\[ d_1(s_1, s_2) = \log \int_{-\pi}^{\pi} \left| \frac{A_2}{A_1} \right|^2 \frac{d\lambda}{2\pi} \]

\[ = \log \left[ \left\| \frac{A_2}{A_1} \right\|_2^2 \right] \]  

(62)

This distance is also called log likelihood ratio because of its asymptotical expression in the gaussian case[23] [48]. We refer to the next section for additional details.

### III.3.4 - Model distance measure

Also introduced by Itakura [23], it is defined by:

\[ d_m^*(s_1, s_2) \triangleq \left\| 1 - \frac{A_2}{A_1} \right\|_2^2 \]  

(63)

where \( A_1 \) and \( A_2 \) are the normalized AR models for \( s_1 \) and \( s_2 \). It can be shown that [17]:

---

29
\[ d_m^* (s_1, s_2) = \left\| \frac{A_2}{A_1} \right\|_2^2 - 1 \]

\[ = \exp (d_I (s_1, s_2)) - 1 \quad (64) \]

and thus \( d_m^* \) and \( d_I \) are completely equivalent. We also have:

\[ d_m^* = d_{IS}^* \]

This distance was introduced as an approximation for \( d_I \) for \( d_I \) small (cf. (64)). It is always an upper bound for \( d_I \).

It is called a model distance measure because it measures how nearly the normalized models or filters \( A_1 \) and \( A_2 \) are to being inverses (see next section).

A similar unnormalized model distance is given by:

\[ d_m (s_1, s_2) = \left\| 1 - \frac{\sigma_1 / A_1}{\sigma_2 / A_2} \right\|_2^2 \]

\[ = \frac{\sigma_1^2}{\sigma_2^2} d_m^* (s_1, s_2) + \left( 1 - \frac{\sigma_1^2}{\sigma_2^2} \right) \]

\[ = \frac{\sigma_1^2}{\sigma_2^2} d_m^* (s_1, s_2) + d_m (\sigma_1^2, \sigma_2^2) \]

But:

\[ d_{IS} (s_1, s_2) = \frac{\sigma_1^2}{\sigma_2^2} \]

\[ = \frac{\sigma_1^2}{\sigma_2^2} d_m^* (s_1, s_2) + d_{IS} (\sigma_1^2, \sigma_2^2) \]

thus:

\[ d_{IS} \iff d_m \]

However \( d_{IS} \) and \( d_m \) are not NN-equivalent.

The optimization of \( d_m \) according to (52) gives:
\[ d_m^{'}(s_1, s_2) = 1 - \frac{1}{\|A_1\|_2^2} \|A_2\|_2^2 \] (66)

which can be shown to be a monotonic function of \( d_m^* \), and thus:

\[ d_m^{'} \iff d_m^* \]

III.3.5 - Symmetrized distance measures

A spectral distance measure \( d \) can be symmetrized by considering arithmetical or geometrical means of \( d(s_1, s_2) \) and \( d(s_2, s_1) \), namely by defining for \( q \geq 1 \):

\[ d^{(q)}(s_1, s_2) = \frac{1}{2} (d(s_1, s_2)^q + d(s_2, s_1)^q)^{1/q} \] (67)

\( d^{(q)} \) is stronger than \( d \).

A symmetrized version of Itakura-Saito distance was introduced in [16] and defined by

\[ d_{cosh}(s_1, s_2) = d_{IS}^{(1)}(s_1, s_2) \] (68)

where the terminology cosh (of the spectral difference measured on a logarithmic scale, ie \( \log \frac{s_1}{s_2} \) comes from (54).

\( d_{cosh} \) is related to a decibel scale [16] with the aid of the quantity \( D \) such that:

\[ \cosh(D) - 1 = d_{cosh} \]

namely:

\[ D = \log (1 + d_{cosh} + \sqrt{d_{cosh}(2 + d_{cosh})}) \]
From (58), we conclude that Kullback divergence:

\[ J_N (s_1, s_2) \triangleq K_N (s_1, s_2) + K_N (s_2, s_1) \]

satisfies:

\[ \lim_{N \to \infty} \frac{1}{N} J_N (s_1, s_2) = d_{\cosh} (s_1, s_2) \]  \( (69) \)

It can also be shown that [18] [36]

\[ 2 d_{\cosh} (s_1, s_2) = \bar{\rho} (Y^{(1)}, Y^{(2)}) \]

where \( Y^{(1)} \) and \( Y^{(2)} \) are two gaussian processes with spectral densities \( \frac{s_1}{s_2} \) and \( \frac{s_2}{s_1} \) respectively, and where \( \bar{\rho} \) is the Ornstein distance [18] between processes already mentioned at the end of section I. For gaussian processes \( X^{(1)} \) and \( X^{(2)} \) with spectral densities \( s_1 \) and \( s_2 \), we have

\[ \bar{\rho} (X^{(1)}, X^{(2)}) = 2 H^2 (s_1, s_2) \]

where \( H^2 \) is Hellinger distance defined in (6). This leads to the following (simple) relationship:

\[ d_{\cosh} (s_1, s_2) = H^2 (s_1, s_2) \] \( (70) \)

III.3.6 - Summary of the equivalences

Many other symmetric distance measures may be defined by symmetrizing the previously mentioned distances or by gain optimizing or gain normalizing the above mentioned symmetrical distances.

Recall that we always have:

\[ d^{(1)} \Rightarrow d \]

\[ d^* \Rightarrow d' \]

\[ d \Rightarrow d' \]
The known equivalences between the above distance measures are summarized in the following diagram [17]:

\[
\begin{align*}
    d_1^{(1)} & \iff d_{cosh}^{(1)} \iff d_m^{(1)*} \iff d_1 = d_{IS} \iff d_m^{*} = d_{IS} \iff d_m \\
    d_{cosh} & \iff d_{IS}^{(1)} \iff d_m^{(1)} \iff d_{IS} \iff d_m \\
    d_2 & \downarrow
\end{align*}
\]

Other results are described in [36] together with their consequences on robustness issues of linear predictive coding.

III.3.7 - The case of multidimensional gaussian processes

In [30] closed form numerically computable formulas were obtained for Bhattacharrya distance, Chernoff distance, Kullback distance and Kullback divergence between two r-dimensional gaussian processes \( Y^{(1)} \) and \( Y^{(2)} \). These expressions are in terms of the two spectral densities matrices \( S_1(\lambda) \) and \( S_2(\lambda) \) corresponding to the two covariance matrices sequences, and of the spectral density matrix \( M(\lambda) \) of the difference between the process means.

For example [30]:

\[
2 \, K(Y^{(2)}, Y^{(1)}) = \int_{-\pi}^{\pi} \left( \text{tr} \, S_1^{-1}(\lambda) \left[ S_2(\lambda) - S_1(\lambda) \right] - \log S_1^{-1}(\lambda) S_2(\lambda) \right) \frac{d\lambda}{2\pi} \\
+ \int_{-\pi}^{\pi} \sum_{k=1}^{r} \sum_{j=1}^{r} m_{kj}(\lambda) \, s_{kj}(0,\lambda) \frac{d\lambda}{2\pi}
\]

where

\[
M(\lambda) = (m_{kj}(\lambda))_{1 \leq k, j \leq r}
\]

\[
\left[ (1 - t) \, S_1(\lambda) + t \, S_2(\lambda) \right]^{-1} = (s_{kj}(t,\lambda))_{1 \leq k, j \leq r}
\]
IV. PARAMETRIC SPECTRAL DISTANCE MEASURES

In this section, we investigate the practically important special case where the spectra are described by AR or ARMA parametric models. We describe the useful expressions for many previously mentioned distance measures. The relationships between some of them together with the possible problems related to the interaction between these distances and the choice of parameters (and the way by which they have been estimated) are also addressed. We mention some variants still currently introduced for speech recognition systems performance improvement. Finally, we present some qualitative results from comparative studies for distance measures.

IV.1 - L2-NORM AND CEPSRAL DISTANCE

In the last section (III.3.1), we indicated that the L$_2$ norm of the log-spectra difference is a commonly used distance measure especially for speech processing. However the main drawback of this distance $d_2$ is of computational nature, because it requires two FFT, two logarithms and one summation. In this section, we show how it can be efficiently approximated by an euclidian distance: the cepstral distance.

Given a $p$th order minimum phase filter, namely:

$$A(z) = \sum_{k=0}^{n} a_k z^{-k}$$

(71)

with $a_0 = 1$, having all its the roots inside the unit cercle, we define the cepstral coefficients [16] by the coefficients of the Taylor expansion of the logarithm of the filter transfer function, ie:

$$\text{Log } A(z) = - \sum_{k=1}^{\infty} c_k z^{-k}$$

(72)

They are also the Fourier coefficients of the log-spectrum, because:

$$\text{Log } \frac{\sigma^2}{1A(e^{i\lambda})} = \sum_{k=-\infty}^{\infty} c_k e^{-jk\lambda}$$

(73)
where
\[ c_0 = \log(\sigma^2) \quad (74) \]
\[ c_{-k} = c_k \]

These cepstral coefficients may be estimated in two ways. The traditional first one consists in two FFT starting from the filter impulse response:
\[ H(z) \triangleq \frac{1}{A(z)} = \sum_{n=0}^{\infty} h_n z^{-n} \quad (75) \]

For a transfer function with poles only, the cepstrum can be obtained directly from the impulse response coefficients \( h_n \) by:
\[ c_n = \sum_{k=1}^{n-1} \left(1 - \frac{k}{n}\right) h_k c_{n-k} + h_n \quad (n > 1) \quad (76) \]
\[ c_1 = h_1 \]

or from the linear prediction coefficients by:
\[ c_1 = -a_1 \]
\[ c_n = -a_n - \sum_{k=1}^{n-1} \frac{k}{n} c_k a_{n-k} \quad 1 < n \leq p \quad (77) \]
\[ c_n = -\sum_{k=1}^{p} \frac{n-k}{n} c_{n-k} a_k \quad p + 1 \leq n \]

In order to obtain (77) - or (76) -, derive the two handsides of (72) with respect to \( z^{-1} \) and use (75).

Notice that the two resulting cepstra ("Fourier" or "parametric") are not identical [2]. The difference is due to the truncation of the signal over a finite time interval which is done in a Fourier analysis and which produces a signal with poles only, whatever the content (poles or zeroes) of the transfer function is. On the other hand, the "parametric" cepstrum explicitly takes into account the hypothesis that the transfer function has only poles. The consequences of these two choices on speech recognition systems will be described later.
More generally, the cepstrum of a minimum phase rational transfer function can be defined [39]. In this case, the cepstral coefficients can be interestingly expressed as a function of the poles \( (z_k)_{1 \leq k \leq p} \) and the zeroes \( (w_j)_{1 \leq j \leq q} \) [39] [34]:

\[
c_n = -\frac{1}{n} \left[ \sum_{k=1}^{p} z_k^n - \sum_{j=1}^{q} w_j^n \right] \quad (n > 0)
\]

(78)

This formula is obtained from (72) by a residual calculus. A consequence will be mentioned later.

The interest of the cepstral coefficients \( c_n \) for computing the distance \( d_2 \) (53) is as follows.

Using (73) and applying Parseval formula to \( d_2 \) (53), we get:

\[
d_2^2 = \sum_{k=-\infty}^{+\infty} (c_k^{(1)} - c_k^{(2)})^2
\]

(79)

\[= (c_0^{(1)} - c_0^{(2)})^2 + 2 \sum_{k=1}^{\infty} (c_k^{(1)} - c_k^{(2)})^2\]

where the \( c_k^{(i)} \) \((i = 1,2)\) are the cepstral coefficients associated to the spectral density \( s_l \).

Furthermore, the finite sums:

\[
d^2(L) = \sum_{k=-L}^{L} (c_k^{(1)} - c_k^{(2)})^2 \quad (L \geq p)
\]

(89)

can be shown to be positive definite and to converge, when \( L \to \infty \), towards \( d_2^2 \).

Moreover, experiments with speech signals [16] have shown that, for small values of \( L \), \( d(L) \) is closed to \( d_2 \). The usual values for \( L \) are \( p \) and \( 2p \).

Therefore, as far as spectral distance measures are concerned, the "good" euclidian distance is between the cepstral coefficients \( c_n \) (77) (and not between the autoregressive coefficients \( a_n \) !). Furthermore, the cepstral distance is experimentally better than the euclidian distance between the reflection coefficients [2] [51]. We shall discuss further this point in the paragraph IV.4.
Moreover, from (78) and (80), we conclude that, for causal spectra:

\[ d^2(L) = \sum_{k=L}^{1} \frac{1}{k^2} \left[ \sum_{i=1}^{p} (z_i^{(2)k} - z_i^{(1)k})^2 \right] \]  

(81)

where \( z_i^{(j)} (j = 1, 2, \ i = 1, p) \) are the poles of the spectrum \( s_j \). This shows that one can be very far from a true spectral distance when one tries -in an intuitively "natural" way - to measure the deviation between two spectra with the aid of an euclidian or absolute value distance between the poles (or the Fourier spectrum lines).

A last important remark about the cepstral distance concerns the interaction between parameter estimation and distance. Actually, it seems that the distance \( d(L) \) (80) is not to be used when the AR coefficients \( (a_k) \) used in (77) are estimated with the autocorrelation method [3].

### IV.2 - DISTANCES \( d_{1s} \) AND \( d_1 \)

We now consider the parametric formulation of the Itakura-Saito distance \( d_{1s} \) (54) and Itakura distance \( d_1 \) (60); then we present a variant of \( d_1 \) and we describe the link between \( d_1 \) and the model validation tool introduced in 1.5.

A parametric expression of the distance \( d_{1s} \) has already been given in (56). From (61) and (56) we get for \( d_1 \):

\[
d_1(s_1, s_2) = \log \frac{T_p^{(1)} (a_2)}{\sigma_1^2}
= \log \frac{a_2^T R_p^{(1)} a_2}{\sigma_1^2}
\]

(82)

Notice that, if from (62) \( d_1 \) is a distance between models, from (82) it is rather a distance between a model \( a_2 \) and a signal (y) summarized in its autocorrelation matrix \( R_p^{(1)} \) and "residual energy" \( \sigma_1^2 \) (47).
The dissymmetry of $T_{p}^{(1)}(a_{j})$ with respect to i and j - embarrassing for solving the problem inverse of linear prediction - is also met in $d_{l}$ and $d_{IS}$ and reflects nothing but the known dissymmetry of Kullback distance (see (58)).

The distance $d_{l}$ is widely used in speech recognition systems, but its main drawback - as for many other distance measures - is its lack of robustness in presence of noise, especially if the learning step has been done with non noisy speech signals. For this reason, a weighted Itakura distance was recently introduced [46]. The weighting is done with the aid of Atal perceptual filter, which gives higher weights to spectral deviations around peaks than around valleys of the spectrum, and these weights are adapted according to an estimated signal to noise ratio. More precisely, the distance is (compare with (62)):

$$d_{w_{l}} = \log \int_{-\pi}^{\pi} \frac{1}{|A_{1}(e^{j\lambda})|^{2}} \left| \frac{A_{2}(e^{j\lambda})}{|A_{1}(e^{j\lambda})|^{2}} \right|^{2} d\lambda$$  \hspace{1cm} (83)

where $A_{1}(e^{j\lambda}) = A_{1}(\alpha e^{j\lambda})$

$$= 1 + \alpha a_{1}^{(1)} e^{-j\lambda} + ... + \alpha^{p} a_{p}^{(1)} e^{-jp\lambda}$$

and $0 \leq \alpha \leq 1$ allows to increase the band pass width.

This filter has also been used in order to improve the performances of the cepstral distance (80) [35].

Finally, let us conclude this paragraph with a link between $d_{l}$ (82) and the model validation tool introduced in 1.5. This tool, initially designed for the validation of the AR part of a multidimensional ARMA process, looks like (82) in the special case of a scalar AR(p) process. Indeed, keeping the index 1 for the signal and 2 for the model, define $\theta_{2}^{T} = (a_{1} ... a_{p})$ ie $a_{2}^{T} = (1 \theta_{2}^{T})$. (41) becomes:

$$Z_{k} = \phi_{k}^{T}(y_{k} + \phi_{k}^{T} \theta_{2})$$

where $\phi_{k}^{T} = (y_{k-1}, ..., y_{k-p})$. We then deduce:
\[ \sum_{k} Z_k = (\gamma_p^{(1)} \mid R_p^{(1)}) a_2 \]

where \( \gamma_p^{(1)T} = (r_1^{(1)} \ldots r_p^{(1)}) \), \( R_p^{(1)} \) is the Toeplitz matrix used in (45), and where the covariances \( r_j^{(1)} \) are the empirical covariances.

On the other hand, in the local framework of small deviation and with the notations of I.5., one can assume that:

\[ R(\theta_2) = \sigma_1^2 R_{p-1}^{(1)} \]

(42) then becomes:

\[ t = \frac{a_2^T (\gamma_p^{(1)} \mid R_p^{(1)}) R_{p-1}^{(1)} (\gamma_p^{(1)} \mid R_{p-1}^{(1)}) a_2}{\sigma_1^2} \]

which reduces to:

\[ t = \frac{a_2^T R_p^{(1)} a_2}{\sigma_1^2} \quad (84) \]

where

\[ R_p^{(1)} = \begin{bmatrix} \sigma_1^2 & \gamma_p^T \\ \gamma_p & R_{p-1}^{(1)} \end{bmatrix} \]

differs from the Toeplitz matrix \( R_p^{(1)} \) only via the first coefficient which is equal to \( \sigma_1^{(1)} \) and not \( r_0 \).

IV.3 - SOME OTHER DISTANCE MEASURES

IV.3.1 - Variants of the cepstral distance
Let us first consider variants of the cepstral distance \( d_2 \) introduced in (79). \([52]\) \([25]\) \([35]\) introduced several distance measures based upon the derivative of the phase spectrum - namely the group delay - rather than the logarithm of the spectrum which, at least for speech signals, propagates over several formants the delay which may exist only on one formant \([52]\).
Let us consider the Taylor expansion of the phase $\phi(z)$ of $\Log A(z)$. From (72):

$$\phi(e^{-j\lambda}) = \sum_{k=1}^{\infty} c_k \sin(k\lambda)$$

(85)

Thus the expansion of the group delay is:

$$\phi'(\lambda) = \frac{d\phi(e^{-j\lambda})}{d\lambda} = \sum_{k=1}^{\infty} k c_k \cos(k\lambda)$$

(86)

Introducing as a new spectral distance the quantity:

$$d = \| \phi_1 - \phi_2 \|_2$$

Yegnanarayana [52] suggests to use the following euclidian distance:

$$d^2(L) = \sum_{k=1}^{L} k^2 (c_k^{(1)} - c_k^{(2)})^2$$

(86)

where $L$ has to be chosen higher than the order $p$ because the convergence of the serie (86) is slower than that of (80).

More generally, in [25] Itakura recently suggested to use an euclidian distance based upon a "smoothed" group delay, namely upon $w_k c_k$, where

$$w_k = k^s \ e^{-k^2/2\tau^2} \quad (s \geq 0)$$

The coefficient $k^s$ is used for isolating the spectral peaks but also for equalizing the spectral envelop. The term $e^{-k^2/2\tau^2}$ is used for cancelling the cepstral components with high order $k$.

Finally, still more recently [35] introduces spectral distances based upon the cosine of the angle between two cepstral coefficients arrays - with $c_0$ excluded -, which are more robust than the euclidian distance between these two vectors with respect to the presence of noise:

$$\left| C_1 \right|^2 (1 - \cos^2 \beta)$$
\[ |C_1|^\alpha (1 - \cos \beta) \quad , \quad \alpha = 0, 1, 2 \]

where
\[ \cos \beta = \frac{C^T_1 C_2}{|C_1||C_2|} \]

\(C_j\) is the vector of the cepstral coefficients \(c_k^{(j)} (k > 0) (j = 1,2)\); and where \(j = 1\) is again the "test" and \(j = 2\) the "reference".

Other weightings, by the inverse of the variance of the \(c_k\) computed during the learning phase, have been investigated in [8].

**IV.3.2 - A divergence between conditional laws**

As an end point for this incomplete catalogue, let us mention a special distance used for signal segmentation [3]. This "distance" is based upon Kullback divergence between the conditional laws \(p_j(y_n | y_{n-1}, \ldots, y_{n-p})\) of the observed signal \((y_n)\) computed for two estimated gaussian AR(p) models \((j = 1,2)\) long-term and short-term respectively. The reasons for this choice are explained in [3]. The particular point here is that the resulting distance is:

\[
\frac{e_n^{(1)} e_n^{(2)}}{\sigma_2^2} + \frac{1}{2} \left[ 1 + \frac{\sigma_1^2}{\sigma_2^2} \right] \frac{e_n^{(1)^2}}{\sigma_1^2} - \frac{1}{2} + \frac{\sigma_1^2}{2 \sigma_2^2} \tag{87}
\]

(where the \(e_n^{(j)}\) are the innovations of the two filters).

Thus this distance is actually a random variable, which turns out to have high sensitivity with respect to spectral changes in speech signals.

An interesting practical property of (87) is that the quality of the resulting segmentation is better when the identification methods for computing \(e_n^{(j)}\) and \(\sigma_n^{(j)}\) are approximated least squares than when they are exact. We have no theoretical explanation for this strange parameters/distance interaction (see also the remark at the end of IV.1.).
IV.4 - COMPARISONS OF DISTANCES AND PARAMETRIZATIONS

Many comparative studies for distances, and also for choices of parametric representations, have been conducted in the field of speech recognition, but also in other domains [21] [51]. The oldest ones are probably due to Atal [2] who already noticed that the cepstral distance (80) is better than the euclidian distance between the reflection coefficients. These results were conforted for example in [20] and [12], where the cepstrum (73) obtained by Fourier analysis - in the so-called mel scale - seemed to lead to a better distance measure than the parametric cepstrum computed by (77), maybe because of consonants; moreover, in this study, the cepstral distance \( d_2 \) appeared to be better than the Itakura distance \( d_1 \). (Notice that they cannot be compared in the table of II.3.6). Similar conclusions concerning the cepstrum have been obtained in the recent work [8].

Other comparisons have been done in [38], with different weighting variants introduced for speech signals ("spectral slope", ...).

Recall that the variants of \( d_1 \) or \( d_2 \) introduced respectively in [46] and [25] [35] have been compared to the original distance \( d_1 \) or \( d_2 \).

It is not easy to draw a synthetic picture from these comparative studies, even for the only domain of speech recognition, because their experimental conditions are highly variable (sets of reference signals used for learning and of test signals used for recognition).

Recall that the most fundamental comparative analysis has been conducted by Matsuyama [36] [17] and is partly summarized in the table of paragraph III.3.6.
V. CONCLUSION

From this whole set of studies concerning distance measures arise some elements leading to a kind of conclusion about the distance measures to be preferred in practice. Actually, from (10), (11) for $r = 2$, (17), (58), (69) and (70), we conclude that Kullback divergence $J$ (8) and Hellinger distance $H$ (6) take a key part for proving complex theoretical results as well as solving applied problems. Furthermore, it is quite stimulating to find out that the same tools are preferred by theoreticians and practitioners.

In addition to $J$ and $H$, we also recommend to use $d_2$ (79) in practice, because of its euclidian nature.
