Global measurements of HCN and C$_2$H$_2$ from IASI

V. Duflot et al.
Abstract

We present global distributions of C$_2$H$_2$ and HCN total columns derived from the Infrared Atmospheric Sounding Interferometer (IASI). These distributions are obtained with a fast method allowing to retrieve C$_2$H$_2$ abundance globally with a 5% precision and HCN abundance in the tropical (subtropical) belt with a 10% (30%) precision. IASI data are compared for validation purposes with ground-based Fourier Transform Infrared (FTIR) spectrometer measurements at four selected stations. We show that there is an overall agreement between the ground-based and space measurements. Global C$_2$H$_2$ and subtropical HCN abundances retrieved from IASI spectra show the expected seasonality linked to variations in the anthropogenic emissions and seasonal biomass burning activity, as well as exceptional events, and are in good agreement with previous spaceborne studies. IASI measurements are also compared to the distributions from the Model for Ozone and Related Chemical Tracers, version 4 (MOZART-4). Seasonal cycles observed from satellite data are reasonably well reproduced by the model. However, the model seems to overestimate (underestimate) anthropogenic (biomass burning) emissions and a negative global mean bias of 1% (16%) of the model relative to the satellite observations was found for C$_2$H$_2$ (HCN).

1 Introduction

Hydrogen cyanide (HCN) and acetylene (or ethyne, C$_2$H$_2$) are ubiquitous atmospheric trace gases with medium lifetime, which are frequently used as indicators of combustion sources and as tracers for atmospheric transport and chemistry. For HCN, biomass burning is the primary source, followed by fossil fuel combustion and higher plants, bacteria and fungi (Cicerone and Zellner, 1983; Li et al., 2000), and its primary sink is thought to be ocean uptake (Li et al., 2000). For C$_2$H$_2$, biofuel combustion is considered as the dominant source, followed by fossil fuel combustion and biomass burning
Reaction with hydroxyl radical (OH) is the main sink for $\text{C}_2\text{H}_2$, which may also act as a precursor of secondary organic aerosols (Volkamer et al., 2009).

With a tropospheric lifetime of 2–4 weeks for $\text{C}_2\text{H}_2$ (Logan et al., 1981) and 5–6 months for HCN (Li et al., 2000; Singh et al., 2003), these two species are interesting tracers for studying atmospheric transport. The study of the ratio $\text{C}_2\text{H}_2$/CO (carbon monoxide) can also help to estimate the age of emitted plumes (Xiao et al., 2007).

Long-term local measurements of HCN and $\text{C}_2\text{H}_2$ are sparse and mainly performed from ground-based Fourier transform infrared (FTIR) spectrometer at selected stations of the Network for the Detection of Atmospheric Composition Change (NDACC, http://www.ndacc.org) (Vigouroux et al., 2012, and references therein). Global distributions of HCN and $\text{C}_2\text{H}_2$ may thus help to reduce the uncertainties remaining with regard to the magnitude of their sources and sinks, as well as to their spatial distribution and seasonality in the atmosphere (Li et al., 2009; Parker et al., 2011).

Satellite sounders have provided considerable new information in the past years, with measurements from the Atmospheric Chemistry Experiment (ACE-FTS) (Lupu et al., 2009; Gonzalez Abad et al., 2011), the Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) (Parker et al., 2011; Wiegele et al., 2012; Glatthor et al., 2015) and the Microwave Limb Sounder (MLS) (Pumphrey et al., 2011). These measurements were all made in limb geometry and consequently mostly in the upper troposphere or higher; also the spatial sampling from these instruments is limited, making it less well-suited when studying dynamical events on short time-scales.

Having a twice daily global coverage and a 12 km diameter footprint at nadir, the IASI infrared sounder (Clerbaux et al., 2009) aboard the MetOp-A satellite has the potential for providing measurements for these two species globally, and with higher spatial resolution and temporal sampling than what has been obtained up to now.

Previous studies have demonstrated that HCN and $\text{C}_2\text{H}_2$ can be observed with the IASI infrared nadir-looking hyperspectral sounder, e.g. in a specific biomass burning plume (Clarisse et al., 2011a), as well as in an anthropogenic pollution plume uplifted in the free troposphere (Clarisse et al., 2011b). More recently, Duflot et al. (2013) have
shown that HCN and C$_2$H$_2$ columns can be routinely retrieved from IASI spectra, even in absence of exceptional columns or uplift mechanisms, when CO$_2$ line mixing is accounted for in the inversion scheme. These previous works were based on an optimal estimation method (OEM) developed and formalized by Rodgers (2000).

In this paper, we first present a fast scheme for the global detection and quantification of HCN and C$_2$H$_2$ total columns from IASI spectra. We describe 2008–2010 time series and analyze the seasonality of the columns of these two species above four NDACC sites in comparison with ground-based FTIR measurements. We finally present the global distributions for the years 2008 to 2010 that we compare with model outputs for these two species.

2 Instrument and method

2.1 IASI

IASI is on board the MetOp-A platform launched in a Sun-synchronous orbit around the Earth at the end of 2006. The overpass times are 09:30 and 21:30 mean LT. Combining the satellite track with a swath of 2200 km, IASI provides global coverage of the Earth twice a day with a footprint of 12 km at nadir. IASI is a Fourier transform spectrometer that measures the thermal infrared radiation emitted by the Earth’s surface and atmosphere in the 645–2760 cm$^{-1}$ spectral range with a spectral resolution of 0.5 cm$^{-1}$ apodized and a radiometric noise below 0.2 K between 645 and 950 cm$^{-1}$ at 280 K (Clerbaux et al., 2009). The IASI spectra used in this study are calibrated radiance spectra provided by EUMETCast near-real-time service.

2.2 Retrieval strategy

Up to now, 24 trace gases have been detected from IASI radiance spectra, including HCN and C$_2$H$_2$ (see Clarisse et al., 2011a, for the list of detected species), with an OEM (Rodgers, 2000) implemented in a line by line radiative transfer model called
Atmosphit (Coheur et al., 2005). In the cases of HCN and C₂H₂, the accuracy of the retrievals has been recently improved by taking into consideration the CO₂ line mixing in the radiative transfer model (Duflot et al., 2013). This retrieval method, relying on spectral fitting, needs a high computational power and is time consuming, especially when a large number of spectra has to be analyzed and fitted. This is therefore not suitable for providing global scale concentrations distributions of these trace gases in a reasonable time.

One of the commonly used methods for the fast detection of trace gases is the brightness temperature difference (BTD) between a small number of channels, some being sensitive to the target species, some being not. Such a method has been used from IASI spectra for sulfur dioxide (SO₂) (Clarisse et al., 2008) and ammonia (NH₃) (Clarisse et al., 2009). It is of particular interest in operational applications (quick alerts) or when large amounts of data need to be processed. However, relying on a cautious selection of channels to avoid the contamination with other trace gases, the BTD method does not fully exploit all the information contained in hyperspectral measurements. Especially, low concentrations of the target species may not be detected with such a method.

Walker et al. (2011) presented a fast and reliable method for the detection of atmospheric trace gases that fully exploits the spectral range and spectral resolution of hyperspectral instruments in a single retrieval step. They used it to retrieve SO₂ total column from a volcanic plume and NH₃ total column above India. More recently, Van Damme et al. (2014) presented a retrieval scheme to retrieve NH₃ from IASI spectra based on the work of Walker et al. (2011), and introduced a metric called Hyperspectral Range Index (HRI). We use in the present study a similar approach.

### 2.2.1 Hyperspectral Range Index (HRI)

The method used in this study is a non-iterative pseudo retrieval method of a single physical variable or target species $x$ expressed as, following the formalism developed...
by Rodgers (2000):
\[ \hat{x} = x_0 + (K^T S^{-1} \epsilon^{\text{tot}} K)^{-1} K^T S^{-1} \epsilon^{\text{tot}} (y - F(x_0)) \] (1)

where \( y \) is the spectral measurements, \( x_0 \) is the linearization point, \( F \) is the forward model (FM), \( S^{\text{tot}} \) is the covariance of the total error (random + systematic), and the Jacobian \( K \) is the derivative of the FM to the target species in a fixed atmosphere.

\( S^{\text{tot}} \) can be estimated considering an appropriate ensemble of \( N \) measured spectra which can be used to build up the total measurement error covariance \( S^{\text{obs}}_y \):

\[ S^{\text{tot}} \approx \frac{1}{N-1} \sum_{j=1}^{N} (y_j - \bar{y})(y_j - \bar{y})^T = S^{\text{obs}}_y \] (2)

where \( \bar{y} \) is the calculated mean spectrum for the ensemble.

To generate \( S^{\text{obs}}_y \), we randomly chose 1 million spectra observed by IASI all over the world, above both land and sea, during the year 2009. Then, we applied a BTD test to remove the spectra contaminated by the target species. For HCN (\( C_2H_2 \)), the wavenumbers 716.5 and 732 cm\(^{-1} \) (712.25 and 737.75 cm\(^{-1} \)) were used as reference channels and 712.5 cm\(^{-1} \) (730 cm\(^{-1} \)) was used as test channel (Fig. 1, middle panel). Given the medium lifetimes of the target species (few weeks for \( C_2H_2 \) to few months for HCN), and the limited accuracy of the BTD test due to the weak spectral signatures of the target species, it is likely that such randomly chosen and filtered spectra still contain a small amount of the target species whose signal may come out from the noise. This limitation decreases the sensitivity of the method, which is discussed in Sect. 2.2.3.

The spectral ranges considered to compute the \( S^{\text{obs}}_y \) matrices are 645–800 cm\(^{-1} \) for HCN and 645–845 cm\(^{-1} \) for \( C_2H_2 \) (Fig. 1, top panel). These ranges were chosen as they include parts of the spectrum which have a relatively strong signal from the target species but also from the main interfering species (\( CO_2, H_2O \) and \( O_3 \), Fig. 1, bottom panel) in order to maximize the contrast with the spectral background.
Having calculated $S_{obs}^y$ and $\bar{y}$, the HRI of a measured spectrum $y$ can be defined as:

$$\text{HRI} = G(y - \bar{y})$$

(3)

with $G$ the measurement contribution function

$$G = (K^T S_{obs}^y K^{-1} K^T S_{obs}^y)^{-1}$$

(4)

The HRI is a dimensionless scalar similar, other than units, to the apparent column retrieved in Walker et al. (2011). Unlike the optimal estimation method, no information about the vertical sensitivity can be extracted. Note also that the use of a fixed Jacobian to calculate HRI does not allow generating meaningful averaging kernels.

### 2.2.2 Conversion of HRI into total columns

Having calculated the matrices $G$ for HCN and $C_2H_2$, each observed spectrum can be associated through Eq. (3) with a value of HRI for HCN ($\text{HRI}_{\text{HCN}}$) and $C_2H_2$ ($\text{HRI}_{C_2H_2}$). These HRIs are only metrics for determining whether levels of the gas are enhanced with respect to the climatological background over the vertical levels where the instrument is sensitive. For a given atmosphere atm, the main challenge is then to link the HRI to a column amount of the target molecule, i.e. to find $B_{\text{HCN atm}}$ and $B_{C_2H_2 \text{atm}}$ such as:

$$[X] = B_{X \text{ atm}} \text{HRI}_X$$

(5)

$[X]$ being the species abundance in molec cm$^{-2}$.

To determine these coefficients linking the HRIs to total column amounts, HCN and $C_2H_2$ profiles have been constructed, with enhanced concentrations of the species located in a 1 km thick layer, whose altitude is varied from the ground up to 30 km for HCN and up to 20 km for $C_2H_2$ (the choice of these maximum altitudes are made with respect to the Jacobians of the FM that are shown in Fig. 3 and commented
in Sect. 2.2.3). Each of the constructed profile has been associated with a spectrum through the FM of Atmosphit considering standard absorption profiles. The associated values of HRI_{HCN} and HRI_{C_{2}H_{2}} have then been computed for each of the simulated spectra. Figure 2 shows the look up tables (LUTs) of HRI_{HCN} (top) and HRI_{C_{2}H_{2}} (bottom) as a function of the abundance of the target molecule and of the altitude of the polluted layer in a standard tropical modeled atmosphere (Anderson et al., 1986). Similar LUTs have been computed for standard temperate (US standard atmosphere) and polar (Anderson et al., 1986) atmospheres (data not shown). The satellite viewing angles were taken into account in the HRI calculation similarly to Van Damme et al. (2014).

One can see that, for a given atmosphere and for a given altitude of the polluted layer, the abundances of both species linearly depend on the HRI value, which validates Eq. (5). For a given atmosphere atm and a given species X, the different values of B with respect to the altitude z of the polluted layer will be noted b_{X_{atm}}(z) and b_{X_{atm}}(z) in the following.

Figure 3 shows the normalised Jacobians of the FM for HCN and C_{2}H_{2} averaged over the spectral ranges given in Sect. 2.2.1 (645–800 cm\(^{-1}\) for HCN and 645–845 cm\(^{-1}\) for C_{2}H_{2}) and for each of the three standard modeled atmospheres. These Jacobians express the sensitivity of the FM, i.e. both the radiative transfer model and IASI (through its instrumental function), to the target species abundance X in a fixed atmosphere atm:

\[
K_{X_{atm}} = \left[ \frac{\partial F_{atm}}{\partial X}(z_1) \ldots \frac{\partial F_{atm}}{\partial X}(z_n) \right] = \left[ k_{X_{atm}}(z_1) \ldots k_{X_{atm}}(z_n) \right]
\]

We then obtain the coefficients B_{X_{atm}} by multiplying the b_{X_{atm}}(z) by the value of the Jacobian at the altitude z:

\[
B_{X_{atm}} = \sum_{i=1}^{n} \left( b_{X_{atm}}(z_i) \times k_{X_{atm}}(z_i) \right) \quad \text{with} \quad \sum_{i=1}^{n} k_{X_{atm}}(z_i) = 1
\]
Applying this method to the three standard modeled atmospheres (tropical, temperate and polar), we get a \( B_X \) value for each, which we have associated with the corresponding range of latitude ([±20°], [±45° : ±60°], [±75° : ±90°], respectively), and linearly interpolated between. Figure 4 gives the resulting values of \( B_{\text{HCN}} \) (blue) and \( B_{\text{C}_2\text{H}_2} \) (green) in function of the latitude.

### 2.2.3 Sensitivity and stability of the method

The sensitivity of the method can be assessed from the Jacobians presented in Fig. 3. For HCN, one can see that there is no sensitivity at the surface and above \( \sim 30 \) km, and the altitude of the sensitivity peak is located close to the tropopause at \( \sim 9, \sim 11 \) and \( \sim 14 \) km for the polar, temperate and tropical atmospheres, respectively. For \( \text{C}_2\text{H}_2 \), there is no sensitivity above \( \sim 20 \) km, and the maximum sensitivity is reached at \( \sim 8, \sim 10 \) and \( \sim 11 \) km for the polar, temperate and tropical atmospheres, respectively.

The HRIs presented here above are sensitive to the abundance of the target species – this is what they are made for – and to their vertical distribution. However, the measured column amount may also depend on: (1) the proper suppression of the spectral background, (2) the conditions of thermal contrast with the surface (TC), and (3) the accuracy of the FM to simulate the spectra used to build up the LUTs. The latter was discussed already by Duflot et al. (2013). In order to test the impact of the two first factors (spectral background suppression and TC) on the retrieved column amount, HCN and \( \text{C}_2\text{H}_2 \) profiles have been constructed with varying TC and concentrations of the interfering and target species. The TC is defined here as the difference between the skin (surface) temperature and that of the air at an altitude of \( 1.5 \) km. These variations in interfering species abundances and TC were considered to be independent and were taken within the range \( \pm 2 \% \) for \( \text{CO}_2 \) and \( \pm 20 \% \) for \( \text{H}_2\text{O} \) and \( \text{O}_3 \), and in the range \( \pm 10 \) K for the TC. For a fixed column amount of the target species, the HRIs were compared one by one to a HRI corresponding to a standard spectrum (i.e. with background concentrations of the interfering species and a TC equal to zero) and if the
difference between the two HRIs was lower than 10\%, then this fixed abundance of the target species was tagged as detectable independently from the listed parameters.

The TC was found to be the major source of HRI variation for both target species, and a serious cause of limitation only for HCN. Figure 5 shows the variation of HRI_{HCN} caused by a TC equal to \pm 10\,K. One can see that HCN column amount can be detected with a variation due to the TC below 10\% when its abundance is higher than $0.28, 1.2$ and $1.6 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$ for the tropical, temperate and polar atmospheres, respectively. This gives the stability thresholds above which HCN column amount can be measured with a 10\% confidence in the independence of the retrieval method to the atmospheric parameters. Consequently, as the stability thresholds of the method for HCN in temperate and polar atmospheres are too high ($1.2$ and $1.6 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$, respectively) to allow the detection of HCN background abundances as compared to usual background column of typically $0.35 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$ (Vigouroux et al., 2012; Duflot et al., 2013), IASI HCN measurements have to be rejected in these two types of atmosphere, and considered in the tropical belt for values above $0.28 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$. In order to broaden the exploitable latitude range, we take into account the IASI HCN measurements at subtropical latitudes with the same stability threshold ($0.28 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$), assuming a 30\% confidence in the independence of the retrieval method to the atmospheric parameters – which is quite a prudent assumption. As a result, in the following, IASI HCN measurements is considered in the $\pm 35^\circ$ latitude band with a stability threshold of $0.28 \times 10^{16}\,\text{molec}\,\text{cm}^{-2}$, and confidence in the stability of the method is 10\% at tropical latitudes ($[\pm 20^\circ]$) and 30\% at subtropical latitudes ($[\pm 35^\circ : \pm 20^\circ]$). Oppositely to HCN, for C$_2$H$_2$, the variation of HRI$_{C_2H_2}$ due to varying TC was found to be lower than 5\% for every C$_2$H$_2$ abundances (data not shown). Consequently, in the following no IASI C$_2$H$_2$ measurements is rejected.
3 Results

The goal of this section is to describe and evaluate the $\text{C}_2\text{H}_2$ and HCN total columns as measured by IASI. We first compare HCN and $\text{C}_2\text{H}_2$ total columns retrieved from IASI spectra and from ground-based FTIR spectra. We then depict the $\text{C}_2\text{H}_2$ and HCN total columns at global and regional scales. IASI global and regional distributions are finally compared with output from the Model for Ozone and Related Chemical Tracers, version 4 (MOZART-4) in order to evaluate the agreement between the model and the IASI distributions.

3.1 Comparison with ground-based observations

We compare in this section HCN and $\text{C}_2\text{H}_2$ total columns retrieved from IASI spectra and from ground-based FTIR spectra for the years 2008–2010 for four selected ground-based FTIR observation sites: Wollongong (34° S; 151° E; 30 m a.m.s.l.), Reunion Island (21° S; 55° E; 50 m a.m.s.l.), Izaña (28° N; 16° W; 2367 m a.m.s.l.) and Jungfraujoch (46° N; 8° E; 3580 m a.m.s.l.) (Fig. 6). IASI cloudy spectra were removed from the data set using a 10 % contamination threshold on the cloud fraction in the pixel. As exposed in Sect. 2.2.3, errors in retrieved species abundances from IASI spectra due to variations in atmospheric parameters are 10 % at tropical latitudes ($\pm 20^\circ$) and 30 % at subtropical latitudes ($\pm 35^\circ : \pm 20^\circ$) for HCN and 5 % for $\text{C}_2\text{H}_2$, and comparison with ground-based HCN measurements are only performed for tropical and subtropical sites (Reunion Island, Wollongong and Izaña).

Total errors for ground-based measurements at Reunion Island are 17 % for both species, total error for HCN ground-based measurements at Wollongong is 15 %, total error for HCN ground-based measurements at Izaña is 10 %, and total error for $\text{C}_2\text{H}_2$ ground-based measurements at Jungfraujoch is 7 %. Detailed description of ground-based FTIR data set, retrieval method and error budget can be found in Vigouroux et al. (2012) for Reunion Island and in Mahieu et al. (2008) for Jungfraujoch. However, at Reunion Island, the retrieval strategies have been slightly improved from Vigouroux
et al. (2012), mainly concerning the treatment of the interfering species, but the same spectral signatures are used. Izaña data set and error budget were obtained from the NDACC database (ftp://ftp.cpc.ncep.noaa.gov/ndacc/station/izana/). Wollongong data set and error budget were calculated by N. Jones from the University of Wollongong (N. Jones, personal communication, 2015).

Figure 7 shows the mean total column averaging kernels for the ground-based FTIR at each of the four sites. Similarly to IASI (Fig. 3), information content from ground-based instruments measurements is mostly in the middle-high troposphere for both species. The main difference can be observed for tropical C$_2$H$_2$: while IASI Jacobian peaks at 10 km for C$_2$H$_2$ in a tropical atmosphere, ground-based FTIR averaging kernel peaks at 15 km for C$_2$H$_2$ at Reunion Island.

Figure 8 shows the comparison between the IASI and the ground-based measurements. IASI retrieved total columns were averaged on a daily basis and on a $1^\circ \times 1^\circ$ area around the observation sites. HCN retrieved abundances below $2.8 \times 10^{15}$ molec cm$^{-2}$ have been removed from both ground-based and space measurements to allow comparison of both datasets (cf. Sect. 2.2.3). One can see that there is an overall agreement between the IASI and the ground-based FTIR measurements considering the error bars. An important result from this study is that IASI seems to capture the seasonality in the two species in most of the cases. This is best seen by looking at the IASI monthly mean retrieved total columns (black circles and lines in Fig. 8). The scatter of the IASI daily mean measurements (red dots) are due to the averaging on a $1^\circ \times 1^\circ$ area around the observation sites.

At Reunion Island HCN and C$_2$H$_2$ peak in October-November and are related to the Southern Hemisphere biomass burning season (Vigouroux et al., 2012). We find maxima of around $12 \times 10^{15}$ molec cm$^{-2}$ for HCN and $10 \times 10^{15}$ molec cm$^{-2}$ for C$_2$H$_2$. The seasonality and interannual variability matches very well that of the ground-based FTIR measurements for HCN (correlation coefficient of 0.81 for the entire daily mean dataset, and of 0.98 for the monthly mean data set) but with the IASI columns being biased high by $0.79 \times 10^{15}$ molec cm$^{-2}$ (17%). For C$_2$H$_2$ at Reunion Island, the sea-
seasonality and interannual variability matches reasonably well that of the ground-based measurements (correlation coefficient of 0.40 for the entire daily mean dataset, and of 0.72 for the monthly mean data set) but with the IASI columns being biased high by $1.10 \times 10^{15} \text{molec cm}^{-2}$ (107%). Such a high bias between the two datasets could be due to the difference between space and ground-based instruments sensitivity (Figs. 3 and 7). One can also notice that the C$_2$H$_2$ and HCN peaks are higher in 2010. As South American biomass burning plumes are known to impact trace gases abundance above Reunion Island (Edwards et al., 2006a, b; Duflot et al., 2010), these 2010 higher peaks are probably due to the 2010 great Amazonian fires (Lewis et al., 2011) influence.

At Wollongong HCN peaks also in October–November due to the Southern Hemisphere biomass burning season (Paton-Walsh et al., 2010). We find maxima of around $11 \times 10^{15} \text{molec cm}^{-2}$ in October 2010, which is, similarly to Reunion Island, very likely to be a signature of the great Amazonian fires as South American biomass burning plumes are known to impact trace gases abundance above Australia (Edwards et al., 2006a, b). The seasonality and interannual variability matches well that of the ground-based FTIR measurements (correlation coefficient of 0.55 for the entire daily mean dataset, and of 0.83 for the monthly mean data set), with the IASI columns being biased low by $0.48 \times 10^{15} \text{molec cm}^{-2}$ (10%).

At Izaña HCN peaks in May-July due to the biomass burning activity occurring in Northern America and Europe (Sancho et al., 1992). We find maxima of around $8 \times 10^{15} \text{molec cm}^{-2}$. The seasonality and interannual variability matches poorly that of the ground-based FTIR measurements for HCN (correlation coefficient of 0.28 for the entire daily mean dataset, and of 0.64 for the monthly mean data set), with the IASI columns being biased high by $0.45 \times 10^{15} \text{molec cm}^{-2}$ (11%). One can notice that HCN total columns as measured by ground-based FTIR are below the HCN stability threshold in boreal winter, which may result in erroneous IASI measurements (because unstable) and explain this poor match between the two datasets.

For C$_2$H$_2$ at the Jungfraujoch site, the agreement between IASI and the ground-based retrieved columns is good (correlation coefficient of 0.70 for the entire daily mean
dataset, and of 0.85 for the monthly mean data set), with the IASI columns being biased low by $0.15 \times 10^{15}$ mole $\text{cm}^{-2}$ (12%), opposite to the observations at Reunion. The larger columns observed in late winter are caused by the increased $C_2H_2$ lifetime in that season (caused by the seasonal change in OH abundance) (Zander et al., 1991), and we find corresponding maxima of up to $4 \times 10^{15}$ mole $\text{cm}^{-2}$.

### 3.2 IASI Global distributions

We focus in this section on the description of the $C_2H_2$ and HCN distributions retrieved from IASI spectra. For practical reasons, the figures used in this section also show simulated distributions that will be analyzed afterwards.

The left panels of Figs. 9 and 10 provide the seasonal global and subtropical distributions of $C_2H_2$ and HCN total columns, respectively, as measured by IASI and averaged over the years 2008 to 2010.

Looking at IASI measurements (Figs. 9 and 10 – left panels), one can notice the following main persisting features for both $C_2H_2$ and HCN:

- the hot spots mainly due to the biomass burning activity occurring in Africa and moving southward along the year (Sauvage et al., 2005; van der Werf et al., 2006);

- the hot spot located in South East Asia being likely a combination of biomass burning and anthropogenic activities;

- the transatlantic transport pathway linking the African west coast to the South American east coast and moving southward along the year (Edwards et al., 2003, 2006a, b; Glatthor et al., 2015).

The following seasonal features can also be observed:

- the transpacific transport pathway linking Eastern Asia to Western North America, especially in March-April-May (MAM) (Yienger et al., 2000);
– the transport pathway from Southern Africa to Australia in June-July-August (JJA) and September-October-November (SON) (Annegarn et al., 2002; Edwards et al., 2006a, b);

– the transport pathway linking South America (especially Amazonia) to Southern Africa and Australia during the SON period (Edwards et al., 2006a, b; Glatthor et al., 2015);

– the transport of the northern African plume over southern Asia to as far as the eastern Pacific by the northern subtropical jet during the MAM period (Glatthor et al., 2015);

– the Asian monsoon anticyclone (AMA), which is the dominant circulation feature in the Indian-Asian upper troposphere-lower stratosphere (UTLS) region during the Asian summer monsoon, spanning South East Asia to the Middle East and flanked by the equatorial and sub-tropical jets (Hoskins and Rodwell, 1995). The AMA is a known region of persistent enhanced pollution in the upper troposphere, linked to rapid vertical transport of surface air from Asia, India, and Indonesia in deep convection, and confinement by the strong anticyclonic circulation (Randel et al., 2010). The enhanced abundance of C$_2$H$_2$ and HCN within the AMA in JJA observed by IASI is in accordance with previous studies (Park et al., 2008; Randel et al., 2010; Parker et al., 2011; Glatthor et al., 2015); however, one should keep in mind that this enhanced abundance measured by IASI is likely due to the combination of this pollution uplift and confinement with the higher sensitivity of the method in the upper troposphere (Fig. 2).

One can also notice the very good agreement between the seasonal HCN distributions shown in our Fig. 10 and the ones published recently in Glatthor et al. (2015, Fig. 3).

Figures 11 and 12 show the C$_2$H$_2$ and HCN total columns time series, respectively, as measured by IASI (red dots) with the associated SD (light red lines) for each of the zones defined in Fig. 6.
In Northern America, Europe and Boreal Central Asia (Fig. 11 – Zones NAM, EUR and BCA), C$_2$H$_2$ peaks in late boreal winter due to the increased C$_2$H$_2$ lifetime as already noticed over Jungfraujoch (Fig. 8). The boreal summer 2008 California wildfires event (Gyawali et al., 2009) is clearly visible in the NAM plot, as well as the August 2009 Russian wildfires in the NAM, EUR and BCA plots (Parrington et al., 2012; R’honi et al., 2013).

In North Central America (Fig. 12 – Zone NCA), the annual HCN peak in April-June is driven by local fire activity (van der Werf et al., 2010).

In South America, Southern Africa and Australia (Figs. 11 and 12 – Zones SAM, SAF and AUS), the Southern Hemisphere biomass burning season clearly drives the C$_2$H$_2$ and HCN peaks in September–November each year. The signature of the great 2010 Amazonian fires (Lewis et al., 2011) is visible on each of the these three Zones, South American fire plumes being known to impact Southern Africa and Australia (Edwards et al., 2003, 2006a, b). The February 2009 Australian bush fires (Glatthor et al., 2013) are also noticeable on Zone AUS for both species.

In Northern Africa (Figs. 11 and 12 – Zone NAF), C$_2$H$_2$ and HCN peak in boreal winter because of the biomass burning activity occurring in the Zone, and peak also in boreal summer because of the European and South Mediterranean fires (Van der Werf et al., 2010).

In South East Asia (Figs. 11 and 12 – Zone SEA), the observed C$_2$H$_2$ and HCN peaks in July–September and January–March are due to local fire activity (Fortems-Cheiney et al., 2011; Magi et al., 2012). Additionally, the July–September peaks are also likely due to the combination of the pollution uplift and confinement within the AMA with the higher sensitivity of the method in the upper troposphere.

In Equatorial Asia (Figs. 11 and 12 – Zone EQA), local fire activity is visible in July–October, as well as the South East Asian fire activity in January–March (Fortems-Cheiney et al., 2011; Magi et al., 2012). The high biomass burning activity occurring in Indonesia from July to December 2009 (Yulianti et al., 2013; Hyer et al., 2013) is also clearly noticeable.
C$_2$H$_2$ and HCN sharing important common sources (cf. Introduction), the same annual and seasonal features are observed for both species. However, biomass burning being the major source for HCN (while it is biofuel and fossil fuel combustions for C$_2$H$_2$), one can notice the especially high increase in HCN abundance (up to $13 \times 10^{15}$ molec cm$^{-2}$) in the Southern Hemisphere during the austral biomass burning season (September to November). These observations are in accordance with previous studies (Lupu et al., 2009; Glatthor et al., 2009; Wiegele et al., 2012).

3.3 Comparison with model

In order to further evaluate the HCN and C$_2$H$_2$ distributions retrieved from IASI spectra, they are compared in this section to the output of MOZART-4 for the years 2008–2010. We first describe the simulation set up before comparing simulated and observed distributions.

3.3.1 MOZART-4 simulation set up

The model simulations presented here are performed with the MOZART-4 global 3-D chemical transport model (Emmons et al., 2010a), which is driven by assimilated meteorological fields from the NASA Global Modeling and Assimilation Office (GMAO) Goddard Earth Observing System (GEOS). MOZART-4 was run with a horizontal resolution of 1.875° latitude × 2.5° longitude, with 56 levels in the vertical and with its standard chemical mechanism (see Emmons et al., 2010a, for details). The model simulations have been initialized by simulations starting in July 2007 to avoid contamination by the spin-up in the model results. MOZART-4 simulations of numerous species (CO, O$_3$ and related tracers including C$_2$H$_2$) have been previously compared to in situ and satellite observations and used to track the intercontinental transport of pollution (e.g., Emmons et al., 2010b; Pfister et al., 2006, 2008, 2011; Tilmes et al., 2011; Clarisse et al., 2011b; Wespes et al., 2012).
The emissions used in this paper include surface anthropogenic sources (including fossil fuel and biofuel) from D. Streets – ARCTAS inventory (see http://bio.cgrer.uiowa.edu/arctas/emission.html for more information), developed in the frame of the POLAR-CAT Model Intercomparison Program (POLMIP) as a composite dataset of global emissions as representative of current emissions as possible, and fire emissions from global Fire INventory from NCAR (FINN) version 1 (Wiedinmyer et al., 2010). The anthropogenic emissions, which are taken from the 2006 inventory of Zhang et al. (2009), are constant in time with no monthly variation. The VOC speciation is based on the RETRO emissions inventory, as in Lamarque et al. (2005). The fire emissions for individual fires, based on daily MODIS fire counts, were calculated and then gridded to the simulation resolution (Wiedinmyer et al., 2006, 2010). The oceanic emissions are taken from the MACCity emissions dataset and the biogenic emissions from MEGAN-v2 dataset inventory (Guenther et al., 2006).

Model emissions for HCN and C$_2$H$_2$ used in this study are summarized in Table 1 and presented in Fig. 13. The majority of the emissions for both C$_2$H$_2$ and HCN are from anthropogenic source (about 80 and 55% of the global source of C$_2$H$_2$ and HCN, respectively; see Table 1). Averaged over the period 2008–2010, the highest HCN and C$_2$H$_2$ anthropogenic surface emissions are observed over China, with elevated emissions over India, Europe and USA, due to intense industrialization, where values larger than $4 \times 10^{-12}$ kg(C$_2$H$_2$) m$^{-2}$ s$^{-1}$ are entered in the model. The most intense HCN and C$_2$H$_2$ emissions due to biomass burning are observed over South East Asia, equatorial and southern Africa, South America, Siberia and Canada.

### 3.3.2 IASI vs. model global distributions

Figures 9 and 10 provide the seasonal global and subtropical distributions of C$_2$H$_2$ and HCN total columns, respectively, as measured by IASI and as simulated by MOZART-4 averaged over the years 2008 to 2010. Comparison between model simulations and instrumental observations are usually done by applying the averaging kernels of the retrieval method on the modeled profiles. As our retrieval scheme does not provide such
information, we rather applied on each of the MOZART-4 simulated profiles the Jaco-
bians of the used forward model (cf. Sect. 2.2.3 and Fig. 3) to take into account the sen-
sitivity of both the radiative transfer model and IASI. Note that here again HCN abun-
dances below \(2.8 \times 10^{15}\) molec cm\(^{-2}\) have been removed from both space measure-
ments and simulated columns to allow comparison of both datasets (cf. Sect. 2.2.3).

MOZART-4 simulations can be evaluated by looking at Figs. 9 and 11 for \(\text{C}_2\text{H}_2\), and
Figs. 10 and 12 for HCN. Figures 11 and 12 show the simulated \(\text{C}_2\text{H}_2\) and HCN total
columns time series, respectively, for each of the zones defined in Fig. 6 superimposed
to IASI observations. Table 2 summarizes the biases and correlation coefficients re-
sulting from the comparison between model and observations. Looking at these Table
and Figures, the following conclusions can be drawn:

- seasonal cycles observed from satellite data are reasonably well reproduced by
  the model;

- the African, South American, Asian and Indonesian hot spots are clearly visible
  in the model;

- exceptional events that are captured by IASI (cf. Sect. 3.2) are not simulated by
  MOZART-4;

- the model is more negatively biased in the Southern Hemisphere (Bias = −61 %
  for \(\text{C}_2\text{H}_2\) and Bias = −25 % for HCN) than in the Northern Hemisphere (Bias =
  40 % for \(\text{C}_2\text{H}_2\) and Bias = −3 % for HCN), suggesting that anthropogenic (biomass
  burning) emissions are likely overestimated (underestimated) in the model;

- the model reasonably reproduces the main transport pathways identified on IASI
  observations (cf. Sect. 3.2). However, the low background concentrations in the
  Southern Hemisphere as simulated by the model, especially for Southern Africa
  and Australia (Figs. 11 and 12 – Zones SAF and AUS), suggest that the model
  transportation scheme and/or the modeled species’ lifetime still can be improved
to simulate the impact of their long range transport.
In Table 2, for C$_2$H$_2$, the correlation coefficients are good ($\geq 0.6$) to very good ($\geq 0.9$) except for the zones SAM (South America), SEA (South East Asia) and EQA (Equatorial Asia). For HCN, the correlation coefficients are good ($\geq 0.6$) except for the zones NCA (North Central America), NAF (Northern Africa), SEA and EQA.

For South America (Zone SAM), correlation coefficient is not as good for C$_2$H$_2$ ($R = 0.54$) due to a backward shift of the species abundance peaks in years 2008 and 2009: in the model, this increase occurs from July to October while observations (and previous studies, e.g. van der Werf et al., 2010) show an increase from August to December. This backward shift is also visible for HCN (Fig. 12), but to a lesser extent.

For South East Asia and Equatorial Asia (Zones SEA and EQA), the low correlation coefficients (cf. Table 2) can be attributed to the difficulty of locating precisely with the model the intercontinental convergence zone (ITCZ) which drives the long-range transport of C$_2$H$_2$ and HCN-loaded plumes into the zone. Additionally, for Equatorial Asia, the too low fire emissions considered in the model for Indonesia from July to December 2009 may also be a cause for these low correlation coefficients.

For HCN in northern Africa (Zone NAF), correlation coefficient is very low ($R = 0.07$) because the model sets the abundance peaks around August while observations show peaks occurring around December, which is in accordance with previous studies (van der Werf et al., 2010). This inadequate timing for HCN in the model simulations could be due to an overestimation of the Southern African contribution to the Northern African loading and is visible on Fig. 10 (JJA).

4 Conclusions

We have presented a fast method to retrieve HCN and C$_2$H$_2$ total columns from IASI spectra. The sensitivity of this method to the two species is mostly in the mid-upper troposphere. With this method, C$_2$H$_2$ total columns can be retrieved globally with 5 % precision, while HCN abundances can be retrieved for abundances greater than
0.28 \times 10^{16} \text{molec cm}^{-2} \text{ with 10\% precision in the } \pm 20^\circ \text{ latitudinal band and with 30\% precision in the } [\pm 35^\circ : \pm 20^\circ] \text{ latitudinal band.}

Total columns have been retrieved globally for a three year period and compared to routine FTIR measurements available at Reunion Island (HCN and C$_2$H$_2$), Wollongong (HCN), Jungfraujoch (C$_2$H$_2$), and Izaña (HCN). The comparison between IASI and FTIR retrieved total columns demonstrates the capabilities of IASI to capture the seasonality in HCN and C$_2$H$_2$ in most cases.

Global seasonal distributions, as well as regional time series of the total columns, have been shown for the two species. IASI is able to capture persisting, seasonal and exceptional features for both species, and the observed patterns are in a general good agreement with previous spaceborne studies (ACE-FTS and MIPAS).

The comparison between these observations and MOZART-4 simulations leads to the following conclusions: (i) the model is able to capture most of the hot spots and seasonal cycles, but not the exceptional events, (ii) the model seems to overestimate (underestimate) anthropogenic (biomass burning) emissions for both species, (iii) the model dynamical scheme and/or the modeled species lifetime could be improved to simulate the impact of the long range transport for these species.

**Acknowledgements.** IASI has been developed and built under the responsibility of the Centre National d’Etudes Spatiales (CNES, France). It is flown onboard the MetOp satellites as part of the EUMETSAT Polar System. The IASI L1 data are received through the EUMET-Cast near real time data distribution service. Part of the research is supported by EUMETSAT through the O3SAF project. P. F. C. is Senior Research Associate and L.C. is Research Associate at the F.R.S.-FNRS. The research in Belgium was funded by the F.R.S.-FNRS, the Belgian Science Policy Office, and the European Space Agency (ESA Prodex arrangements and the AGACC-II project). The Australian Research Council has provided financial support over the years for the NDACC site at Wollongong, most recently as part of project DP110101948. The Liège team further acknowledges the Fédération Wallonie-Bruxelles for supporting travel costs to the Jungfraujoch station and wishes to thank the International Foundation High Altitude Research Stations Jungfraujoch and Gornergrat (HFSJG, Bern) for supporting the facilities needed to perform the observations. Since 1999, the Izaña FTIR activities have been...
supported by different funding agencies: European Commission, European Research Council, European Space Agency, EUMETSAT, Deutsche Forschungsgemeinschaft, Deutsches Zentrum für Luft- und Raumfahrt, and the Ministerios de Ciencia e Innovación and Educación from Spain. The authors also wish to thank the French regional, national (INSU, CNRS), and international (NASA/GFSC) organizations for supporting the OPAR (Observatoire de Physique de l’Atmosphère de la Réunion) station. The NDACC is also acknowledged for providing consistent and well-documented datasets.

Figure 1. (Top) Simulated spectra in the region of the HCN $\nu_2$ band and C$_2$H$_2$ $\nu_5$ band. The green (brown) double sided arrow gives the spectral range used to compute the $S_c$ matrices for HCN (C$_2$H$_2$). (Middle) Contributions of climatological background levels of HCN and C$_2$H$_2$. (Bottom) Contribution of CO$_2$ (red line), O$_3$ (green line) and H$_2$O (blue line) to a simulated spectrum for background concentrations. Calculations have been made for the US Standard Atmosphere (US Government Printing Office, 1976) with CO$_2$ concentrations scaled to 390 ppmv.
Figure 2. Variations of the HRI with HCN (top) and C$_2$H$_2$ (bottom) column (molec.cm$^{-2}$) integrated over the 1 km-thick polluted layer in a standard modeled subtropical atmosphere from forward model simulations. The colorscale gives the altitude of the polluted layer.
Figure 3. Normalised Jacobians of the forward model implemented in Atmosphit for HCN (solid lines) and $\text{C}_2\text{H}_2$ (dotted lines) and for the standard modeled polar (blue lines), temperate (green lines) and subtropical (red lines) atmospheres. These are averaged Jacobians over the spectral ranges $645–800 \text{ cm}^{-1}$ for HCN and $645–845 \text{ cm}^{-1}$ for $\text{C}_2\text{H}_2$. 
Figure 4. Values of $B_{\text{HCN}}$ (blue) and $B_{\text{C}_2\text{H}_2}$ (green) as a function of the latitude.
Figure 5. Variation of HRI$_{\text{HCN}}$ caused by a TC equal to $\pm 10$ K for the polar (solid line an circles), temperate (dashed line and squares) and tropical (dotted line and crosses) atmospheres.
Figure 6. Locations of the 4 ground-based FTIR measurements sites (Jungfraujoch, Izaña, Reunion Island and Wollongong) and map of the 10 regions used in this study: NAM: Northern America, NCA: North Central America, SAM: South America, EUR: Europe, NAF: Northern Africa, SAF: Southern Africa, BCA: Boreal Central Asia, SEA: South East Asia, EQA: Equatorial Asia, AUS: Australia.
Figure 7. Total column averaging kernels of ground-based FTIR in molec cm$^{-2}$/molec cm$^{-2}$ for C$_2$H$_2$ at Reunion Island (red stars and line), HCN at Reunion Island (black circles and line), HCN at Wollongong (green dots and line), HCN at Izaña (light blue diamonds and line) and C$_2$H$_2$ at Jungfraujoch (blue squares and line).
Figure 8. Time series of HCN (left panel) and C$_2$H$_2$ (right panel) measurements for Reunion Island (HCN and C$_2$H$_2$), Wollongong (HCN only), Izaña (HCN only), and Jungfraujoch (C$_2$H$_2$ only). IASI measurements are shown as daily and 1° × 1° means (red dots) with associated SDs (light red lines), and as monthly and 1° × 1° means (black circles and line) with associated SD (vertical black lines). Ground-based FTIR measurements are shown as daily means with associated total error by green crosses and lines. Correlation coefficients are given on each plot for daily means in red and for monthly means in black.
Figure 9. Seasonal distribution of the C$_2$H$_2$ total column (in molec cm$^{-2}$) as measured by IASI (left panel) and simulated by MOZART-4 (right panel) averaged over the years 2008 to 2010. The IASI global distributions are given with the same horizontal resolution as MOZART-4 (1.875° latitude × 2.5° longitude). DJF = December–January–February, MAM = March–April–May, JJA = June–July–August, SON = September–October–November.
Figure 10. Same as Fig. 9 for HCN.
Figure 11. Evolution with time of the mean C$_2$H$_2$ total column (in molec cm$^{-2}$) over the zones defined in Fig. 6 as measured by IASI (red dots) with associated SD (light red lines), and as simulated by MOZART-4 (black dots). Correlation coefficients ($R$) and biases (Bias) between IASI and MOZART-4 are given on each plot for daily means.
Figure 12. Same as Fig. 11 for HCN.
Figure 13. C$_2$H$_2$ and HCN surface emission fluxes (kg m$^{-2}$ s$^{-1}$) averaged over the period 2008–2010 from the anthropogenic and fire emissions inventories used in MOZART-4.
