(Dated: February 9, 2009)

We demonstrate theoretically a scheme for cluster state generation, based on atomic ensembles and the dipole blockade mechanism. In the protocol, atomic ensembles serve as single qubit systems. Therefore, we review single-qubit operations on qubit defined as collective states of atomic ensemble. Our entangling protocol requires nearly identical single-photon sources, one ultra-cold ensemble per physical qubit, and regular photodetectors. The general entangling procedure is presented, as well as a procedure that generates *in a single step* Q -qubit GHZ states with success probability $p_{success} \sim \eta^{Q/2}$, where η is the combined detection and source efficiency. This is significantly more efficient than any known robust probabilistic entangling operation. GHZ states form the basic building block for universal cluster states, a resource for the one-way quantum computer.

I. INTRODUCTION

The construction of a quantum computer is an important goal of modern physics. One of the prominent approaches to the physical implementation of a quantum computer and quantum computation is linear quantum optics [1] [2]. Photons are perfect carriers of quantum information and can therefore be utilized in quantum communication [3]. The drawback of photonic systems for quantum computation is the fact that there is no direct interaction between photons. Moreover, all linear optical gates that process quantum information are probabilistic. These problems impose a requirement for a medium that would facilitate an interaction between photons, and store photonic qubits. Hence, a concept of optical quantum memory realized in atomic vapour (atomic ensemble) was introduced. Atomic ensembles consist of several hundreds of the same species of atoms kept in room temperature or cooled to μK temperature. A large number of atoms increases the coupling strength of an interaction between light and matter, and therefore allows us to coherently manipulate the quantum state of the ensemble with light and vice versa. Moreover, a large number of atoms helps to suppress the negative impact of decoherence on an information stored in atomic ensemble [4, 5, 6, 7, 8].

Initially, atomic vapours were used as a fast quantum memory. However, it is also possible to define a “good” qubit in an atomic ensemble, and the question remains how to implement the entangling operations between the qubits that enable universal quantum computation. It suffices to create a large entangled multi-qubit resource—the cluster state—after which the entire computation proceeds via single-qubit measurements [9, 10]. Cluster states are large arrays of isolated qubits connected (entangled) via CZ operations. The cluster states are a scalable resource and can be built up with probabilis-

tic entangling operations with $p_{success} > 0$ [11]. When the success probability of entangling operation is low, a very large overhead in optical elements is required. Moreover, finite coherence times of the qubits limit practical use of the cluster states. Hence, it is extremely important to build them up in the efficient way. Here, we show how to efficiently create these cluster states using single photons interacting with an atomic ensembles via the dipole blockade mechanism. The protocol requires identical single-photon sources, one ensemble per physical qubit placed in the arms of a Mach-Zehnder interferometer, and regular photodetectors. We present a general entangling procedure, as well as a procedure that generates Q -qubit GHZ states with success probability $p_{success} \sim \eta^{Q/2}$, where η is the combined detection and source efficiency. This is significantly more efficient than any known robust probabilistic entangling operation [11, 12]. The GHZ states are locally equivalent to the cluster state and form the basic building block for universal cluster states. Our protocol significantly reduces an overhead in optical elements and leads to better quantum computing prospects.

The paper is organized as follows. In Sec. II, we introduce a notion of the Rydberg state and the dipole blockade mechanism. In Sec. III, we review the concept of an atomic ensemble as single qubit system and single-qubit operations in atomic ensembles. In Sec. IV, we review the one-way model of quantum computation realized on the cluster states. We also give a description of a new entangling operation and consider its usefulness for generation of the GHZ and cluster states. In Sec. V, we consider all major errors and decoherence mechanisms that enter the entangling procedure. Moreover, we describe how our ideas can be implemented experimentally.

II. RYDBERG STATE AND DIPOLE BLOCKADE MECHANISM

The Rydberg state is a state of an alkali atom characterized by a high principal quantum number n [13].

*Electronic address: php07mz@sheffield.ac.uk

Rydberg atoms possess a number of interesting properties. To begin, Rydberg atoms are very large compared to normal atoms. The radius of a Rydberg atom scales as $n^2 a_0$, where a_0 is the Bohr radius. Therefore, the valence electron is very weakly bound to the nucleus. The binding energy of a Rydberg state is given by

$$E = -\frac{R}{(n - \delta)^2} = -\frac{R}{n^{*2}}, \quad (1)$$

where R is the Rydberg constant, n^* is the effective quantum number, and δ is the quantum defect which corrects for the deviation from a case of the hydrogen atom [14]. The Rydberg states have a very long lifetime, which

FIG. 1: The dipole blockade mechanism. A laser pulse couples ground state $|g\rangle$ and Rydberg state $|r\rangle$. (a) One of the atoms is excited to the Rydberg state $|r\rangle$. (b) Presence of a single atom in the Rydberg state $|r\rangle$ shifts energy levels and blocks further excitations.

scales as $\tau_0 n^5$ where τ_0 is the typical lower level lifetime of around ~ 10 ns. Hence, Rydberg states possess lifetimes of order of ms and even longer. One of the most important properties of the Rydberg atoms is their sensitivity to external electric fields. The Rydberg energy levels are easily perturbed by modest electric fields. Higher electric fields can even ionize Rydberg atoms. Commonly, ionization is used as one of the detection methods. This sensitivity to electric fields is the source of a phenomenon called the *dipole blockade mechanism*. Atoms in Rydberg states have large dimensions and large dipole moments, resulting in a strong dipole-dipole interaction [15]. The dipole blockade mechanism was observed experimentally in small clouds of alkali atoms, such as Rubidium in a vapour cell [16, 17]. This mechanism prevents populating states of an atomic ensembles with two or more atoms excited to the Rydberg level [5]. A single atom in a micron-sized atomic ensemble excited to a Rydberg state with a narrowband laser can inhibit excitation of the other atoms in the sample if the long range Rydberg-Rydberg interactions are much larger than a linewidth of the Rydberg state.

The physics of the dipole blockade is shown in [Fig. 1]. An optical pulse resonant with a transition to the Rydberg state $|r\rangle$ will create a Rydberg atom with a very large dipole moment [Fig. 1a]. When the atoms in the ensemble are sufficiently close, the long range Rydberg-Rydberg interactions (dipole interactions) between the

Rydberg atom and the other atoms will cause a shift in the Rydberg transition energy of the other atoms. Therefore, the optical pulse becomes off-resonant with the other atoms, and the ensemble is transparent to the pulse. Under dipole blockade conditions, the mesoscopic vapour behaves as one superatom with a two-level structure. A single excitation is shared by all atoms in a sample and Rabi oscillations can be observed. Effectiveness of the blockade depends on an average strength of the interaction between atoms in the ensemble.

Depending on the separation between atoms, long range Rydberg-Rydberg interactions have different type. The usual van der Waals interaction of types C_5/R^5 or C_6/R^6 can be resonantly enhanced by Förster processes to the C_3/R^3 long range interaction. In the absence of an external electric field, the Rydberg-Rydberg interactions are of the van der Waals type C_5/R^5 or C_6/R^6 [18]. In a static electric field, a Rydberg atom possesses a large permanent dipole moment p , which scales as $\sim qa_0 n^2$ with q the electron charge, which leads to a much stronger and longer C_3/R^3 interaction. A pair of Rydberg atoms i and j interact with each other via dipole-dipole potential V_{dd} ,

$$V_{dd} = \frac{\mathbf{p}_i \mathbf{p}_j - 3(\mathbf{p}_i \cdot \mathbf{e}_{ij})(\mathbf{p}_j \cdot \mathbf{e}_{ij})}{4\pi\epsilon_0 |\mathbf{r}_i - \mathbf{r}_j|^3} = \frac{p^2}{4\pi\epsilon_0 R^3} (1 - 3 \cos^2 \theta), \quad (2)$$

where \mathbf{e}_{ij} is a unit vector along the interatomic direction, θ is the angle between the interatomic separation $R = |\mathbf{R}| = |\mathbf{r}_i - \mathbf{r}_j|$ and the electric field \mathbf{z} direction. In general, the interaction between Rydberg atoms is very strong. However, for some angles V_{dd} vanishes which is undesirable for dipole blockade purpose [18]. Fortunately, there is another method to induce a strong, isotropic interaction between Rydberg atoms, comparable to V_{dd} . The resonant collisional process (Förster process) transfers energy between two atoms through the dipole-dipole interaction with strength $\sim \rho_1 \rho_2 / R^3$, where ρ_1 and ρ_2 are the dipole matrix elements between initial and final energy states of the interacting atoms [19]. Therefore, the usual van der Waals interaction can be resonantly enhanced by Förster processes such as

$$nl + nl \rightarrow n'l' + n''l'' \quad (3)$$

when the $nl + nl$ states are degenerated in energy with the $n'l' + n''l''$ states. The Förster process induces an interaction potential of the form

$$V_{\pm}(R) = \frac{\delta}{2} \pm \sqrt{\frac{4U_3(R)^2}{3} + \frac{\delta^2}{4}}, \quad (4)$$

where

$$U_3(R) = q^2 \langle nl || r || n'l' \rangle \langle n'l' || r || n''l'' \rangle / R^3, \quad (5)$$

with $\delta = E(n'l') + E(n''l'') - 2E(nl)$ is the Förster energy defect. There is no angular dependence for the potential $V_{\pm}(R)$ so an interaction is isotropic. For perfect Förster degeneracy ($\delta = 0$) $V_{+}(R)$ would be of similar strength and range to V_{dd} [18]. Although at the large separations,

a non-zero Förster energy defect reduces long-range interaction between the atoms to be van der Waals C_6/R^6 type. However, if the Förster energy defects are smaller than the fine-structure splitting, then strong C_3/R^3 interaction occurs at longer range as well.

Although Förster processes are very promising as a method to induce very long-range C_3/R^3 interactions, there are some selection rules that need to be fulfilled for obtaining high fidelity dipole blockade. Only for $l' = l'' = l + 1$ there are no so-called Förster zero states with $C_3 = 0$ [18]. Therefore, a fidelity of the dipole blockade mechanism may be reduced due to weakest interactions between degenerate Rydberg states. In the case of the Förster zero states, a strength of the interaction between Rydberg atoms is not enhanced and reduces to the usual van der Waals long-range type. Hence, for attaining a strong dipole blockade, resonances need to be tuned with an electric field [18]. The other possibility for attaining strong dipole blockade is to rely on the van der Waals interaction which at smaller distances, less than $5 \mu\text{m}$, is large enough to mix the fine-structure levels together, so the interaction is of the V_{dd} type [20].

The dipole blockade mechanism has been proposed as a method to entangle large numbers of atoms [5]. The exact strength of the dipole blockade is not important as long as it is greater than the linewidth of a Rydberg state. Hence, the atoms can be at random distances R from each other [18]. Moreover, since states with two or more atoms in the Rydberg state are never populated, the atoms avoid mechanical interactions between each other. Therefore, the atoms avoid heating and the internal states of the atoms are decoupled from the atomic motion [5].

The range and quality of the dipole interaction has been studied extensively: Walker and Saffman analyzed the primary errors that enter the blockade process [17, 20]. For Rubidium atoms with principal quantum number $n = 70$, the blockade energy shift is approximately 1 MHz. Hence, a strong and reliable blockade is possible for two atoms with separation up to $\sim 10 \mu\text{m}$ [20]. Moreover, decoherence associated with spontaneous emission from long-lived Rydberg states can be quite low ($\sim 1 \text{ms}$). The dipole blockade mechanism can be used to build fast quantum gates, i.e., a two qubit phase gate [21, 22, 23]. The long-range dipole-dipole interaction between atoms can be employed to realize a universal phase gate between pairs of single-photon pulses [24, 25, 26]. Most importantly, the ideas based on the dipole blockade mechanism are experimentally feasible.

The single quantum sensitivity suggests that the dipole blockade can be used to create cluster states: The blockade mechanism can be used in a heralding type of entangling operations and render them to be nearly deterministic. Before introducing the entangling protocol, let us review a scheme for implementing single-qubit operations on the qubit defined in atomic ensemble and analyze it in detail.

FIG. 2: Relevant atomic level structure with allowed atomic transitions. States $|g\rangle$, $|e\rangle$, and $|s\rangle$ can be realized by the electronic low-lying, long lived states of alkali atoms. The transition between states $|g\rangle$ and $|s\rangle$ is always dipole-forbidden. The state $|g\rangle$ is coupled to the state $|e\rangle$ through a classical field Ω_g . A second classical field Ω_s is applied to the transition between the highly excited Rydberg level $|r\rangle$ and the state $|s\rangle$ (it may possibly be a two-photon process). States $|e\rangle$ and $|r\rangle$ are coupled via a quantum field. In general, Δ is a small detuning.

III. ATOMIC ENSEMBLE AS SINGLE QUBIT SYSTEM – SINGLE-QUBIT GATES

A qubit may be represented by a micron-sized atomic ensemble, cooled to μK temperatures by the far off-resonant optical trap or magneto-optical trap (MOT). The N atoms at positions r_j in an ensemble have three lower, long lived energy states $|g\rangle$, $|e\rangle$, and $|s\rangle$ (see Fig. 2). The qubit states in a mesoscopic ensemble are collective states given by

$$|0\rangle_L \equiv |g\rangle = |g_1, g_2, \dots, g_N\rangle, \quad (6)$$

$$|1\rangle_L \equiv |s\rangle = \frac{1}{\sqrt{N}} \sum_{j=1}^N e^{i\mathbf{k}\cdot\mathbf{r}_j} |g_1, g_2, \dots, s_j, \dots, g_N\rangle. \quad (7)$$

The states $|e\rangle$ and $|r\rangle$ participate in the interaction part of the scheme. Levels $|g\rangle$ and $|s\rangle$ play the role of a storage states. In the case of the qubit states defined as collective states of mesoscopic ensemble, single-qubit operations are more complex than in a case of a qubit realized on a single atom. The simplest approach to this problem is to realize single-qubit rotations by means of classical optical pulses and the dipole blockade mechanism. In a paper by Brion, Mølmer, and Saffman [23], the single-qubit rotations are performed by means of three laser pulses (see Fig. 3). First, a π -pulse transfers the population from $|s\rangle$ to $|r\rangle$, then a coherent coupling of states with zero and one Rydberg excited atom is applied for appropriate amount of time and finally, a π -pulse transfers the population from $|r\rangle$ to $|s\rangle$ (the reader may notice that two additional π -pulses are depicted in Fig. 3 that transfer population from the storage level $|g\rangle$ to $|e\rangle$ and back again). Therefore, in the case of a bit flip operation (X) the coherent coupling is just a π -pulse with a real Rabi frequency, and the Hadamard gate (H) can be performed by a $\pi/2$ -pulse on the same transition. An

FIG. 3: The bit flip operation (X) and the Hadamard gate (H). (a) Rotation $|0\rangle_L \rightarrow |1\rangle_L$ or $|0\rangle_L \rightarrow 1/\sqrt{2}(|0\rangle_L + |1\rangle_L)$ (b) rotation $|1\rangle_L \rightarrow |0\rangle_L$ or $|1\rangle_L \rightarrow 1/\sqrt{2}(|0\rangle_L - |1\rangle_L)$. See the text for an explanation.

FIG. 4: The collective states of a mesoscopic atomic ensemble. $|e\rangle$ is the collective low-lying state, $|r\rangle$ is the singly excited state, $|rr\rangle$ is the doubly excited state, and $\bar{\Delta}$ is the mean dipole shift.

arbitrary phase gate $\Phi(\phi) = \exp(-i\phi Z/2)$ is realized by a detuned optical pulse applied to the transition between $|s\rangle$ and an auxiliary level $|a\rangle$ (not shown in Fig. 3). The gates $\Phi(\phi)$, X , and H generate all single-qubit operations. The readout of a qubit is based on the resonance fluorescence and again requires an auxiliary level $|a\rangle$. An optical laser drives a transition between $|s\rangle$ and $|a\rangle$ producing a large number of fluorescence photons. If the measurement gives no fluorescence photons, the qubit is in $|0\rangle_L$. Otherwise, a state of the qubit is projected into $|1\rangle_L$.

The scheme for implementing single-qubit operation relies heavily on the dipole blockade mechanism. We analyze the above scheme for the case of a bit flip operation X . Therefore, we need to consider carefully the evolution of the system under a π -pulse applied to the transition between $|e\rangle$ and $|r\rangle$.

In general, the interaction of atoms with an optical laser pulse, within the dipole approximation and in the rotating frame approximation, is governed by interaction

Hamiltonian \hat{H}_{int}

$$\hat{H}_{int} = -i\hbar \sum_{j=1}^N \Omega_j \sigma_{re}^j \exp[i(\omega_{re} - \omega)t] \quad (8)$$

$$-i\hbar \sum_{j,k>j}^N \Omega_k \sigma_{rr}^{jk} \exp[i(\omega_{re} - \omega)t] + \text{H.c.}, \quad (9)$$

where $\Omega_j = \Omega e^{i\mathbf{k}\cdot\mathbf{r}_j}$ is the Rabi frequency, $\omega = kc$ is the frequency of an optical laser pulse, $\sigma_{re}^j = |r_j\rangle\langle e|$ and $\sigma_{rr}^{jk} = |r_j r_k\rangle\langle r_j r_k|$ are the atomic transition operators (see Fig. 4) [27]. The first transition operator σ_{re}^j corresponds to the transition between the collective state $|e\rangle$ and the singly excited state

$$|r\rangle = 1/\sqrt{N} \sum_{j=1}^N e^{i\mathbf{k}\cdot\mathbf{r}_j} |r_j\rangle. \quad (10)$$

The second one corresponds to the transition between the singly excited state $|r\rangle$ and the doubly excited state

$$|rr\rangle = \sqrt{2/N(N-1)} \sum_{j,k>j}^N e^{i(\mathbf{k}\cdot\mathbf{r}_j + \mathbf{k}\cdot\mathbf{r}_k)} |r_j r_k\rangle. \quad (11)$$

We assume that the optical laser pulse is resonant with a transition between $|e\rangle$ and $|r\rangle$ ($\omega_{re} - \omega = 0$). Then, the dipole interaction between two Rydberg atoms is given by

$$\hat{V}_{dd} = \hbar \sum_{j,k>j}^N \Delta_{jk} |r_j r_k\rangle\langle r_j r_k|, \quad (12)$$

where $\Delta_{jk} = \frac{C_6}{|\mathbf{r}_j - \mathbf{r}_k|^6}$ is the dipole shift of the weakest van der Waals type. Hence, the coupling of levels $|e\rangle$ and $|r\rangle$ is described by the Hamiltonian $\hat{H} = \hat{H}_{int} + \hat{V}_{dd}$. The state vector of an atomic ensemble is given by

$$|\psi(t)\rangle = c_g |g\rangle + \sum_{j=1}^N c_j e^{i\mathbf{k}\cdot\mathbf{r}_j} |r_j\rangle + \sum_{j,k>j}^N c_{jk} e^{i(\mathbf{k}\cdot\mathbf{r}_j + \mathbf{k}\cdot\mathbf{r}_k)} |r_j r_k\rangle. \quad (13)$$

In the limit where the dipole shift is much larger than the Rabi frequency of an optical laser pulse $\Delta_{jk} \gg \Omega_j$, the Schrödinger equation for amplitudes of the state vector gives

$$\dot{c}_g = \sqrt{N}\Omega c_r, \quad (14)$$

$$\dot{c}_r = -\sqrt{N}\Omega c_g + \frac{\Omega}{\sqrt{N}} \sum_{j,k>j}^N c_{jk}, \quad (15)$$

$$\sum_{j,k>j}^N \dot{c}_{jk} = - \sum_{j,k>j}^N \Omega c_j - i \sum_{j,k>j}^N c_{jk} \Delta_{jk}, \quad (16)$$

with $c_r = \sqrt{N}c_j$ [27]. Elimination of the doubly excited Rydberg state described by Eq. (16) by means of an

adiabatic approximation yields

$$\dot{c}_g = \sqrt{N}\Omega c_r, \quad (17)$$

$$\dot{c}_r = -\sqrt{N}\Omega c_g + \frac{i\bar{\Delta}\Omega^2}{N}c_r, \quad (18)$$

where $\bar{\Delta} = \sum_{j,k>j}^N \frac{1}{\Delta_{jk}}$ is the mean dipole shift. The solution of Eq. (18) for $c_g(0) = 1$ (initially all atoms are in their ground state $|g\rangle$) reads as

$$|c_r(t)|^2 = \sin^2(\sqrt{Nl}\Omega t)/l, \quad (19)$$

with $l = 1 + \frac{\bar{\Delta}^2\Omega^2}{4N^3}$. The evolution from collective state $|e\rangle$ to singly excited state $|r\rangle$ in time $t = \frac{\pi}{2\sqrt{Nl}\Omega}$ occurs with probability $P_1 = 1/l$. In the limit of finite dipole blockade, the probability of unwanted double excitations after the π pulse is given by

$$P_2 = \sum_{j,k>j}^N |c_{jk}|^2 = \frac{\bar{\Delta}_{P_2}\Omega^2}{N}, \quad (20)$$

with $\bar{\Delta}_{P_2} = \sum_{j,k>j}^N \frac{1}{\Delta_{jk}^2}$. A finite blockade also implies a frequency shift of the effective two-level system ($|g\rangle$ and $|r\rangle$). The resonance frequency is shifted by $\delta\omega = \frac{\Omega^2\bar{\Delta}}{N}$.

The above results can be applied to the case of any single-qubit operations. We assume that a qubit is realized by a quasi one-dimensional (cigar shaped) atomic vapour consisting of ~ 300 ^{87}Rb atoms. The spatial distribution (probability density) of an atomic cloud is given by

$$P(z) = (2\pi\sigma^2)^{-1/2} \exp(-z^2/2\sigma^2), \quad (21)$$

where z is a dimension along the ensemble and $\sigma = 3.0$ μm is the variance. The level $|r\rangle$ may correspond to $43D_{5/2}$ or $58D_{3/2}$. The probability of double excitation given by Eq. (20) can be rewritten in terms of the mean blockade shift B [20]. Hence, the probability of double excitation is $P_2 = \Omega_N^2(N-1)/2NB^2$, where $\Omega_N = \sqrt{N}\Omega$. For $43D_{5/2}$ and $58D_{3/2}$, the mean blockade shift is $B = 0.25$ MHz and $B = 2.9$ MHz in a trap with $\sigma = 3.0$ μm , respectively [20]. Hence, the probability of double excitation for the $43D_{5/2}$ level is $P_2 \cong 2.3 \cdot 10^{-3}$ and for the $58D_{3/2}$ level is $P_2 \cong 1.7 \cdot 10^{-5}$.

The fidelity of the single-qubit rotations can be as high as $F_{\text{single}} = \exp(-2P_2) = 0.999$, where $P_2 = 1.7 \cdot 10^{-5}$ (the probability of doubly-excited states and singly-excited states outside the desired two-level system are similar). Above fidelity is given for the worst case scenario when the separation of atoms is maximal and the dipole-dipole interaction is of the weakest (van der Waals) type. The time of a π -pulse applied to the transition between $|e\rangle$ and $|r\rangle$ is ~ 14.6 μs . We estimate that the rest of the π -pulses which are necessary to realize any single-qubit rotation (see Fig. 3) can be applied in time significantly shorter than the above time.

In the above experimental implementation, the single-qubit rotations can be carried out on a microsecond timescale. Hence, the spontaneous emission from the Rydberg state and the black-body transfer (to other Rydberg states) which occur with low rates of order 10^3 Hz are negligible. Moreover, a low temperature of the atomic vapour implies low atomic collision rate and negligible Doppler broadening.

The single-qubit rotations are one of the basic operations that are necessary in any model of quantum computation. The above fast and reliable implementations of the single-qubit operations open a possibility for a realization of the measurement-based model of quantum computation. However, we are still lacking a scheme for efficient generation of the cluster states. Before introducing an efficient protocol for cluster states generation, let us review the concept of the measurement-based model of quantum computation realized on the cluster states.

IV. ENTANGLING OPERATIONS FOR THE CREATION OF CLUSTER STATES

A. Cluster states and one-way model of quantum computation

There are many approaches to scalable quantum computing (QC), such as the standard circuit model of QC, adiabatic QC or measurement-based QC, realized on the cluster states [28, 29]. Cluster states are large entangled states that act as a universal resource for the one-way quantum computer [9, 10, 28]. Graphically cluster states are represented in a form of lattice or a graph. We associate with every node j of a graph an isolated qubit in the state $|+\rangle = \frac{1}{\sqrt{2}}(|0\rangle_j + |1\rangle_j)$ connected (entangled) with adjacent qubits via the CZ_{jk} (controlled-Z) operations

$$CZ_{jk} = |0\rangle_j\langle 0| \otimes \hat{\mathbb{I}}_k + |1\rangle_j\langle 1| \otimes Z_k, \quad (22)$$

where $|0\rangle, |1\rangle$ are the computational basis states and Z is the Pauli σ_z operator. Commonly, cluster states are described in terms of the stabilizer operators. A set of commuting operators S_j constitutes a stabilizer of quantum state $|\phi\rangle$ under which the state is invariant. The stabilizer formalism allows us to describe quantum states of a set of qubits and its evolution in terms of few stabilizer operators, which usually consist of operators from the Pauli group G_n . The state $|\phi_N^C\rangle$ of cluster C consisting of N qubits is completely specified by the following set of eigenvalue equations:

$$S_j|\phi_N^C\rangle = |\phi_N^C\rangle, \quad (23)$$

with

$$S_j = X_j \prod_{k \in \text{ngb}(j)} Z_k, \quad (24)$$

where $\text{ngnb}(j)$ is the set of all neighbours of qubit j [9]. The S_j are Hermitian stabilizer operators whose eigenstates (the cluster states) are mutually orthogonal and form a basis in the Hilbert space of the cluster [9].

FIG. 5: A cluster state. Nodes represent physical qubits which are connected via the CZ operations. A horizontal strings of physical qubits constitute a logical qubit. The vertical links between logical qubits represent two-qubit CZ gates.

In the measurement-based model of QC, the entire resource for quantum computation is provided from the beginning as a cluster state [Fig. 5]. Quantum computation consists of single-qubit measurements on the cluster states and every quantum algorithm is encoded in a measurement blueprint. Measurement of a qubit in the Z eigenbasis (in the computational basis) removes a qubit from a cluster and all links to its neighbours are broken. In conclusion, a cluster is reduced by one qubit, and possible corrective Z operation is applied to its neighbours depending on the measurement output (if the measurement result is $|0\rangle$ then nothing happens, but when the measurement output is $|1\rangle$ a phase-flip is applied). By means of a Z measurement, any cluster can be carved out from a generic, fully connected cluster (Fig. 5). Other measurements are performed in the basis $B(\alpha) \in \{|\alpha_+\rangle, |\alpha_-\rangle\}$ where $|\alpha_\pm\rangle = \frac{1}{\sqrt{2}}(e^{i\alpha/2}|0\rangle \pm e^{-i\alpha/2}|1\rangle)$. For $\alpha = 0$ the measurement is realized in the X eigenbasis. An interesting feature of X measurement is that two neighboring X measurements in a linear cluster remove measured qubits and connects their neighbours with each other resulting in a shortened cluster. For $\alpha = \pi/2$, the Y measurement is performed. In result of the Y measurement, the measured qubit is removed from a cluster and its neighbours are connected (up to a corrective phase operation). Measurements in the X and Y eigenbases propagate quantum information through cluster. In general, any quantum computation proceeds as a series of measurement governed by an appropriate blueprint. The choice of measurement basis for every physical qubit is encoded in this measurement blueprint. Moreover, all measurement bases depend on the outcomes of the preceding measurements. This is called feed-forward operation. Although the result of any measurement is completely random, information processing is possible because of the feed-forward operations. The feed-forward operations ensure that measurement bases are correlated and deterministic computation can be realized. In this way quantum information propagates through cluster until the last column of qubits, which are then ready to be read out. Readouts are performed in the Z eigenbasis up

FIG. 6: Diagram of the protocol. We send an entangled pair of photons in the state $|\phi_{light}\rangle = \frac{i}{\sqrt{2}}(|02\rangle + |20\rangle)$ into the arms of a Mach-Zehnder interferometer. The photons interact with atomic vapours: One and only one alkali atom in the ensemble is excited by one of the photons to the Rydberg state $|r\rangle$. Absorption of the second photon is prohibited by the dipole blockade mechanism. After BS_2 , the state of ensemble-light system has the following form $|\phi_{out}\rangle = \frac{i}{\sqrt{2}}(|\psi^+\rangle|01\rangle + |\psi^-\rangle|10\rangle)$, where $|\psi^\pm\rangle = \frac{1}{\sqrt{2}}(|re\rangle \pm i|er\rangle)$. Detection of a single photon will leave the atomic ensembles entangled.

to Pauli correction and the output of the computation is a classical bit string [9].

Cluster states are a promising resource for quantum information processing and quantum computer. One possible way of creating arrays of qubits is trapping single atoms or small atomic ensembles in optical lattices. However, since a cluster consists of a large set of entangled qubits, efficient protocols for generating entanglement between pairs of qubits in lattice are required.

B. Protocol - entangling operation

We propose a scheme for cluster state generation, based on the dipole blockade mechanism. The entangling operation is constructed as follows: Two atomic ensembles are placed in the arms of a Mach-Zehnder interferometer (see Fig. 6). Initially, we prepare each ensemble A and B in the state $|\phi_{A,B}\rangle = |e\rangle \equiv |e_1, e_2, \dots, e_N\rangle$ (see Fig. 2). Two indistinguishable photons enter each input mode of the interferometer, and due to the Hong-Ou-Mandel (HOM) effect, after the first beam splitter (BS_1), the two photons are in the state $|\phi_{light}\rangle = |11\rangle \xrightarrow{BS_1} \frac{i}{\sqrt{2}}(|02\rangle + |20\rangle)$ where $|0\rangle$ and $|2\rangle$ denote the vacuum and a two-photon state, respectively. After BS_1 the photons interact with the atomic ensembles: One and only one atom in the ensemble is excited by one of the photons to the Rydberg state $|r\rangle$, and the absorption of the second photon is prohibited by the dipole blockade mechanism. The total state of a ensemble-light system after interaction is given by

$$|\phi_{int}\rangle = \frac{i}{\sqrt{2}}(|er\rangle|01\rangle + |re\rangle|10\rangle). \quad (25)$$

FIG. 7: The scheme for creating the 4-qubit GHZ state. The four ensembles A , B , C , and D are prepared in the state $|\phi_{ABCD}\rangle = |eeee\rangle$. Four indistinguishable photons are sent into the beam splitters. The interaction of photons with the atomic vapours is followed by the beam splitters and four photodetectors. Conditional on photodetector clicks at the photodetector (D_1, D_2) , (D_1, D_3) , (D_4, D_2) or (D_4, D_3) , a state of the four qubits is projected onto the 4-qubit GHZ state (up to phase correcting operations) with success probability $p_{success} = \eta^2/2$.

After the second beam splitter (BS_2), the total state is

$$|\phi_{out}\rangle = \frac{i}{\sqrt{2}}(|\psi^+\rangle|01\rangle + |\psi^-\rangle|10\rangle), \quad (26)$$

where $|\psi^\pm\rangle = \frac{1}{\sqrt{2}}(|re\rangle \pm i|er\rangle)$. Conditional on a single photodetector click, the ensembles are projected onto a maximally entangled state. After establishing entanglement, the qubits are transferred to their computational basis states $|0\rangle_L \equiv |g\rangle$ and $|1\rangle_L \equiv |s\rangle$ by classical optical pulses Ω_g and Ω_s . This means that ideally every run of the procedure would give an entangled state of ensembles with success probability $p_{success} = \eta$, where η is the combined detection and source efficiency. This is a significant improvement compared to the success probability $p_{success} = \eta^2/2$ of the double heralding protocol in Ref. [11].

C. Generation of the GHZ and cluster states

The entangling operation can be used to efficiently create arbitrary cluster states, including universal resource states for quantum computing. However, a modification of the entangling procedure yields an even more dramatic improvement in the efficiency of cluster state generation. By arranging the ensembles in a four-mode interferometer as shown in Fig. 7, the detection of two photons will create the four-qubit GHZ state *in a single step*. Moreover, since only two photons are detected, the protocol

is relatively insensitive to detector losses. The success probability is $p_{success} = \eta^2/2$. Higher GHZ states can be created by a straightforward extension. A subsequent cluster states are generated with success probability

$$p_{success} = \eta^{Q/2}(Q-2)/2^{Q-2}, \quad (27)$$

where $Q = 4, 6, \dots$ is the number of the qubits.

The efficiently generated large GHZ states may serve as building blocks for cluster states. By entangling small clusters with the above entangling procedure, large cluster states can be constructed. A single photon applied to a pair of qubits (each from two different 4-qubit cluster states) followed by a single photodetector click creates a 8-qubit cluster state with success probability $p_{success} = \eta/8$. This procedure can be repeated in an efficient manner [30]. In case of failure, the two qubits that participated in linking are measured in the computational basis, and the rest of the cluster state is recycled [31].

V. ERRORS, DECOHERENCE MECHANISMS AND FIDELITY

The dominant errors and decoherence mechanisms that enter the entangling operation are the following: *(i)* The coincident event in the HOM effect, *(ii)* the spontaneous emission rate of the Rydberg state, *(iii)* the black-body transfer rate (to other Rydberg states), *(iv)* the atomic collision rate, *(v)* the doubly-excited Rydberg states and singly-excited states outside the desired two-level system, *(vi)* no absorption event, and *(vii)* the inefficiency and the dark count rate of the photodetectors. We analyze in more detail the dominant error and decoherence mechanisms on the following experimental implementation.

A. Experimental implementation of the entangling operation

First, consider the coincident events in the HOM effect. The single indistinguishable photons that recombine at the first beam splitter (BS_1) can be generated by means of the spontaneous parametric down-conversion (SPDC) process or any other source of a single-photon pulses such as atomic ensemble inside an optical cavity [32]. However, we believe that the SPDC source is better suited for the entangling protocol because of a very complex setup structure of the atomic-based source. The SPDC source (the non-linear crystal) must be pumped with a narrow-band (~ 1 MHz) laser or placed inside a cavity. These kind of cavity-enhanced SPDC sources produce pairs of a single, identical photons with a narrow bandwidth of order of MHz and a spectral brightness of ~ 1500 photons/s per MHz bandwidth [33, 34]. In general, successful generation of the entangled state of light depends on the proper setup, where both photons from the SPDC source recombine at BS_1 at the same

FIG. 8: Example of an experimental implementation of the protocol. The source of a single-photon pair consists of the type I nonlinear crystal. Generated single-photon pulses are entangled in the momentum (path) degree of freedom.

time. In a recent experiment, the coincident event in the HOM effect happens with a rate of 1500 counts/s [35]. We assume that the rate of coincident events is negligible comparing to the time scale of the protocol which is $t \cong 3 \mu\text{s}$ (the origin of this value will be given later on). In fact, it is possible to completely eliminate the coincident event in the HOM effect by getting rid of the BS_1 . In place of single-photon sources and BS_1 , one can use a SPDC source generating pairs of single-photons entangled in momentum (path) degree of freedom [36, 37]. The state of the photons is given by $|\phi_{\text{light}}\rangle = \frac{1}{\sqrt{2}}(|20\rangle_{AB} + |02\rangle_{AB})$, where A and B are the single-photon pairs that interact with an ensemble A and B , respectively (see Fig. 8). Moreover, since the SPDC process is a phase and energy matching phenomenon, no phase difference appears between two paths (pairs) A and B [36]. In general, the whole Mach-Zehnder interferometer needs to be phase-stable. In case of a GHZ state generation, phase locking of a large number of Mach-Zehnder interferometers is very demanding (although possible). Therefore, by replacing single-photon sources and BS_1 with the SPDC source generating entangled photon pairs we solve another potential roadblock to an experimental realization of the entangling operation. Recently, it has been shown that these kind of entangle pairs of photons can be generated very effectively [37].

Now, assume that an atomic vapour consists of 300 ^{87}Rb atoms placed in the far off-resonant optical trap or magneto-optical trap (MOT). The atomic levels $|g\rangle$, $|e\rangle$, and $|r\rangle$ may correspond to $(5S_{1/2}, F=1)$, $(5P_{3/2}, F=2)$ and $43D_{5/2}$ or $58D_{3/2}$, respectively. State $|s\rangle$ may correspond to the hyperfine state $(5S_{1/2}, F=2)$, which implies that the transition from $|s\rangle$ to $|r\rangle$ is a two-photon process (see Fig. 2). We have identified state $|e\rangle$ with a short lived state $(5P_{3/2}, F=2)$, when in fact it must be a long lived energy level. However, in case of the MOT trap, the requirement of a long relaxation time of the state $|e\rangle$ can be lifted since the trap lasers produce a constant population in the $|e\rangle$ state [14, 38]. In general, a requirement of state $|e\rangle$ is imposed to simplify experimental realization of the protocol where usually two-photon

excitation are used to obtain Rydberg atoms. The spatial distribution of an atomic cloud is a quasi one-dimensional (cigar shaped) ensemble with probability density given by Eq. (21). Atomic vapours described with quasi one-dimensional probability density have been demonstrated experimentally [16].

When a protocol is based on a quantum optical system, its performance is limited by the inefficiency and the dark count rate of the photodetectors. The dark count rate of the modern photodetector γ_{dc} can be as low as 20 Hz and efficiency reaches $\eta \approx 30\%$ for wavelengths around 480 nm. The probability of the dark count is $P_{dc} = 1 - \exp(-\gamma_{dc}t/p_{\text{success}}) \cong 3.2 \cdot 10^{-4}$. In general, the probability of the dark count is negligible for $p_{\text{success}} > \gamma_{dc}t$.

Since the length of the atomic ensemble needs to be of an order of several μm , the most important source of errors is the lack of absorption event. The probability of an absorption of a single photon by a cigar shaped atomic ensemble is given by $P_{abs} \cong 1 - e^{-N_i\sigma_0/A}$, with N_i the number of atoms in the interaction region, $\sigma_0 = 3\lambda^2/(2\pi)$ is the on-resonance scattering cross section of a single-photon pulse, and $A = \pi w_0^2$ is the area of a single-photon pulse with a waist w_0 [39]. With $\lambda_{43D} = 485.766 \text{ nm}$, $\lambda_{58D} = 485.081 \text{ nm}$, and $w_0 \approx \pi\lambda$, the probability of an absorption for both Rydberg states is $P_{abs} \cong 0.989$.

The probability of doubly-excited Rydberg states (absorption of both photons by an ensemble) depends on the quality of the dipole blockade and was given in Sec. III. Here, we rewrite it in terms of the mean blockade shift B [20]. Hence, the probability of doubly-excited Rydberg states is $P_2 = g_N^2(N-1)/2NB^2$, where $g_N = \sqrt{N}g_0$ with g_0 the atom-light coupling constant written as

$$g_0 = \frac{\sqrt{2}\rho}{\hbar} \sqrt{\frac{\hbar\omega}{2\epsilon_0 V}}, \quad (28)$$

with ρ being the dipole moment of the $|e\rangle$ - $|r\rangle$ transition, ω being the frequency of the optical field and V being the quantization volume of the two-photon radiation field. For $43D_{5/2}$ and $58D_{3/2}$, the mean blockade shift is $B = 0.25 \text{ MHz}$ and $B = 2.9 \text{ MHz}$ in a trap with $\sigma = 3.0 \mu\text{m}$, respectively [20]. Hence, the probability of doubly-excited states for the $43D_{5/2}$ level is $P_2 \cong 0.26$ and for the $58D_{3/2}$ level $P_2 \cong 0.57 \cdot 10^{-3}$. The probability of doubly-excited states and singly-excited states outside the desired two-level system are similar. The above probabilities are given for the worst case scenario when the separation of atoms is maximal and the dipole-dipole interaction is of the weakest (van der Waals) type.

The time scale of the entangling protocol $t \cong 3 \mu\text{s}$ consists of a time given in Sec. III with $\Omega \equiv g_0$ and time of a π -pulse with the Rabi frequency $\Omega_s \cong 1 \text{ MHz}$ applied after a single photodetector click.

The spontaneous emission from the Rydberg state and the black-body transfer (to other Rydberg states) occur with rates of order 10^3 Hz , and are negligible, since after successful entanglement preparation the state of ensemble is stored in the long lived atomic states $|g\rangle$ and $|s\rangle$.

Exact values of these rates are given in Refs. [35, 40]. The atomic collision rate is given by

$$\tau_{col}^{-1} \approx n\sigma_{col}/\sqrt{M/3k_B T}, \quad (29)$$

with n the number density of atoms, σ_{col} the collisional cross section ($\sim 10^{-14}$ cm²), M the atomic mass, k_B the Boltzmann's constant, and T the temperature [41]. Assuming a vapour with the number density of atoms of order 10^{12} cm⁻³ and the temperature of $\sim 10^{-3}$ K, the atomic collision rate can be as low as 2 Hz. Moreover, with a sufficiently large energy difference between states $|g\rangle$ and $|s\rangle$ a single collision is not likely to affect the qubit.

A low temperature of an atomic vapour implies negligible Doppler broadening. The Doppler broadening is described by the Gaussian distribution with a standard deviation of $\Delta\lambda = \lambda_0\sqrt{k_B T/Mc^2}$ where λ_0 is the center wavelength of the Doppler profile (wavelength of a transition between states $|e\rangle$ and $|r\rangle$). For both $\lambda_0 = \lambda_{43D}$ and $\lambda_0 = \lambda_{58D}$, the Doppler broadening is $\Delta\lambda = 0.5 \cdot 10^{-6}$ nm. Hence, the Doppler broadening does not affect fidelity of the protocol.

Considering the time scale of the protocol, the entangling procedure is mostly affected by the no absorption event and inefficiency of the photodetectors. We assume that the coincident event rate in the HOM effect is negligible and $|r\rangle$ corresponds to $58D_{3/2}$ which implies low double excitation probability. In the presence of the above noise and decoherence mechanisms, the final state of the system conditional on a single photodetector click is given by

$$\rho_{fin} = (1 - 2\varepsilon)|\psi^\pm\rangle\langle\psi^\pm| + 2\varepsilon\rho_{noise} + \mathcal{O}(\varepsilon^2), \quad (30)$$

where $|\psi^\pm\rangle = \frac{1}{\sqrt{2}}(|sg\rangle \pm i|gs\rangle)$ and $\varepsilon = 1 - P_{abs}$ where P_{abs} is the probability of an absorption of a single photon by an atomic ensemble. ρ_{noise} denotes the unwanted terms in the state of the two ensembles. The source efficiency does not affect the fidelity of the final state, it only lowers the success probability. After taking into account all dominant error mechanisms, the fidelity of the prepared entangled state is given by

$$F = \langle\psi^\pm|\rho_{fin}|\psi^\pm\rangle \cong 0.982, \quad (31)$$

which is close to current fault-tolerant thresholds [3].

VI. CONCLUSIONS

We have presented and analyzed a scheme for cluster state generation based on atomic ensembles and the dipole blockade mechanism. The protocol consists of single-photon sources, ultra-cold atomic ensembles, and realistic photodetectors. The protocol generates *in a single step* GHZ state with success probability $p_{success} \sim \eta^{Q/2}$, where Q is the number of the qubits, and high fidelity $F \cong 0.982$. The protocol is more efficient than any previously proposed probabilistic scheme with realistic photodetectors and sources. In general, number-resolution photodetectors are not required. The GHZ states are locally (up to Hadamard operation) equivalent to star-shaped cluster states. We also reviewed and analyzed a scheme implementing any single-qubit operation on the qubit defined as collective states of mesoscopic ensemble. The scheme for single-qubit rotations uses classical optical pulses and the dipole blockade mechanism. The experimental implementation may be carried out with high fidelity $F_{single} \cong 0.999$ and on the microsecond timescale with current state-of-the-art experimental setups.

The described protocols for single-qubit rotations and entangling operation open a possibility of experimental implementation of the measurement-based quantum computer based on atomic ensembles.
