Key points

Transpressive deformation at the northern Caribbean plate boundary is imaged

The offshore Enriquillo Plantain Garden Fault Zone has a primary strike-slip motion

A very small compressional component is imaged compared to short-term shortening

28 **Abstract**

29 Transpressive deformation at the northern Caribbean plate boundary is accommodated mostly by two major strike-
30 slip faults, but the amount and location of accommodation of the compressional component of deformation is still debated.
31 We collected marine geophysical data including multi-beam bathymetry and multichannel seismic reflection profiles along
32 this plate boundary around Hispaniola, in the Jamaica Passage and in the Gulf of Gonâve. The data set allows us to image
33 the offshore active strike-slip faults as well as the compressional structures. We confirm that the Enriquillo-Plantain-Garden
34 Fault Zone (EPGFZ) in the Jamaica Passage has a primary strike-slip motion, as indicated by active left-lateral strike-slip-
35 related structures, i.e.: restraining bend, asymmetrical basin, *en echelon* pressures ridges and horsetail splay. Based on
36 topographic cross-sections across the EPGFZ, we image a very limited compressional component, if any, for at least the
37 western part of the Jamaica Passage. Toward the east of the Jamaica Passage, the fault trace becomes more complex and we
38 identify adjacent compressional structures. In the Gulf of Gonâve, distributed folding and thrust faulting of the most recent
39 sediments indicate active pervasive compressional tectonics. Estimates of shortening in the Jamaica Passage and in the Gulf
40 of Gonâve indicate an increase of the compressional component of deformation towards the east, which nonetheless remains
41 very small compared to that inferred from block modelling based on GPS measurements.

45

46 **1- Introduction**

47 A fundamental objective at an obliquely convergent plate boundary is to understand the partitioning of deformation
48 in both the short and long term using offshore and onshore datasets. The relative motion of the Caribbean plate with respect
49 to the North American plate is oblique to the plate boundary, which implies both transpression and partitioning [*Heubeck et*
50 *al.*, 1991; *Mann et al.*, 1991; *Calais and Mercier de Lépinay*, 1995; *Calais et al.*, 1998, 2016; *Mann et al.*, 1998]. The plate
51 motion appears to be partitioned and accommodated in the Hispaniola region along two left-lateral strike-slip structures, the
52 Septentrional-Oriente fault zone (SOFZ) in the north and the Enriquillo-Plantain Garden fault zone (EPGFZ) in the south,
53 and across a fold-and-thrust belt, the Trans-Haitian Belt (Fig. 1). Most of the N070°- trending relative motion between the
54 Caribbean and North America plates, occurring at a rate of ~20 mm/yr, is thought to be accounted for by these two strike-
55 slip fault systems [*Calais et al.*, 2002; *DeMets and Wiggins-Grandison*, 2007; *Manaker et al.*, 2008; *Hayes et al.*, 2010].
56 However, the 2010 Mw 7.0 Haiti earthquake showed that the deformation in southwest Haiti cannot be accounted for solely
57 by the EPGFZ, and appears to involve nearby compressional structures [*Calais et al.*, 2010; *Mercier de Lépinay et al.*, 2011;
58 *Nettles & Hjorleifsdottir*, 2010]. Moreover, for the EPGFZ, block modelling of GPS velocities [*Benford et al.*, 2012]
59 predicts fault-normal convergence of about the same magnitude as fault-parallel strike-slip, suggesting significant
60 transpression across the plate boundary. It remains to identify the structures that account for the present-day transpression
61 onshore and offshore and then evaluate the respective strike-slip and compressional components over time scales longer
62 than those accessible with GPS.

63 The aim of this study is to identify in detail the active structures in the Jamaica Passage and in the Gulf of Gonave
64 and therefore to improve our understanding of how the transpressive plate motion between the Caribbean and North
65 American plates is accommodated offshore. The data collected during the Haiti-SIS cruise (R/V *L'Atalante*, December
66 2012) include full multibeam coverage of the area and seismic reflection profiles crossing the active tectonic structures (Fig.
67 2). Based on these new data, we can precisely map and characterize the geometry of this major strike-slip fault system and
68 its associated features, as well as the compressional structures, in the context of transpressive tectonics.

69

70 **2- Tectonic setting, historical seismicity and kinematics**

71 Numerous reports on seismic activity and the damage caused by historical earthquakes along the north-east
72 Caribbean plate boundary over the past 500 years allow researchers to identify the major historical seismic events and
73 estimate their presumed locations (Fig.1) [*Scherer*, 1912; *Taber*, 1920; *Dolan and Wald*, 1998; *Doser et al.*, 2005; *McCann*,

74 2006]. However, it remains difficult to confirm the location estimates of historical events and, in particular, to determine the
75 causative fault structures. Here, we focus on seismic events on or near the EPGFZ. *Bakun et al.* [2012] estimated the
76 intensity magnitudes and locations of certain historical earthquakes on Hispaniola. They proposed to relate the earthquakes
77 of 1701 (M_1 6.6), 21 November 1751 (M_1 6.6) and 3 June 1770 (M_1 7.5) to the EPGFZ, as well as possibly the M_1 7.4–7.5
78 earthquake of 18 October 1751. By contrast, the M_1 6.3 event of 18 April 1860 might have occurred offshore on a secondary
79 structure (Fig. 1). *Bakun et al.* [2012] further suggested that historical events on or near the EPGFZ might be complicated,
80 involving unknown thrust or normal faults, as revealed by the complexity of the Mw 7.0 earthquake in 2010. This
81 destructive earthquake involved significant slip on one or several blind thrusts adjacent to the EPGFZ [*Calais et al.*, 2010;
82 *Hayes et al.*, 2010; *Mercier de Lépinay et al.*, 2011], with no observed surface rupture [*Prentice et al.*, 2010]. In the case of
83 Jamaica, *Koehler et al.* [2013] claim that the 1692 and 1907 earthquakes were not associated with surface rupture along the
84 main EPGFZ. They concluded that these historical earthquakes might have occurred either on the main EPGFZ without
85 surface rupture, along blind structures associated with the EPGFZ, or along other on-land or offshore faults. Owing to the
86 difficulty of conducting paleoseismic studies in a wet tropical environment, the sources of historical earthquakes remains
87 very uncertain, especially since the regional seismicity and tectonic geomorphology suggest that plate-boundary
88 deformation is partitioned across multiple structures that together accommodate transpressive plate motion in the northern
89 Caribbean.

90 Several geological and geodetic studies have provided estimates of the slip rates along the major structures of the
91 northern Caribbean plate boundary. The strike-slip component is mostly accommodated along the SOFZ in the north and
92 along the EPGFZ in the south (Fig. 1). The Holocene strike-slip rate on the SOFZ has been estimated at 6-12 mm/yr
93 [*Prentice et al.*, 2003]. On the EPGFZ, the poorly constrained Holocene strike-slip rate is about 4 mm/yr in Jamaica [*Burke*
94 *et al.*, 1980] and about 8 mm/yr in Haiti, based on cumulative left-lateral offsets [*Mocquet and Aggarwal*, 1983]. The slip-
95 rates of active faults are also estimated using GPS measurements and block modelling, by assuming geometries and block
96 boundary locations that are compatible as far as possible with the fault network. These models predict slip-rates not only on
97 faults close to the GPS measurement sites but also along the offshore segments of the faults. *Manaker et al.* [2008]
98 estimated a purely strike-slip velocity of 8 +/- 5 mm/yr for the SOFZ and 7 +/- 2 mm/yr for the EPGFZ, while *Calais et al.*
99 [2010] estimated 12 +/- 3 mm/yr and 6 +/- 2 mm/yr respectively. The compressional component of the transpression is
100 mostly accommodated by the North Hispaniola Fault and the Trans-Haitian belt (Fig. 1). Although there are no geological
101 estimates of the shortening rate, several geodetic estimates are available. The north Hispaniola reverse fault accommodates

102 2 to 6 mm/yr, while about 4 mm/yr of shortening is accommodated across the southern half of western Hispaniola in the
103 Trans-Haitian belt [Calais et al., 2010]. A recent block modelling study based on a larger GPS data set [Benford et al., 2012]
104 shows that the movement is currently transpressive on the EPGFZ, with a major compressional component, while mainly
105 purely strike-slip movement occurs on the SOFZ. This model predicts 6.8 mm/yr of left-lateral slip and 5.7 mm/yr of
106 compression onshore along the EPGFZ. Offshore in the Jamaica passage, the same model predicts 5.0 mm/yr of left-lateral
107 slip and 2.7 mm/yr of compression in the west, with 7.3 mm/yr and 3.2 mm/yr, respectively, in the east (Fig. 1). Most
108 authors [Mann et al., 1995; Pubellier et al., 2000; Calais et al., 2010; Benford et al. 2012] favour a diffuse zone of
109 deformation that encompasses the Haiti fold-and-thrust belt onshore and part of the Gulf of Gonâve offshore, covering an
110 area where the compression may be accommodated along oblique thrust faults.

111

112 **3- Data collection and analysis**

113 In December 2012, the cruise HAITI-SIS onboard the R/V *L'Atalante* of IFREMER carried out mapping of the
114 offshore Haitian area including acquisition of high-resolution multibeam bathymetry data and multichannel seismic
115 reflection profiles [Leroy et al., 2015]. In this paper, we focus on the Gulf of Gonâve and the Jamaica Passage where we
116 obtain a total of 190 seismic profiles. The seismic reflection shot records were collected using a source comprising two GI
117 air guns (2.46 L, 150 in³) and with a streamer with 24 traces (600 m long) operated at approximately 9.7 knots (rapid
118 seismic system). Processing of the multichannel seismic reflection data used classical steps including CDP gathering (fold
119 6), binning at 25m, detailed velocity analysis, stack and post-stack time migration. All the profiles presented here are time
120 migrated and with a vertical exaggeration of 5. High-resolution swath bathymetry data were jointly acquired along the same
121 profiles, providing a 25-m resolution bathymetric map with almost a full coverage (Fig 2).

122

123 **3.1- Imaging of the Jamaica Passage: identification of the EPGFZ**

124 The Jamaica Passage is 200 km long between the southeastern tip of Jamaica and the Southern Peninsula of Haiti
125 (Fig. 2). The bathymetry data allow a detailed analysis of the geomorphic domains of the Jamaica Passage. The prominent
126 structures of the Jamaica Passage comprise the Morant, Navassa and Matley basins, as well as the Navassa Ridge in the
127 prolongation of the Southern Peninsula of Haiti. The Morant Basin is situated between longitudes 75°55'W and 75°38'W,
128 extending over a length of 24 km and a width of 15 km with a mean depth of 2 725 m. The Morant Basin is almost circular
129 in shape, bordered to the west by the Holmes Bank, with a slope of about 7°, and to the south by the Morant Ridge, with an

130 abrupt slope of 23°. To the north and east of the basin, the slopes are more gentle (about 6°). The Navassa Basin, situated
131 between longitudes 75°21'W and 75°06'W, has a rectangular shape with a length of 30 km and a width of 6 km. The mean
132 depth is 3070 m in the west and 2975 m in the east. The Navassa Basin is separated from the Navassa Ridge to the north by
133 a 15° slope, while the southern part of the basin is characterized by a gentle slope of about 5°. The Matley Basin, situated
134 between longitudes 74°59'W and 74°48'W, is a circular-shaped basin 18 km long by 10 km wide. The mean water depth of
135 2900 m is about the same as in the eastern part of the Navassa Basin. The Matley Basin is bordered to the north by the
136 Navassa Ridge with a slope of 11°. To the south, the basin is bounded by the Matley Ridge with a slope of 8°. The Navassa
137 Ridge forms an offshore prolongation of the Southern Peninsula of Haiti as far as 75°32'W. The ridge is about 25 km wide
138 and 100 km long, including Navassa Island, and shows an average seafloor depth of 1 000 m.

139 Linear scarps across the seafloor are revealed by the high-resolution swath bathymetry map (Figs. 2 and 3). These
140 scarps, interpreted as the superficial expression of cumulative seafloor ruptures along the EPGFZ, extend from Jamaica to
141 Hispaniola, crossing the southern border of the Morant Basin and passing along the northern edge of the Navassa and
142 Matley basins. Along most of its 200-km-length, the fault is bathymetrically well expressed in the seafloor. In the Jamaica
143 Passage, we define three distinct overlapping segments of the EPGFZ on the basis of structural discontinuities and specific
144 morphologies [Leroy et al., 2015]. These three fault segments are distinguished by changes in fault orientation and fault
145 trace complexity (Fig. 2). The western and eastern segments trend about N85°, while the central segment, between the
146 Morant and Navassa basins, trends about N76°. The fault trace is unique in the western part of the western segment,
147 whereas it becomes more complex towards the east with the occurrence of thrusts splaying off the strike-slip fault along the
148 central and eastern segments.

149 Figure 3 presents details of the scarps associated with each segment. Along the western EPGFZ segment (Fig. 3a),
150 the bathymetric close-up view shows a single fault with restraining bend structures on both sides. The main restraining bend
151 structure is described in detail in section 3.2. The seismic reflection profile H12-038 reveals the seafloor fault scarp as well
152 as the vertical dip of the fault plane, with the sediments being slightly deformed close to the fault. We identify a secondary
153 fault plane, not reaching the surface that may correspond to the prolongation of the southern edge of an incipient restraining
154 bend structure. Along the central EPGFZ segment (Fig. 3b), the close-up bathymetry and seismic reflection profile H12-032
155 show two very steep fault planes. The sediments are horizontal and slightly deformed near the fault traces. The southern
156 fault expresses mainly strike-slip motion, since there is no topographic difference or offset of seismic layers on either side of
157 the fault. By contrast, the northern fault shows evidence of thrusting, with horizontal seismic layers abutting against the

158 fault, forming a topographic step, which indicates a significant vertical offset. Along the eastern EPGFZ segment (Fig. 3c),
159 the morphology becomes more complex and we identified several fault scarps. On the close-up bathymetry, several faults
160 are highlighted in a deformed area involving folds and south-verging thrusts. On seismic reflection profile H12-176, we
161 identify two steep fault planes with significant vertical offset within the deformed and folded sediments. Farther to the
162 north, other fault traces observed in the bathymetry were not imaged by the seismic data due to steeper slopes, more
163 strongly dipping layers and the occurrence of lateral echoes.

164 Our analysis of the bathymetry and seismic profiles (Figs. 2 and 3) reveals that the EPGFZ, represented by a single
165 main fault near Jamaica, splits into several parallel fault strands towards the east, where a compressional component of
166 deformation is expressed in the bathymetry in the eastern part of the Jamaica Passage.

167

168 **3.2- Evidence for active left-lateral strike-slip motion of the EPGFZ**

169 The current EPGFZ trace shows several indications of active left-lateral strike-slip motion along the western and
170 central segments of the Jamaica Passage, as identified by *Leroy et al. [2015]*, i.e.: presence of pressure ridges, restraining
171 bend and horsetail splay. Here, we study these structures in detail (Figs. 4 and 5).

172 A horsetail splay, a feature characteristic of strike-slip faults, marks the western end of the western segment at
173 about 75°58'W (Fig. 2). This feature is due to a left step-over between the western EPGFZ and eastern Jamaican segments.
174 Here, the deformation is distributed through the horsetail, which is about 12 km long, 5 km wide, and is composed of
175 several branching, curved normal faults, regularly spaced about 1 km apart.

176 Within the Morant Basin, we identified a compressional step-over in the EPGFZ trace at about 75°47'W and
177 18°02'N (Fig. 4a), that we interpret as a double restraining bend about 4.8 km long and 1.7 km in width. Its northern edge is
178 characterized by a slope of 12° and a difference in seafloor depth of 170 m, while, on its southern border, the difference is
179 165 m and the slope is 18°. The presence of such a compressional step-over, though displaying an apparent right-lateral
180 offset, is however associated with left-lateral motion as illustrated in the evolutionary sketch on Fig. 4b. Such features are
181 extensively described along other gentle bends of main strike-slip systems [*Bayasgalan et al., 1999; Cunningham, 2007*].
182 The local bend along the EPGFZ is now bypassed by the main strike-slip fault in agreement with its primary strike-slip
183 motion at depth (Fig. 4a). The main strike-slip fault bypasses the bend by connecting the two branches entering the step over
184 and forms a 50 m wide strike-slip furrow through the apex of the restraining bend. This elevated topographic structure is a
185 fault-related geomorphic feature providing evidence of active left-lateral strike-slip motion of the EPGFZ. Similar

186 structures, but at different scales, such as the Pic Macaya in Haiti and the Blue Mountains in Jamaica are associated with the
187 EPGFZ onshore (Fig. 1; Mann and Burke, 1984; Mann et al., 1985; 1995; Abbott et al., 2013). The Pic Macaya culminates
188 at 2347 m, representing the highest point in Haiti. This feature has been interpreted by Mann et al. [1995] as a restraining
189 bend indicative of active left-lateral strike-slip faulting. The Blue Mountains restraining bend is also expressed by elevated
190 relief (> 2250 m), with the onset of uplift being estimated as late Miocene in age [Mann et al., 1985; Mitchell, 2006; Abbott
191 et al. 2013].

192 A set of three *en echelon* folds is visible in the eastern Morant Basin, at the western end of the central EPGFZ
193 segment (Fig. 4c). From west to east, the folds have wavelengths of 1.3 km, 1.7 km and 1.5 km. The total structure length is
194 4.3 km. This set of *en echelon* folds trends roughly E-W, is at an angle of about 15° to the main strike-slip fault strike, and is
195 located about 1 500 m south of the major strike-slip fault segment. The southern edge of the *en echelon* fold structure has a
196 slope of 15° and an elevation above the seafloor of 80 m. Similar *en echelon* fold structures have been identified, for
197 example, on the Dead Sea transform fault [Weinberger et al. 2014]. The formation of such folds is commonly attributed to
198 the premature stages of strike-slip deformation [Sylvester, 1988]. The trend of this set of folds is related to the southern
199 strand of the EPGFZ, clearly visible on the bathymetry farther east (Fig. 2). It marks the western tip of the central segment.
200 This EPGFZ segment may currently extend farther to the west at depth, inducing the folding.

201 In this study, we present several topographic cross-sections along the western segment of the EPGFZ and the
202 overlapping central segment in the Morant Basin (Fig. 5), in a zone where we identified *en echelon* folds and restraining
203 bend structures. From west to east, the EPGFZ is represented on 7 cross-sections labeled A to G. The cross-sections A, D
204 and G show that the seafloor on the northern side is elevated by about 8 to 20 m. Conversely, on cross-sections B and C, the
205 southern side is elevated by about 10 to 20 m. Together with the observation that cross-sections E and F do not show any
206 marked difference in elevation, the observations on the other cross-sections lead to the conclusion that there is no systematic
207 vertical offset of the seafloor across the EPGFZ. The vertical offset of the seafloor varies along strike and in places is up to
208 the south or up to the north, with an average difference in level of about 10 m. This is typical of a strike-slip fault, and rules
209 out a significant thrust component, which would produce uplift consistently on one side of the fault and more constant
210 elevation of the seafloor step.

211 Further evidence of active left-lateral strike-slip motion is provided by the Navassa Basin (Fig. 2), which has been
212 identified as an asymmetrical strike-slip related basin based on seismic stratigraphy analysis [Corbeau et al., 2016]. This
213 basin, in the middle of the Jamaica Passage, was previously interpreted by Mann et al. [1995] as a pull-apart basin bounded

214 to the north and south by offset segments of the EPGFZ. However, as discussed in *Corbeau et al.* [2016] and seen in Fig. 2,
215 there is no clear step of the fault trace at the edges of the basin. The trace of the EPGFZ is single and located along the
216 northern edge of the Navassa Basin, meaning that it is an asymmetrical rather than a pull-apart basin. Pull-aparts have
217 nonetheless been identified onshore in Haiti along the EPGFZ, e.g.: small basins near Tiburon, the Clonard Basin and the
218 Miragoane Lakes Basin (Fig.1) [*Mann et al.*, 1995].

219 220 **3.3- Evidence for a compressional component in the Jamaica Passage and Gulf of Gonâve**

221 Even though corresponding to a primary left-lateral motion, several structures in the Jamaica Passage are induced
222 by the transpressive regime in the Morant and Matley basins. These basins are considered to represent pre-existing half-
223 graben basins resulting from the rifting of the Paleocene Cayman trough, which were crosscut by the EPGFZ and
224 subsequently folded and deformed [*Corbeau et al.*, 2016]. In the Morant Basin, profile H12-036 (Fig. 6) shows the EPGFZ
225 and the deformed sediments. Between CMP 1500 and 1300, north of the EPGFZ, the sediments are uplifted and blind faults
226 can be identified. These blind faults are interpreted as branching into the main EPGFZ vertical plane at depth. This structure
227 defines a positive flower structure. Fewer blind faults were able to develop in the southern part of the flower structure,
228 probably due to the normal fault escarpment inherited from the half-graben. In the Matley Basin, we observed a similar
229 structure in profile H12-057 (Fig. 7). As in the Morant Basin, the sediments are uplifted and folded near the main fault, but
230 the deformation here is slightly larger and mostly restricted to the southeastern side of the EPGFZ between CMP 800 and
231 1000. Blind reverse faults are here again interpreted to branch into the main EPGFZ vertical plane at depth. Only the
232 southeastern side of this positive flower structure is developed, possibly due to the presence of the Navassa Ridge on the
233 northwestern side that might have inhibited the formation of reverse faults. Such positive flower structures are characteristic
234 of a transpression regime. The compressive deformation seems to be slightly higher in the eastern part of the Jamaica
235 Passage, as shown by the thrusting structures cutting the sea bottom south of the EPGFZ on the bathymetric map (Fig. 2, 3c
236 and 4d). Several north-dipping reverse faults parallel to the main trace of the EPGFZ may partially accommodate the
237 compression in the eastern Jamaica Passage.

238 We use the method of line length balancing [e.g. *Namson and Davis*, 1988; *Scharer et al.*, 2004] to provide
239 shortening estimates, assuming that the folding process does not change the original bed length. In the Morant and Matley
240 basins, the aim is to capture the shortening of the youngest pre-growth deposits affected by folding. Based on seismic
241 stratigraphic analysis, *Corbeau et al.* [2016] showed that the uppermost sedimentary unit in the basins, deposited in

242 unconformity on the older units, is a syn-tectonic sequence deposited during the activity of the EPGFZ. The horizons
243 marking the base of the uppermost folded sedimentary unit are highlighted by the black bold lines on Figs. 6 and 7. The
244 fivefold vertical exaggeration is taken into account in the calculations. In the Morant Basin, we estimate the line length
245 shortening as 228 m (2.1 %). In the Matley Basin, the line length shortening is almost the same (276 m, i.e. 2.1 %).

246 Evidence for compression is also visible in the Gulf of Gonâve, and is clearly identified in the bathymetric and
247 seismic data (Fig. 2). The Gulf of Gonâve is a 140 km wide embayment situated between the Northwestern and the
248 Southern peninsulas of Haiti. The most prominent features of the Gulf of Gonâve are the Jérémie Basin, Gonâve Island and
249 the Gonâve Rise. The Jérémie Basin (shown on Figure 2) is a triangular basin 65 km in length and 25 km in width, with a
250 water depth of about 3 600 m. It is situated between the western end of the Gulf of Gonâve and Gonâve Island. This basin
251 is delimited by thrusts along its southern and northeastern edges that seem to pinch it. These thrusts are discernible on the
252 bathymetric and seismic data. Figure 8 shows a typical example of a seismic profile in the southwestern corner of the
253 Jérémie Basin. An active reverse fault is visible near CMP 200 on the SSW side, marking the northern side of the Southern
254 Peninsula of Haiti. Northeast of the Jérémie Basin, the Gonâve Rise and Gonâve Island are situated along a NW-SE-
255 trending axis. The seafloor depth along this 30 km wide ridge is about 400 m near Gonâve Island and about 800 m toward
256 the west. Between Gonâve Island and the Northwestern Peninsula, a shallow basin of about 1900 m depth corresponds to
257 the mouth of the Artibonite, the largest river of Hispaniola.

258 The Gonâve Rise and Gonâve Island form a broad anticlinal structure that is interpreted to be the offshore
259 continuity of the onland Trans-Haitian Belt, a well-known fold-and-thrust system on Hispaniola [Mann et al., 1995].
260 N120°E-trending north-dipping active thrusts have been mapped in the Haiti fold-and-thrust belt by Pubellier et al. [2000].
261 Mann et al. [1995] described folds and reverse faults located onshore in Haiti and offshore in the Gulf of Gonâve. Both
262 authors identified regional-scale folds that correspond to present-day, anticlinal topographic mountain chains in the
263 prolongation of offshore anticlinal ridges. In the northern Gulf of Gonâve, Mann et al. [1995] identified young folding and
264 inferred the presence of thrust faults at depth. Our new high-resolution bathymetry data (Fig. 2) highlight such structures
265 and allow precise mapping of the active thrust and folds, which likely absorb the compressional component of transpression
266 in the Gulf of Gonâve. Following the 2010 Haiti earthquake, detailed bathymetry data were collected during the HAITI-
267 OBS cruise [Mercier de Lépinay et al., 2011] in the small Gonâve Basin, south of Gonâve Island. On the basis of the limited
268 dataset available at the time, the northwest boundary of the Gonâve Basin was interpreted as a steep SW-NE normal fault.
269 However, the extensive bathymetric coverage and seismic profiles now available (HAITI-SIS cruise) indicate that this fault

270 is a north-dipping thrust. Several such thrusts, either north-verging or south-verging, can be identified on the bathymetry
271 map and seismic profiles across the whole Gulf of Gonâve (Fig. 2). The orientations of these thrusts, close to the strike of
272 the onshore structures, indicate a SW-NE shortening. The seismic profiles (see example given in Fig. 9) show folding and
273 thrust faulting which disrupt the most recent sediments, thus indicating active compressional tectonics. Furthermore, the
274 uplift and asymmetric folding of the Gonâve Rise and Gonâve Island are difficult to explain without thrust faults (Fig. 9).
275 The interpreted structures correspond to thrust-fault ramps very similar to those interpreted on onshore cross-sections
276 [Pubellier et al., 2000]. Within the Gulf of Gonâve, the compressional deformation is accommodated on multiple folds and
277 thrusts, and thus the compression is distributed over a wide area.

278 Following the same approach as applied for the Jamaica Passage, we can estimate the shortening in the Gulf of
279 Gonâve. The slope and seismic facies of the Gonâve Rise and the Gonâve basin do not allow the identification of
280 continuous seismic horizons. Therefore, we focus solely on the most continuous seismic horizons of the northern Gulf of
281 Gonâve. Mann et al. [1995] interpreted the upper seismic sequence of the Gulf of Gonâve as Late-Miocene to Quaternary
282 deposits (in yellow in Fig. 9). In the absence of stratigraphic studies, drill-holes or direct dating, the uppermost folded
283 sequence, delimited by the solid black line at its base, is used to estimate the shortening. The estimate of line length
284 shortening is about 885 m (2.5%).

285

286 **4- Discussion**

287 The aim of this study is to investigate the relative roles of the EPGFZ and associated faults in accommodating the
288 transpressional plate motion offshore, in order to estimate the ratio between the strike-slip and thrusting components of
289 motion. In the Jamaica Passage, the motion along the EPGFZ is primarily strike-slip. Towards the west, the deformation
290 localizes onto a single fault trace. The deformation becomes more distributed towards the east, with an increasing
291 component of shortening taken up by several parallel thrusts splaying off the main strike-slip trace. While the strike-slip-
292 related Navassa Basin, the restraining bend at a compressional right-hand step-over, the presence of horsetail splay and *en*
293 *echelon* structures are all consistent with primary left-lateral strike-slip motion, the shear component of the transpression
294 remains unknown. Indeed, strike-slip offsets along the EPGFZ are lacking because passive markers may have been masked
295 by sedimentation or destroyed by erosion after being offset.

296 Nevertheless, we can calculate line length shortening to provide some estimates of the shortening in the Morant
297 and Matley basins, using the base of the uppermost folded sedimentary unit. The estimated values are small, being 228 and

298 276 m for the Morant and Matley basins, respectively (Figs. 6 and 7). In the Jamaica Passage area, no drilling data are
299 available, making it difficult to provide an age for the uppermost folded unit, deposited during the activity of the EPGFZ
300 [Corbeau et al., 2016]. Based on conventional field geology and the identification of local unconformities, the onset of
301 activity of the EPGFZ is estimated to be middle Miocene to late Miocene [Draper, 1987; Mann et al., 1985, 2007; James-
302 Williamson et al., 2014; Dominguez-Gonzalez et al., 2015] in Jamaica, and early Miocene in Haiti [Calmus, 1983]. A
303 geodynamical reconstruction based on a synthesis of geological data provides a younger age of 7 Ma for the development of
304 EPGFZ [Leroy et al., 2000]. Considering a large range of 7 to 20 Ma for the age of the EPGFZ, the calculated shortening
305 rates in the basins are between 0.01 mm/yr and 0.04 mm/yr.

306 With respect to the age uncertainties of a few Ma of the sedimentary unit, we nonetheless observe that our
307 shortening rates are considerably lower than those estimated by Benford et al. [2012] based on GPS modelling: 2.7 mm/yr
308 in the western Jamaica Passage (Morant basin) and 3.2 mm/yr in the eastern part (Matley basin) (Fig.1). Although our
309 estimates only account for deformation within the Morant and Matley basins, we cannot identify any other major
310 compressional structures in the Jamaica Passage capable of accommodating a significant amount of shortening. Another
311 possibility is that the shortening is accommodated by other structures north of the Jamaica Passage. Likely candidates are
312 the active folds and reverse faults identified in the Santiago Deformed Belt (Fig. 1) to the south of Cuba [Calais and
313 Mercier de Lépinay, 1990]. However, no long-term shortening rates have been estimated in this latter region, where the GPS
314 model of Benford et al. [2012] predicts 2.4 mm/yr of compression on SOFZ.

315 Further east, the compressional component is thought to increase. Part of the compressional component of the
316 transpressive motion is also accommodated onshore in the Trans-Haitian belt, and offshore in the Gulf of Gonâve,
317 encompassing the Gonâve Rise and the Gonâve basin. In the northern Gulf of Gonâve, the line length shortening is
318 estimated as 885 m, which corresponds to only 2.5% (Fig. 9). Since all our shortening estimates are extremely small, they
319 cannot account for the compressional component of the transpression inferred from GPS modelling. One source of bias in
320 our calculations is that we only take into account shortening due to folding, while ignoring the component associated with
321 decollement or thrust-faulting such as that interpreted in the Jérémie Basin and below Gonâve Island (Figs. 8 and 9). In
322 addition, the deformation may occur on blind structures that are not yet identified. Indeed, the 2010 Mw 7.0 Haiti
323 earthquakes revealed an unmapped blind thrust fault that could account for about 40% of the total slip by reverse dip-slip
324 [Calais et al., 2010]. Vertical motions are also suggested by the occurrence of a tsunami linked with the 2010 earthquake, as
325 well as nine documented tsunamis during the last 318 years in the Gulf of Gonâve and on the southern coast of Haiti

326 [*Hornbach et al., 2010; Fritz et al., 2013*].

327 In the Jamaica Passage, we see primary strike-slip deformation with very little compression compared to short-
328 term shortening. This discrepancy may reflect differences in the long-term and short-term behaviour of this part of the plate
329 boundary. The short-term slip-rates predicted by block modelling based on GPS measurements indicate a predominantly
330 strike-slip motion along the EPGFZ, with a compressional component increasing toward the east. However, the magnitude
331 of the compressional component varies according to the data set, the geometries of the blocks and the choice of location of
332 their boundaries. The recent block model of *Symithe et al. [2015]* indicates a lower amount of shortening in the western part
333 of the Jamaica Passage, but the predicted value for the eastern part of the Jamaica Passage is almost the same than in the
334 model of *Benford et al. [2012]*. GPS shortening estimates are not compatible with the long-term observed morphology. We
335 are unable to identify any significant offshore geological features capable of accommodating the rather large (2-3 mm/yr)
336 amount of short-term shortening.

337

338 **Conclusions**

339 A marine geophysical dataset is used to illustrate the primary strike-slip motion of the EPGFZ in the western part
340 of the Jamaica Passage, where several features are documented that express active left-lateral motion. A secondary
341 shortening is documented which increases in magnitude towards the east of the Jamaica Passage. However, our estimated
342 shortening rates in the basins, between 0.01 mm/yr and 0.04 mm/yr, are considerably smaller than the value inferred from
343 GPS block modeling [*Benford et al., 2012*]: 2.7 mm/yr in the western Jamaica Passage (at the longitude of the Morant basin)
344 and 3.2 mm/yr in the eastern part (at the longitude of the Matley basin). Evidence of shortening is also provided by active
345 folds, thrusts and blind-thrusts imaged in the Gulf of Gonâve, where the estimated compressional component remains also
346 very small (less than 3% of shortening). Our observations are in favour of a small compressional component of the regional
347 transpression. This compressional component is accommodated on multiple folds and thrusts distributed throughout the
348 entire plate boundary rather than partitioned on the main bordering strike-slip faults.

349

350 **Acknowledgements**

351 We thank the crew of the research vessel “L’Atalante” as well as B. Asseray and the French Embassy in Haiti. We are
352 also grateful to the Bureau des Mines et de l’Energie, the SEMANAH, the Université d’Etat d’Haiti, and particularly C.
353 Prépétit, D. Boisson, and J. Jadotte for their support. We thank the Associate Editor and two anonymous reviewers for

354 their constructive comments that helped improved the manuscript. Data used in this study are from the Haiti-SIS cruises
355 (<http://dx.doi.org/10.17600/12010070> and <http://dx.doi.org/10.17600/13010080>).

535 **Figure 1:** Tectonic setting of the study area. SOFZ: Septentrional-Oriente Fault Zone; EPGFZ: Enriquillo-Plantain-Garden
 536 Fault Zone. The circles with a date indicate historical earthquakes with magnitude less than 7 in yellow and greater than 7 in
 537 orange [McCann, 2006; Ali et al., 2008; Bakun et al., 2012]. The yellow star indicates the epicentre of the 12 January 2010
 538 earthquake. The grey arrow labeled 20 mm/yr indicates the plate motion between the Caribbean and North American plates.
 539 The green arrows show geodetically inferred slip rates (in mm/yr) of active faults in the region, from the block model of
 540 Benford et al. [2012]. Along the EPGFZ, fault-parallel and fault-normal components (in mm/yr) are specified according to
 541 this model. Bathymetric background is from the GEBCO one-minute arc grid.

543 **Figure 2:** Main structures of the study area based on the 25-m-resolution bathymetric map of the HAITI-SIS cruise. The left
544 part of the map shows the Jamaica Passage with the trace of the Enriquillo-Plantain-Garden Fault Zone in red. The right part
545 shows the Gulf of Gonâve with thrusts in black. Locations of Figures 6 through 9 shown. J= Jamaica. Segmentation of the
546 EPGFZ is from Leroy et al. (2015). Bathymetric background is the superposition of the HAITI-SIS cruise data
547 (<http://dx.doi.org/10.17600/12010070>) and the GEBCO one-minute arc grid.

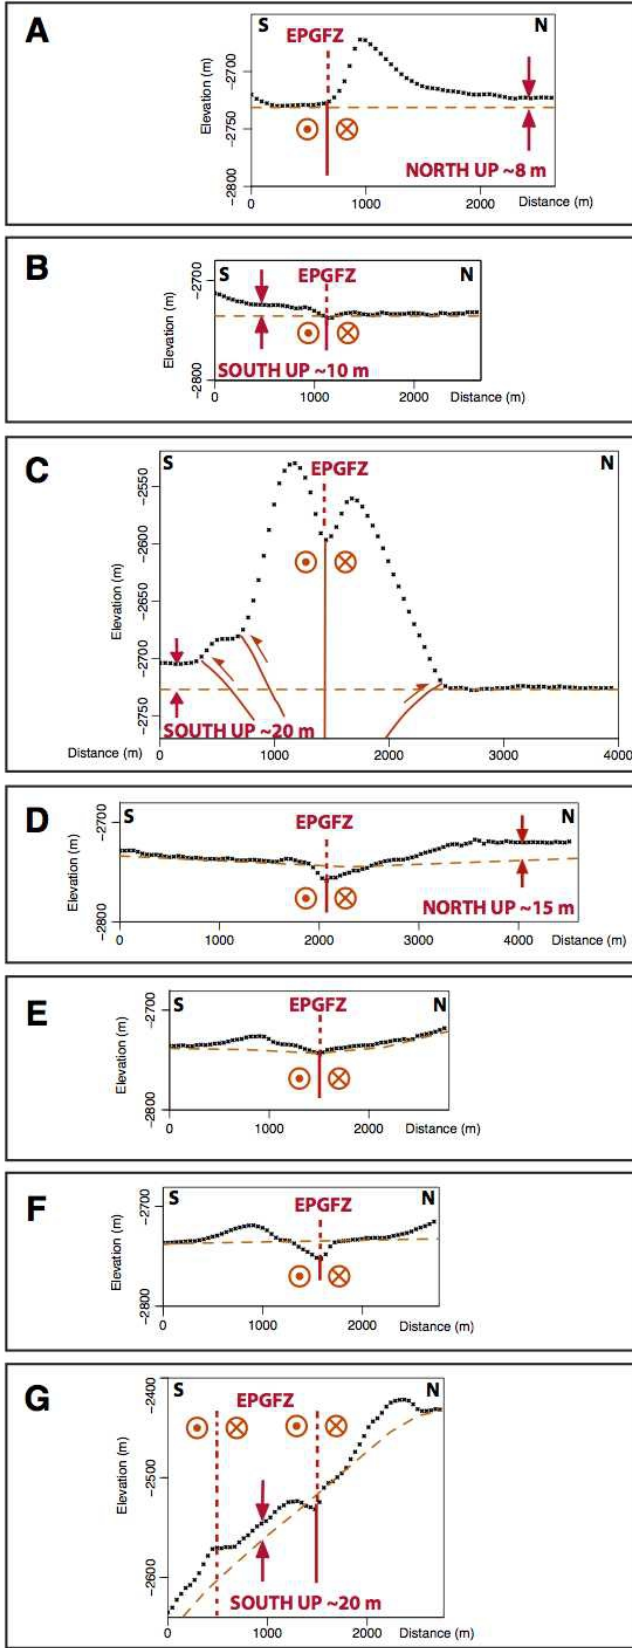

549 **Figure 3:** Structural features of the left-lateral strike-slip EPGFZ in the Jamaica Passage based on bathymetric and seismic
550 reflection data. A-C: for each segment of the fault (western, central and eastern, Fig. 2); upper panels give details of seismic
551 profiles and bathymetric close-up views; lower panels show the corresponding interpretations. The locations of profiles are
552 given in the upper right panel. J= Jamaica, H=Haiti.

554 **Figure 4:** Bathymetric close-up views and elevation cross-sections highlighting different structures in the Jamaica Passage.
555 The locations of the close-up views are given in the upper panel. (a) Double restraining bend located in the EPGFZ western
556 segment: bathymetric view with blue line indicating location of the adjacent topographic and seismic profiles. (b) Sketch
557 illustrating the formation of a double restraining bend. Step 1: right stepping stepover on a left-lateral strike-slip fault. Step
558 2: increasing strike-slip motion induces oblique shortening within the push-up and on the bounding thrusts. Step 3:
559 bypassing of the push-up by a through-going strike-slip. The bounding thrusts merge with the through-going strike-slip fault
560 to account for slip partitioning within the push-up. Thin black arrow figures the motion of the southern side of the fault with
561 respect to the northern side. Red arrows figure the partitioning within the compressive step over. Thin dashed lines figure
562 the abandoned strike-slip portions. (c) *En-echelon* fold structure: bathymetric view with pink line indicating location of the
563 adjacent topographic profile, crossing two overlapping segments of the EPGFZ. We interpret the southern strand as a diffuse
564 zone of deformation, which marks the western end of the EPGFZ central segment. No seismic profile is available in this
565 area. (d) Thrusting structures in the south of the EPGFZ eastern segment. Due to the slopes and lateral echoes, this zone was
566 not imaged by the seismic data.

VERTICAL EXAGGERATION x10

568 **Figure 5:** Topographic cross-sections from west to east in the Morant basin across the western segment of the EPGFZ. The
569 black dotted lines represent the seafloor elevation and the orange dashed lines the average elevation. North up and south up
570 indicate that the seafloor north or south of the EPGFZ has a vertical offset with respect to the average elevation. Profiles E
571 and F do not show a preferential up-lifted side.

Figure 6: Detail of seismic profile H12-036 crossing the Morant basin (upper panel) and its interpretation (lower panel). See inset for location and Fig. 2. The green and yellow units are the rifted basement and the sedimentary infilling, respectively. The red lines represent active faults, while the dashed black line is an inherited normal fault. The bold black horizon marks the base of the uppermost sedimentary unit, with its associated shortening estimated as 228 m.

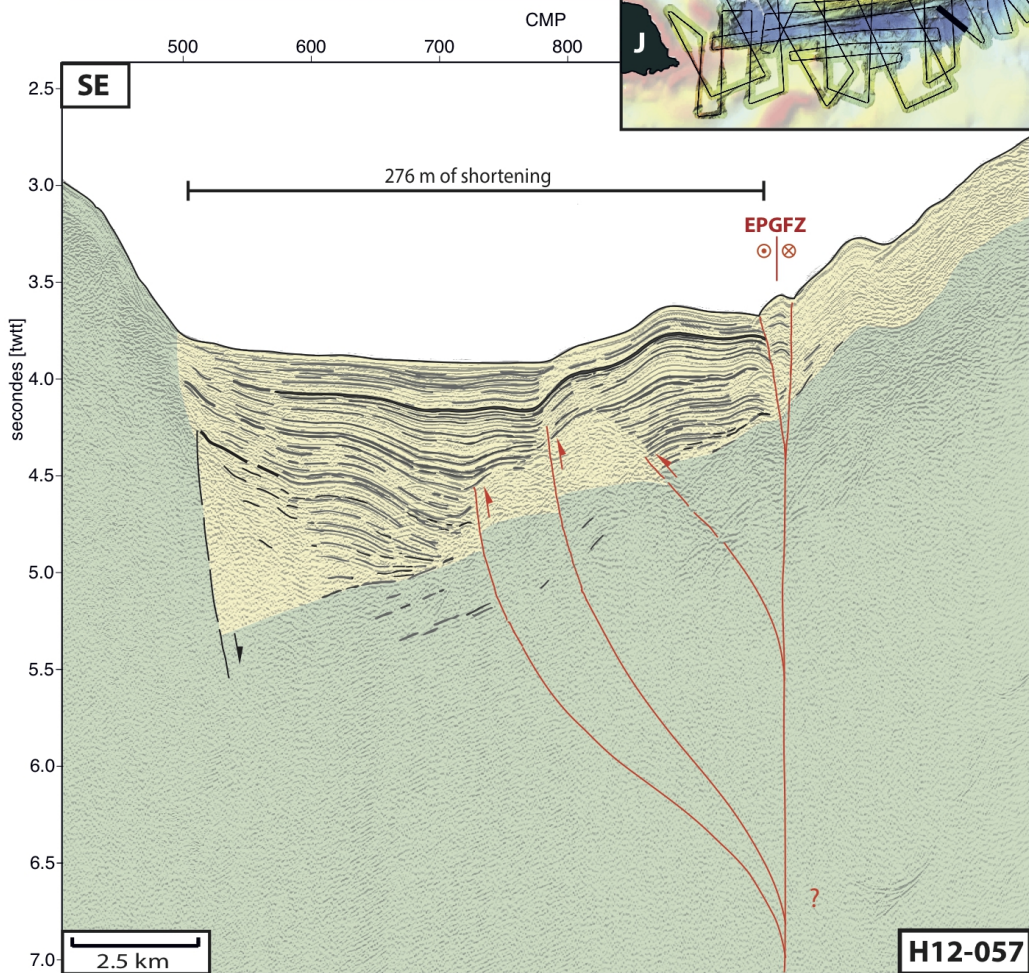

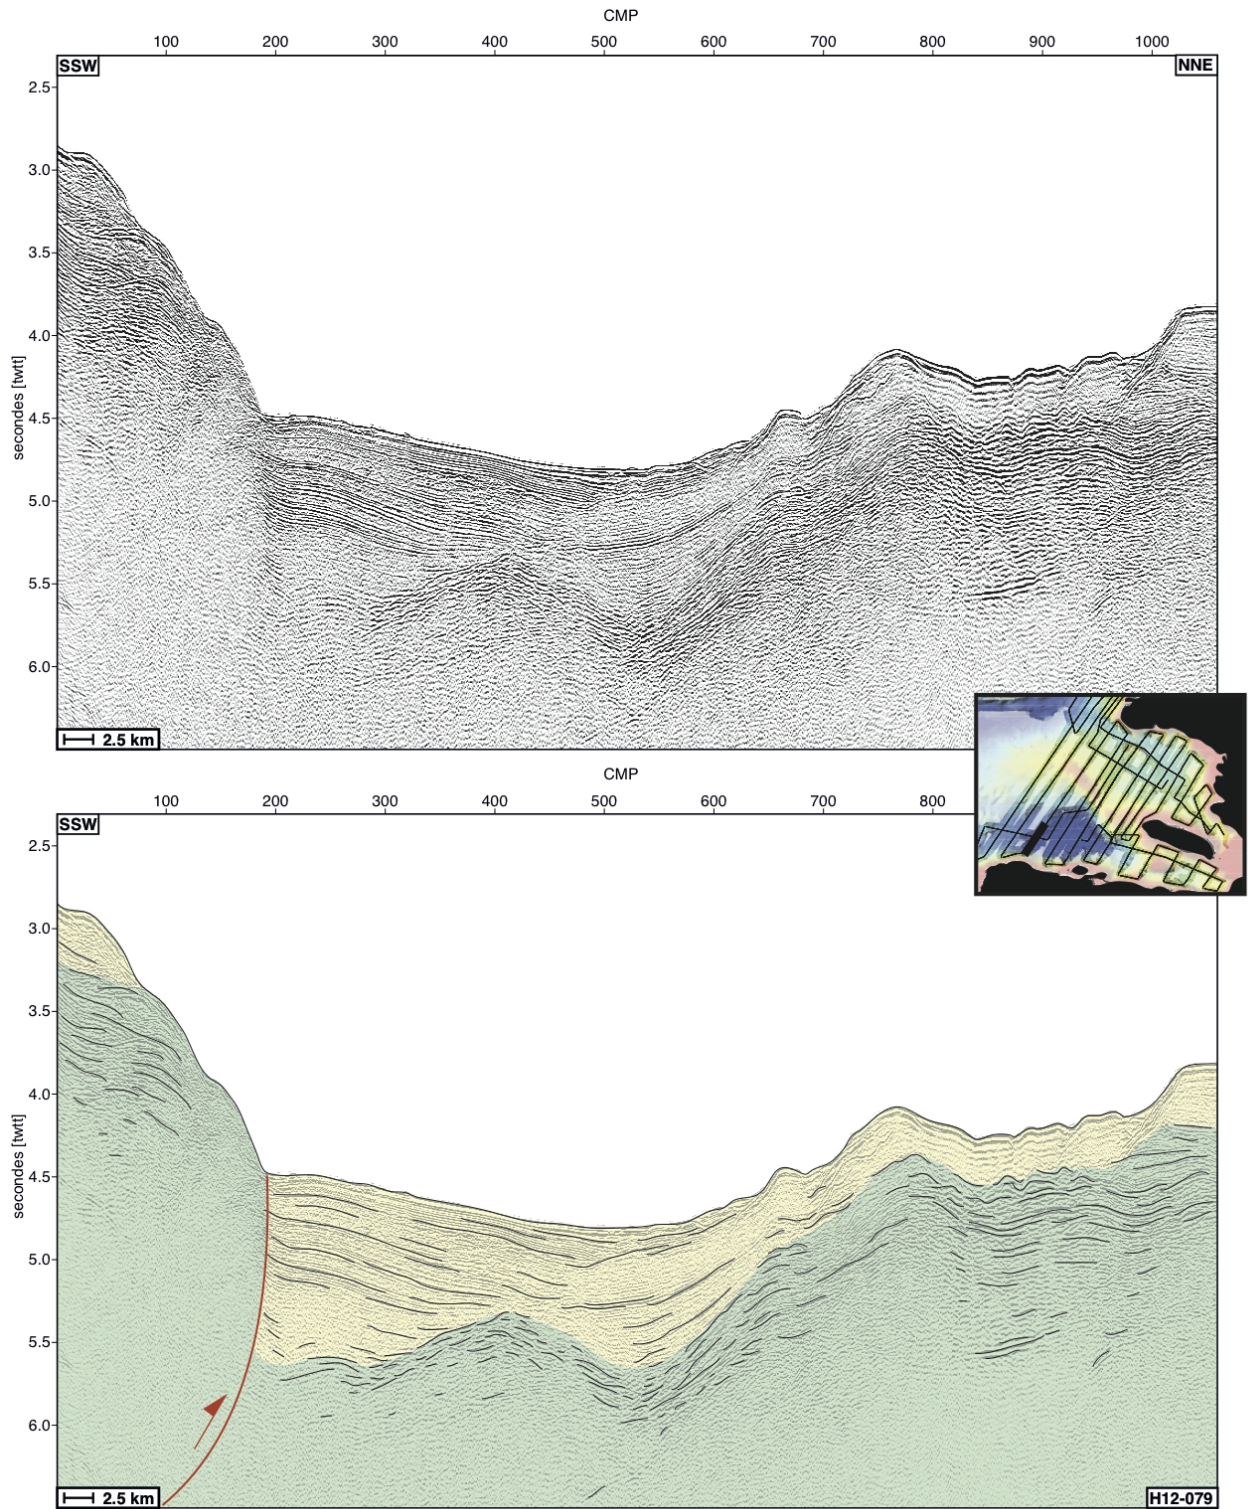

Figure 7: Detail of seismic profile H12-057 crossing the Matley basin (upper panel) and its interpretation (lower panel). See inset for location and Fig. 2. The green and yellow units are the rifted basement and the sedimentary filling, respectively. The red lines represent active faults, while the dashed black line is an inherited normal fault. The bold black horizon marks the base of the uppermost sedimentary unit, with its associated shortening estimated as 276 m.

572 **Figure 8:** Detail of seismic profile H12-079 (upper panel) in the Jérémie Basin and its interpretation (lower panel). See inset
 573 for location and Fig. 2. The green and yellow units are the folded basement and the sedimentary infilling, respectively. The
 574 red line represents an active reverse fault.

576 **Figure 9:** Detail of seismic profile H12-103 (upper panel) in the Gulf of Gonâve and its interpretation (lower panel). See
577 inset for location and Fig. 2. The green and yellow units are the folded basement and the sedimentary infilling, respectively.
578 The red lines represent active reverse faults interpreted as branching into ramps at depth. The lower ramp inferred at depth
579 is responsible for the uplift and the folding of Gonâve Island and the Gonâve Rise, and mapped on the bathymetric image
580 (Fig. 2). The bold black horizon marks the youngest folded sequence, with its associated shortening estimated as 885 m.
