Abstract

The Monglo adakite contains mafic and ultramafic xenoliths, which probably originated from the mantle section of an Early Cretaceous supra-subduction zone ophiolitic complex located within the Luzon arc crust. Spinel-bearing dunites are dominant among this xenolith collection and display evidence for three episodes of subduction-related melt percolation. The first one is evidenced by an undeformed clinopyroxene characterized by convex-upwards REE pattern. This clinopyroxene crystallized from a calc-alkaline basaltic magma, likely formed in the Cretaceous supra-subduction setting of the ophiolite. Then, two metasomatic events, evidenced by orthopyroxene-rich and amphibole-rich secondary parageneses, respectively, affected most of the spinel dunites. The opx-rich paragenesis is related to the circulation within the dunitic upper mantle of hydrous slab-derived melts similar to those affecting the mantle peridotite xenoliths from Papua New Guinea and Kamchatka. Finally the amphibole-rich veins are related to the interaction between the studied dunite xenoliths and the host adakite or an adakitic melt similar to it.

Keywords: Mantle xenoliths; Luzon arc; Metasomatism; Dunite; Trace elements; Adakite

1. Introduction

Deep-seated xenoliths sampled by volcanic rocks represent a major and direct source of information on the nature, the composition and the evolution of the deep crust and upper mantle in continental and oceanic settings (e.g., [Nixon, 1987], [O'Reilly and Griffin, 1987], [Coltorti et al., 1999], [Ionov and Hofmann, 1995], [Ionov et al., 1999], [Grégoire et al., 1997], [Grégoire et al., 1998], [Grégoire et al., 2000] and [Grégoire et al., 2005]). For a long time they were found almost exclusively in intraplate settings, especially within alkali basalts and related lavas ([Mercier and Nicolas, 1975] and [Nixon, 1987]). Indeed, most of the xenoliths collected within subduction-related magmatic rocks are either mafic cognate xenoliths which evidence magma mixing processes (Coulon et al., 1984) or plutonic blocks and cumulate rocks derived from the crystallization or fractionation at depth of calc-alkaline magmas (Arculus and Wills, 1980). However, several occurrences of mantle xenoliths within arc lavas have been described ([Abe et al., 1998], [Arai et al., 2000], [Arai et al., 2003], [Smith et al., 1999], [Brandon and Draper, 1996], [Luhr and Aranda-Gomez, 1997], [Grégoire et al., 2001] and [McInnes et al., 2001]). For instance, the phlogopite- and kaersutite-bearing xenoliths from Batan island in the northern Philippines allow to document metasomatic processes in the mantle wedge involving hydrous fluids ([Vidal et al., 1989] and [Maury et al., 1992]) and adakitic melts ([Schiano et al., 1995] and [Arai et al., 2004]). The mantle xenoliths from Lihir in Papua New Guinea ([McInnes et al., 2001] and [Grégoire et al., 2001]) consist of fibrous, radiating orthopyroxene and fine-grained Fe–Ni sulfide with minor olivine, clinopyroxene, phlogopite, amphibole and magnetite. These metasomatic minerals precipitated from a hydrous melt characterized by low HFSE contents ([McInnes et al., 2001] and [Grégoire et al., 2001]). These authors proposed that some arc magmas could originate from partial melting of mantle wedge regions metasomatised by such HFSE-poor, slab-derived hydrous melts.

The present paper focuses on the metasomatic parageneses and major and trace element characteristics of a set of five fresh dunite xenoliths hosted by the Monglo adakite in the Baguio District, Northern Luzon, which provide an analogue for metasomatism of depleted mantle by slab-derived hydrous melts (adakitic liquids). A less focused companion paper published in Island Arc (Payot et al., 2007) describes the Monglo adakite and the whole suite of mafic and ultramafic xenoliths entrained by the latter (spinel dunites, serpentinites derived from them, amphibolites, gabbros and a single quartz diorite).

2. Host lava and petrography

The Monglo adakite ([Jego et al., 2005] and [Payot et al., 2007]) is a small intrusive body located 16 km northwest of Baguio City in Northern Luzon (N16°28'52; E120°29'55, altitude 720 m). A quarry along the Naguilian road near Monglo village exposes a ca. 50 m thick hornblende-bearing dacitic intrusive sheet dated at 8.65 ± 0.24 Ma (Jego et al., 2005). It crosscuts the Klondyke Formation (Fig. 1), a Middle to Late Miocene sequence of coarse clastic rocks, polymictic conglomerates, sandstones and vitric tuffs, with minor shales and siltstones (Tamesis et al., 1982). The geochemistry of this dacite has been discussed by Jego et al. (2005), who consider it as a “typical” or “genuine” adakite derived from ca. 20% hydrous partial melting of altered oceanic metabasalts converted to eclogite. It displays very low Y and Yb values approximating those of the primitive mantle (Sun and McDonough, 1989), highly fractionated rare earth element (REE) patterns and Sr/Y ratio of 130–150, a diagnostic feature for adakites (Defant and Drummond, 1990). Like many adakites, it contains

relatively high amounts of Ni (50–53 ppm), Co (14–17 ppm) and Cr (62–84 ppm), which might indicate interactions with its ultramafic xenoliths (Jego et al., 2005).

The Monglo adakite contains numerous xenoliths ranging usually in size from 1 to 10 cm (Fig. 2D), which includes spinel dunites, serpentinites derived from them, amphibolites, gabbros and a single quartz diorite. The whole xenolith association, including the five mantle-derived spinel dunites described in the present study, probably originated from a Lower Cretaceous ophiolitic complex (Payot et al., 2007). Indeed, all the transitions between “fresh” dunites and completely serpentinitized ones (lizardite/chrysotile-bearing) can be found, as usual in the mantle section of ophiolitic massifs. Serpentinization occurred before the incorporation of these xenoliths within the adakitic magma, as evidenced by the contact between serpentinite xenoliths and the host adakite which is typically a reaction rim of rather constant thickness (~ 0.5 mm) consisting of a coating of fibrous antigorite and amphibole (actinolite/tremolite) growing perpendicularly to the contact (see Fig. 2 of Payot et al., 2007). As lizardite/chrysotile form under relatively low-temperature conditions while antigorite is a higher-temperature serpentine (Evans, 1977), we ascribe this reaction rim to thermal metamorphism of the already serpentinitized dunites by the host (serpentine-free) adakite. The gabbros display adcumulate textures, primary mineral associations and major and trace element compositions, especially flat to moderately enriched incompatible trace element patterns similar to those of gabbros derived from back-arc basin basalt (BABB) magmas (Payot et al., 2007). Associated amphibolites are considered derived from metapicrites and/or metagabbros of similar affinity. A single quartz diorite xenolith also carrying a BABB-related geochemical signature has been sampled. One amphibolite xenolith provided a whole rock K–Ar age of 115.6 ± 8.33 Ma (Barremian). As a whole, this xenolith association could represent an equivalent of the Early Cretaceous Isabela-Aurora and Pugo-Lepanto MORB- to BABB-type ophiolitic massifs exposed in Northern Luzon ([Tamayo et al., 2004], [Pubellier et al., 2004] and [Andal et al., 2005]), as well as of the Barremian oceanic crust of the adjacent Huatung Basin (Deschamps et al., 2000).

The five studied “fresh” dunites (samples 01c01, 08Ja, 08Jb, 08Jc, 08Jd) are primarily made up of olivine showing protogranular texture (Mercier and Nicolas, 1975) with the exception of sample 08Jb which displays a porphyroclastic texture. Olivine crystals are well-preserved, and show curvilinear edges and undulose extinction. Grain size reaches up to > 5 mm. Primary orthopyroxenes (Opx1) only occur in small amounts (less than 2–3%) in samples 08Je and 08Jf. Rare clinopyroxene crystals (less than 2–3%) have been only observed in sample 01c01 where they occur as undeformed anhedral grains filling the interstices between the primary deformed olivines (Fig. 2A). Brownish to black spinels are also present as anhedral to subhedral isolated coarse crystals (> 1 mm) or in smaller grains usually gathered in clusters. These spinels commonly display a rim darker than the core of the crystal. Four studied dunite xenoliths also display small interstitial patches (especially around spinel) and/or thin veins (< 1 mm wide) filled with secondary minerals. Shear structures are not observed in the veins. They are dilational in nature and are assumed to have formed via hydraulic fracturing. Two secondary mineral parageneses which do not coexist in a given sample have been observed: (i) fibrous orthopyroxene + minor phlogopite and sulfides (samples 08Ja and 08Jb) and (ii) amphibole + minor phlogopite, green spinel and sulfides (samples 08Je and 08Jf). Samples 08Ja and 08Jb display crosscutting networks of orthopyroxene-rich veins containing a secondary mineral assemblage consisting of fibrous, radiating orthopyroxenes (Opx2) often showing euhedral edges and associated to minor phlogopite (Phl-a) crystals and fine-grained Fe–Ni sulfides (Fig. 2B). Samples 08Je and 08Jf also show crosscutting networks of veins but

these veins are amphibole-rich. They contain a secondary mineral assemblage consisting of euhedral to subhedral amphiboles associated to minor phlogopite crystals (Phl-b), rounded green spinel grains (Sp2) and fine-grained Fe–Ni sulfides (Fig. 2C). In the case of the opx-rich veins, euhedral terminations of orthopyroxene in the fracture networks indicate that they grew unrestricted into melt-filled cavities within the mantle prior to xenolith incorporation in the lava. The two metasomatic parageneses also occur in patches surrounding the primary spinels displaying rims darker than their cores. Trails of secondary inclusions containing a liquid phase, a vapour phase, and various daughter minerals occur within primary olivine grains adjacent to the metasomatic veins. Sample 01c1 only contains very rare and tiny phlogopites (in addition to undeformed interstitial clinopyroxene grains) and it is therefore difficult to classify this sample in one of the two above groups. Some evidence of hydraulic fracturing has been observed in sample 08Jb, in which fragments of primary olivines occur within aggregates of fibrous orthopyroxenes (Fig. 2).

3. Analytical techniques

Mineral analyses from the dunite xenoliths were done using a Cameca SX50 electron microprobe at the Electronic Microprobe Service, Université Paul Sabatier, Toulouse, France. Operating conditions were set at 15 kV, 10 nA and 10 s counting time, using natural and synthetic standards for calibration.

Concentrations of trace elements and REE (La, Ce, Nd, Sm, Eu, Gd, Dy, Ho, Er, Yb, Lu, Rb, Ba, Th, U, Sr, Zr, Hf, Nb, Ta, Ti, Ni, V) were determined by laser ablation inductively coupled plasma mass spectrometer (La-ICP-MS), at the ICP-MS common service, Observatoire Midi-Pyrénées (Université Paul Sabatier, Toulouse). This allowed in situ analysis of clinopyroxene (Cpx) on > 120 μm thick polished sections. The Perkin Elmer 6000 ICP-MS instrument was coupled to a Cetac LSX-200 laser ablation module that uses a 266 Nm frequency-quadrupled Nd-YAG laser. The NIST 610 and 612 glass standards were used for external calibration. Amphibole analyses were normalized using CaO values determined by electron microprobe while those of clinopyroxene and orthopyroxene were normalized using MgO values. Ablation was operated on the inter-cleavage domains from the cores of the freshest grains, in order to obtain homogeneous results unaffected by alteration or exsolution processes. A beam diameter of 50–100 μm and a scanning rate of 20 $\mu\text{m}/\text{s}$ were used. Typical theoretical detection limits range from 10 to 20 ppb for REE, Ba, Rb, Th, Sr, Zr and Y; 100 ppb for Sc and V; and 2 ppm for Ti and Ni. The relative precision and accuracy for laser analyses range from 1 to 10%.

4. Results

4.1. Primary mineralogy (Table 1 and Table 2)

The primary (i.e. pre-metasomatic patches and veins) mineral association of the studied dunites has been already analysed by Payot et al. (2007) and therefore we only recall here its main features. The olivines are highly magnesian with Mg# [= 100 Mg/Mg + Fe_{total}] values ranging from 89.8 to 91.2, associated to high NiO contents ranging from 0.31 to 0.39 wt.% (Table 1). Orthopyroxenes also exhibit a very high Mg# (89.7–92) and a relatively high Al₂O₃ content (4.1–4.5 wt.%). Clinopyroxene, which only occurs in sample 01c01, is a highly magnesian Cr-diopside (Mg#: 94.5 and Cr₂O₃ = 1.5 wt.%) containing rather high amounts of Al₂O₃ and Na₂O (4.4 and 0.8 wt.%, respectively). All these compositions are typical of mantle rocks and mantle xenoliths (Payot et al., 2007). The spinels show a wide range of Cr#

($= 100 \times \text{Cr}/[\text{Cr} + \text{Al}]$) values (2.9–72) as well as of corresponding Mg# values (23.7–75.5), but as a whole their core compositions (Mg–Al chromites) are also typical of mantle peridotites (Payot et al., 2007). The spinel rims systematically display a higher Cr# and a lower Mg# than the corresponding cores. In the diagram displaying Cr# spinel vs Fo content of olivine (Fig. 3) the five Monglo dunites plot within the olivine–spinel mantle array (OSMA-[Arai, 1994] and [Arai et al., 2004]). They also display similarities with the Moho transition zone dunites from the Philippines ophiolites (Tamayo et al., 2004) and the Batan peridotite mantle xenoliths representing samples from the Philippines sub-arc lithospheric mantle (Arai et al., 2004) (Table 2).

The clinopyroxene from sample 01c01 displays a convex-upwards REE pattern (Ce_N/Yb_N : 1.2; Ce_N/Sm_N : 0.5; Sm_N/Yb_N : 2.3) ranging from two to five times the primitive mantle values (Fig. 4). Its extended trace element pattern is characterized by slight negative Nb, Sr and Ti anomalies (Fig. 4).

4.2. Metasomatic patches and veins mineralogy (Table 1 and Table 2)

The secondary orthopyroxenes (Opx2) are also highly magnesian (Mg#: 92.4–94.8) but display much lower Al_2O_3 contents (0.5–1.7 wt.%) than the primary orthopyroxene (Opx1). The phlogopites associated with Opx2 are lower in Al_2O_3 than those associated with amphibole (14.94 and 16.9–17.7 wt.%, respectively) for similar high Mg# (91.8 and 91.9–92.3, respectively). In both cases TiO_2 content is very low (Fig. 5). Based on the Al_2O_3 content of its phlogopite (14.8 wt.%) it seems that sample 01c01 could be classified into the group of samples displaying the opx-rich metasomatic paragenesis. Amphiboles (Amph) are tschermakites characterized by Mg# ranging from 87.1 to 89.1, very low TiO_2 contents (0.2–0.5 wt.%) and Al_2O_3 and Na_2O contents ranging from 13 to 13.6 wt.% and from 2.4 to 2.5 wt.%, respectively (Fig. 5). The green spinels (Sp2) associated to amphiboles are Ti-free Cr-pleonastes.

The fibrous orthopyroxene displays a LREE-depleted pattern (Ce_N/Sm_N : 0.3 and Ce_N/Yb_N : 0.2) characterized by a slight La-enrichment over Ce (La_N/Ce_N : 1.5; Fig. 6). This pattern is similar in shape to those of the fibrous orthopyroxenes from Lihir mantle peridotite xenoliths (Papua New Guinea, Grégoire et al., 2001) but at a higher concentration level. The corresponding extended incompatible multielement patterns of these samples also display the same negative Zr and Ti anomalies and the same positive U anomaly (Fig. 6). The amphibole shows a LREE-enriched pattern (Ce_N/Sm_N : 1.5; Ce_N/Yb_N : 3.8; Fig. 7), also similar to those of amphiboles from Lihir mantle xenoliths and from the Finero peridotite massif (Italian Alps, Coltorti et al., 2007). This similarity is also evidenced by the extended incompatible trace element patterns of these samples, which display the same negative Nb, Ta and Ti anomalies (Fig. 7). In this diagram the Monglo amphiboles appear different from the amphiboles of the composite mantle xenoliths from Kerguelen islands (Moine et al., 2001). For example Nb contents of the Kerguelen amphiboles cover a broad range but are systematically higher than those of the Monglo amphiboles (Fig. 7).

5. Discussion

The mineral and chemical features of the Monglo dunites are in good agreement with an origin as depleted upper-mantle rocks from subduction-related lithospheric mantle (see above and Payot et al., 2007) incorporated within the ophiolitic basement of Northern Luzon. This

paper aims to discuss the origin of the secondary orthopyroxene-rich and amphibole-rich metasomatic parageneses, as well as the origin of the undeformed interstitial clinopyroxene occurring in sample 01c01.

5.1. Origin of the clinopyroxene from sample 01c01: interaction with basaltic melt

The shape and undeformed nature of clinopyroxene of dunite 01c01 clearly indicates that it crystallized from a melt which circulated within the primary (deformed) olivine-rich association of this Moho transition zone dunite (Fig. 2A). We have calculated the composition of the theoretical melt in equilibrium with the clinopyroxene and compared the result with some natural melts. We have used the following set of clinopyroxene/basaltic melt partition coefficients:

Ti	0.384	Hart and Dunn 1993
Sr	0.096	Johnson 1994
Zr	0.4	Forsythe et al., 1994
Nb	0.03	Forsythe et al., 1994
La	0.0536	Hart and Dunn 1993
Ce	0.0858	Hart and Dunn 1993
Nd	0.1873	Hart and Dunn 1993
Sm	0.291	Hart and Dunn 1993
Eu	0.41	Frey, 1969
Gd	0.46	Frey, 1969
Dy	0.442	Hart and Dunn 1993
Ho	0.44	Paster et al., 1974
Er	0.39	Hart and Dunn 1993
Yb	0.43	Hart and Dunn 1993
Lu	0.433	Hart and Dunn 1993
Th	0.0127	Hauri et al., 1994

The REE and extended trace element patterns (Fig. 8) of the theoretical melt in equilibrium with the clinopyroxene of the sample 01c01 display strong similarities (shapes of the patterns, levels of enrichment, negative Nb, Zr, Ti anomalies) with those of Neogene low-K to medium-K calc-alkaline basalts from the Luzon arc. A significant basaltic volcanism occurred in the Baguio district from 15.3 to 8 Ma (Polvé et al., 2007). Its initial products were low-K calc-alkaline basalts, which evolved through time by being progressively enriched in K and other large ion lithophile elements.

However, the thermal metamorphism of serpentized dunites by the host adakite implies that the studied dunitic samples were not located in upper-mantle conditions during the Miocene (i.e. they were already tectonically emplaced within the Northern Luzon crust as part of an ophiolitic massif). In such conditions, percolating basaltic melts should be quenched before reacting with the ultramafic rocks to form metasomatic clinopyroxene. We therefore propose that the interstitial undeformed clinopyroxene of the spinel dunite 01c01 crystallized from a calc-alkaline basaltic magma, which percolated through a high-temperature dunitic upper mantle prior to its obduction and cooling, probably during the Early Cretaceous supra-subduction history of the ophiolite.

5.2. Dunite metasomatism by adakitic and other slab-related melts

The other four dunite xenoliths from Monglo evidence modal metasomatic processes highlighted by two types of metasomatic parageneses occurring in crosscutting veins and patches commonly surrounding primary spinels: (i) orthopyroxene-rich paragenesis (samples 08Ja and 08Jb) and (ii) amphibole-rich one (samples 08Je and 08Jf).

The fibrous metasomatic orthopyroxene is characterized by a strong U enrichment and strong HFSE depletions (Nb, Zr, Ti — Fig. 6). This orthopyroxene displays strong major and trace element similarities with the fibrous orthopyroxenes occurring in mantle xenoliths (mostly spinel harzburgites) from the Tubaf and Edison submarine cinder cones located SE of Lihir island (Papua New Guinea; [McInnes et al., 2001] and [Grégoire et al., 2001]) and also with the Al-poor metasomatic orthopyroxenes from Colorado Plateau mantle xenoliths (Smith et al., 1999). These similarities include equivalent (and low) Al₂O₃ content, almost identical REE patterns and respectively positive U- and negative HFSE anomalies (Fig. 6). The rare phlogopites associated to fibrous orthopyroxene in Monglo dunites are less magnesian than those from Lihir xenoliths but display similarly low TiO₂ content which appears to be characteristic of phlogopite associated to subduction-related metasomatic assemblage (Fig. 5; Coltorti et al., 2007).

The amphiboles occurring in the Monglo dunites are strongly enriched in LREE, and appear to be significant mineral repositories for Th, U and Sr as well. Such features are also documented by Moine et al. (2001) for the amphibole-bearing composite mantle xenoliths from the Kerguelen Islands and by Grégoire et al. (2001) for the amphibole-bearing mantle xenoliths from the Tubaf and Edison volcanoes (Lihir Island, Papua New Guinea). The Monglo amphiboles also display similarities with the S-amphiboles (S: Subduction mantle amphibole) defined by Coltorti et al. (2007) and corresponding to amphibole crystallizing in subduction-related mantle metasomatic assemblages (Fig. 5 and Fig. 7). For example, their Na₂O contents and their REE- and trace element patterns are similar to those of the S-amphibole from Lihir Island and from the Finero peridotite massif (Italian Alps; Fig. 5 and Fig. 7). The rare phlogopites associated to the amphibole are also low in titanium (Fig. 5), as well as those associated to the fibrous orthopyroxene. The metasomatic assemblage from Lihir Island has been related to the percolation of slab-derived, hydrous melts within a previously depleted peridotitic upper mantle ([McInnes et al., 2001] and [Grégoire et al., 2001]). A similar origin has been proposed for the metasomatism affecting the mantle peridotite xenoliths from Batan Island (Schiano et al., 1995) which belongs to the northern section of the Luzon arc ([Defant et al., 1989] and [Defant et al., 1990]). Some of these Batan mantle xenoliths display similar fibrous orthopyroxene-rich assemblages (Arai et al., 2004). To emphasize the similarity between the Lihir and Batan mantle metasomatism, Grégoire et al. (2001) pointed out the close similarities between the trace element contents (similar shape

of the patterns and same positive Th–U and negative Ta anomalies) of two metasomatised spinel harzburgites from Lihir island and one metasomatised spinel harzburgite from Batan island.

All these features and comparisons are in good agreement with an origin of the two Monglo metasomatic parageneses (opx-rich and amphibole-rich) by percolation of slab-derived hydrous melts similar to the host adakite. The hydrous nature of the metasomatic melt is also supported by the similar petrographic characteristics of the Monglo metasomatic veins with those of Lihir xenoliths, i.e. evidence for hydraulic fracturing, trails of secondary inclusions and euhedral features of fibrous orthopyroxenes and crystals of amphibole. The incompatible trace element compositions of the secondary minerals suggest that the metasomatic enrichment of dunitic mantle xenoliths in Sr, Th and U and REE from La to Gd occurred during the percolation of such slab-derived hydrous melts or interaction with the host adakite during emplacement. An interesting feature of the Monglo dunites is that they bear two different metasomatic parageneses, which do not coexist in the same sample but which seem to be both related to slab-derived melts. In particular, as far as we know the amphibole-rich mineral vein assemblage has never been described before in Moho transition zone dunites. The simpler explanation would be that the degree of SiO₂ saturation of the two metasomatic melts was different, that of the melt producing the opx-rich veins and pockets being higher than that of the melt forming the amphibole-rich veins and pockets. But these two melts also should have different Al₂O₃, MgO, FeO and incompatible trace element compositions, as evidenced by the difference in the contents of those elements in orthopyroxenes and amphiboles which form more than 90% of the modal composition of orthopyroxene-bearing and amphibole-bearing metasomatic parageneses, respectively. That means that either: (i) slab-derived melts/fluids of contrasting compositions have metasomatised the same ophiolite mantle basement and therefore that the slab could generate different fluids/melts during its descent, or alternatively that (ii) the two vein types (amph-rich and opx-rich) are related to the circulation within the dunites of adakitic melts similar to the host lava. Indeed, experimental studies have shown that dacitic melts, and especially adakitic ones such as the Monglo host lava, may produce orthopyroxene, amphibole and phlogopite when they react with peridotitic paragenesis (e.g. [Rapp et al., 1999], [Prouteau et al., 2001] and [Prouteau and Scaillet, 2003]). An “intermediate” hypothesis is that the formation of amphibole-rich veins is related to interaction with the host lava (or a similar adakitic melt percolating the dunites before their uplift by the host lava), and that the orthopyroxene-rich veins are related to the circulation of a different type of slab-derived melt/fluid prior to the incorporation of the dunites within the host lava. The comparison of our data with the compositions of southern Kamchatka mantle peridotite xenoliths (Ishimaru et al., 2007) and with the experimental results of Prouteau and Scaillet (2003) gives strong support to this “intermediate” hypothesis. Indeed, Ishimaru et al. (2007) describe southern Kamchatka peridotite xenoliths coated by hornblendites forming thin selvages as well as veinlets cutting the xenoliths. Similar features have been observed in other sub-arc mantle xenoliths exhumed by arc magmas and especially in those from Iraya volcano, Batan island, Philippines ([Vidal et al., 1989], [Maury and Didier, 1991] and [Arai et al., 1996]). Interaction between the ultramafic xenoliths from Cerro del Fraile (Patagonia) and adakitic glass veins crosscutting them also produced metasomatic amphibole (Kilian and Stern, 2002). Moreover, the amphiboles of our study display major element compositions similar to those of interstitial and discrete amphiboles from the amphibolites selvages coating the southern Kamchatka xenoliths. Finally the major element compositions of amphiboles from Monglo dunites are also similar to those of the amphiboles produced during the 1991 Pinatubo dacite–peridotite interaction experiments of Prouteau and Scaillet (2003).

Regarding the opx-rich veins, no coatings of orthopyroxenes forming thin selvage around xenoliths such as the amphibole selvages have been observed in the sub-arc mantle xenoliths exhumed by arc magmas. Moreover, the orthopyroxene-rich veins crosscutting the Monglo dunite xenoliths contain orthopyroxenes exhibiting complex fibrous textures similar to those of the metasomatic orthopyroxenes from Lihir and southern Kamchatka mantle xenoliths ([Grégoire et al., 2001], [McInnes et al., 2001] and [Ishimaru et al., 2007]). Such fibrous textures have been related by the authors to low-viscosity hydrous metasomatic agents. The major and trace element contents of the Monglo orthopyroxenes are also very similar to those of Lihir (Table 1; Fig. 6 and Table 2 of McInnes et al., 2001). On the other hand, their major element contents (lower Al and Ca and higher Si) are different from those of the orthopyroxenes produced during the Pinatubo dacite–peridotite interaction experiments of Prouteau and Scaillet (2003). Therefore, we propose that the formation of amphibole-rich veins in the studied dunites is related to their interaction with the host Monglo adakitic magma (or a similar adakitic melt) and that the orthopyroxene-rich veins are rather related to the circulation of a different type of slab-derived melt/fluid. This interpretation implies that the amphibole-rich paragenesis has been probably the last metasomatic paragenesis to crystallize and that its formation occurred after the tectonic emplacement of the studied dunites within the crust as ophiolitic materials. However, available data do not allow us to constrain the temporal relationship between the crystallization of the opx-rich metasomatic paragenesis and the tectonic emplacement of the dunites.

Although some authors have argued that amphibole and phlogopite may be reservoirs for HFSE in subduction zones ([Hofmann, 1988], [Ionov et al., 1997] and [Bodinier et al., 1996]), we found no apparent HFSE enrichment in orthopyroxenes and amphiboles which are by far the main constituents of the Monglo metasomatic mineral assemblages. They in fact display apparent HFSE depletions (Fig. 6 and Fig. 7). In agreement with the conclusion of Grégoire et al. (2001), we propose that these depletion trends simply reflect low HFSE abundances (compared to Th, U and Sr and, in some cases, LREE) in the metasomatic slab-derived metasomatic agents (adakitic or hydrous melts). This implies that the HFSE flux through the mantle wedge was low, and that the slab-derived, hydrous melts crystallizing the orthopyroxene-rich and the amphibole-rich veins and pockets have high LREE/HFSE and LILE/HFSE ratios, like the host adakite. This finding supports experimental data showing that Th, U and LREE mobilities in hydrous mantle melts (or fluids) are higher than those of HFSE ([Tatsumi et al., 1986], [Ayers and Eggler, 1995] and [Brenan et al., 1995]).

6. Conclusions

The present study indicates that the Monglo Moho transition zone spinel dunite xenoliths, which probably originated from the mantle section of an Early Cretaceous supra-subduction zone ophiolitic complex located within the Luzon arc crust, display evidence for three episodes of subduction-related melt percolation.

– The first one is evidenced by the undeformed clinopyroxene occurring in sample 01c01. This clinopyroxene crystallized in hot mantle conditions from a percolating calc-alkaline basaltic magma probably related to the Cretaceous supra-subduction setting of the amphibolites.

– The two other metasomatic events are evidenced by the orthopyroxene-rich and the amphibole-rich secondary parageneses occurring in four studied samples. The opx-rich paragenesis may be related to the circulation within the dunitic upper mantle of hydrous slab-

derived melts similar to those affecting the mantle peridotite xenoliths from Papua New Guinea and Kamchatka. Finally the amphibole-rich veins are probably related to the interaction between the studied dunite xenoliths and the host adakite (or an adakitic melt similar to it).

Acknowledgements

Fieldwork and laboratory studies have been conducted with the financial and logistic help of UP-Diliman, the DUO-France program, the Ministère des Affaires Etrangères (French Embassy in Manila), the SUCRI program “Asie du Sud-Est”, Université de Bretagne Occidentale, Brest and of the CNRS and Université Toulouse III. Helpful comments and reviews by Drs S. Arai and M. Roden led to significant improvements of the manuscript. We thank F. and P. de Parseval for their help with the making of the thin and thick sections and with the electron microprobe as well as R. Freydier and F. Candaudap who are in charge of the ICP-MS and associated laser items.

Figures

Fig. 1. Simplified geological map of the Baguio area in Northern Luzon, adapted from Yumul et al. (1995). The main tectonic features of Northern Luzon are shown in the inset. The ages of the geological formations are as follows: Pugo Metavolcanics: Eocene; Pico Formation and Klondyke Formation: Middle to Late Miocene; Mirador Limestone: Late Miocene.

Fig. 2. A), B) and C): Photomicrographs of the Monglo spinel dunite xenoliths: A) interstitial clinopyroxene between big olivine crystals (sample 01c01); B) a fibrous orthopyroxene-rich vein cross-cutting a dunite (sample 08jb). Note that a relict dunitic olivine occurs within the vein; C) an amphibole-rich vein (perpendicular view) cross-cutting a dunite (sample 08je). D): Field photograph of the Monglo quarry adakite and its xenoliths. The surface shown by the photograph is ca. 1 m². The host lava (white) contains numerous mafic and ultramafic xenoliths (grey to black) ranging in size from 1 to 10 cm.

Fig. 3. The spinels of the Monglo dunite xenoliths are plotted in the Cr# spinel vs Fo olivine diagram and they lie within the Olivine–Spinel Mantle Array (OSMA) (Arai, 1994). They also display similarities with the spinels occurring within the Iraya peridotites (Batan Island, Philippines; Arai et al., 2004) and those from the peridotites from the Philippines ophiolites ([Tamayo, 2001] and [Andal et al., 2005]).

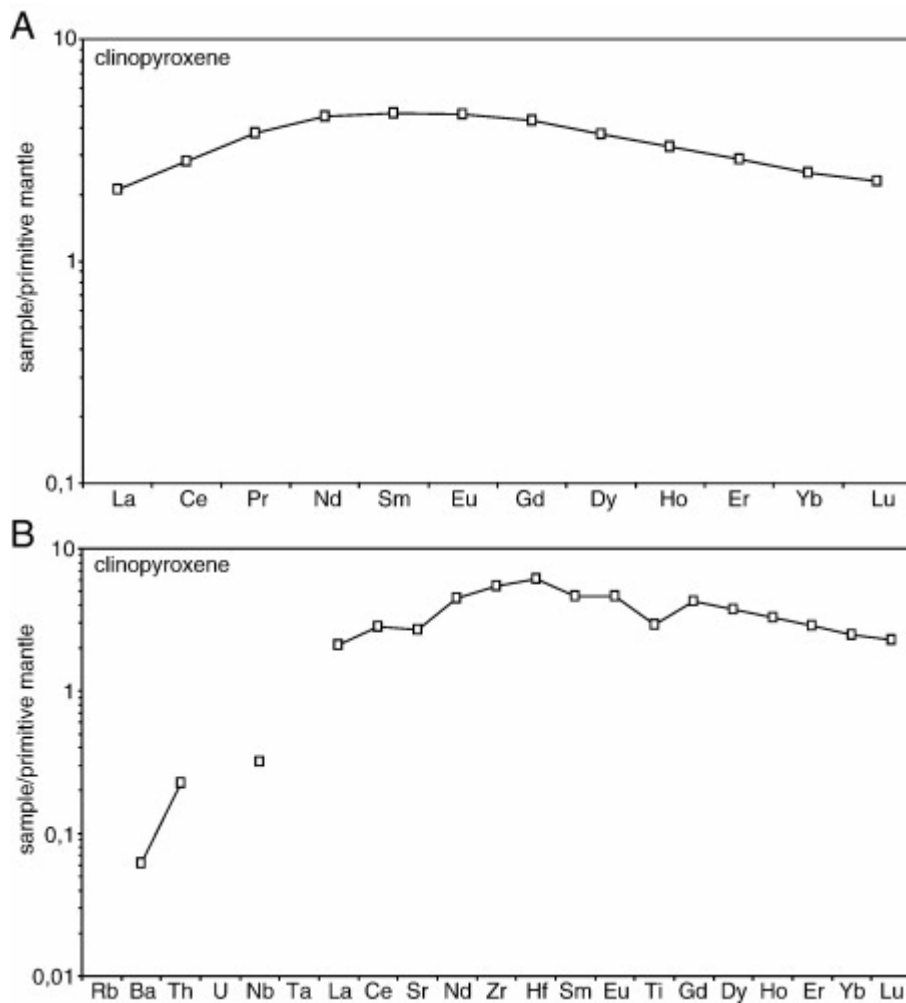

Fig. 4. Primitive mantle-normalized REE patterns (A) and incompatible trace element patterns (B) for clinopyroxene of Monglo dunite xenolith 01c01. Normalizing values after McDonough and Sun (1995). In primitive mantle-normalized trace element plots, the sequence of elements is related to their decreasing incompatibility during partial melting of upper-mantle peridotites (Sun and McDonough, 1989).

Fig. 5. Diagrams Na₂O vs SiO₂ and Na₂O vs Mg number ($100 \times \text{Mg}/\text{Mg} + \text{Fe}_{\text{total}}$) for amphiboles and TiO₂ vs Mg number for phlogopites of the Monglo spinel dunites (filled

squares) compared with the S-Amph and S-Phlogo (diamonds — subduction mantle amphiboles and phlogopites; the biggest diamond corresponds to the amphibole from Lihir peridotite; Grégoire et al., 2001), the I-Amph (crosses — intraplate mantle amphiboles) defined by Coltorti et al. (2007) and the experimental amphiboles of Prouteau and Scaillet (2003) filled circles, see Section 5.2 for explanation).

Fig. 6. Primitive mantle-normalized REE patterns (A) and incompatible trace element patterns (B) for fibrous orthopyroxenes of Monglo dunite xenolith 08ja compared to those of fibrous orthopyroxenes in spinel peridotite xenoliths from Lihir Island (samples 61-1ka and 61-1e, Papua New Guinea, Grégoire et al., 2001). Normalizing values after McDonough and Sun (1995).

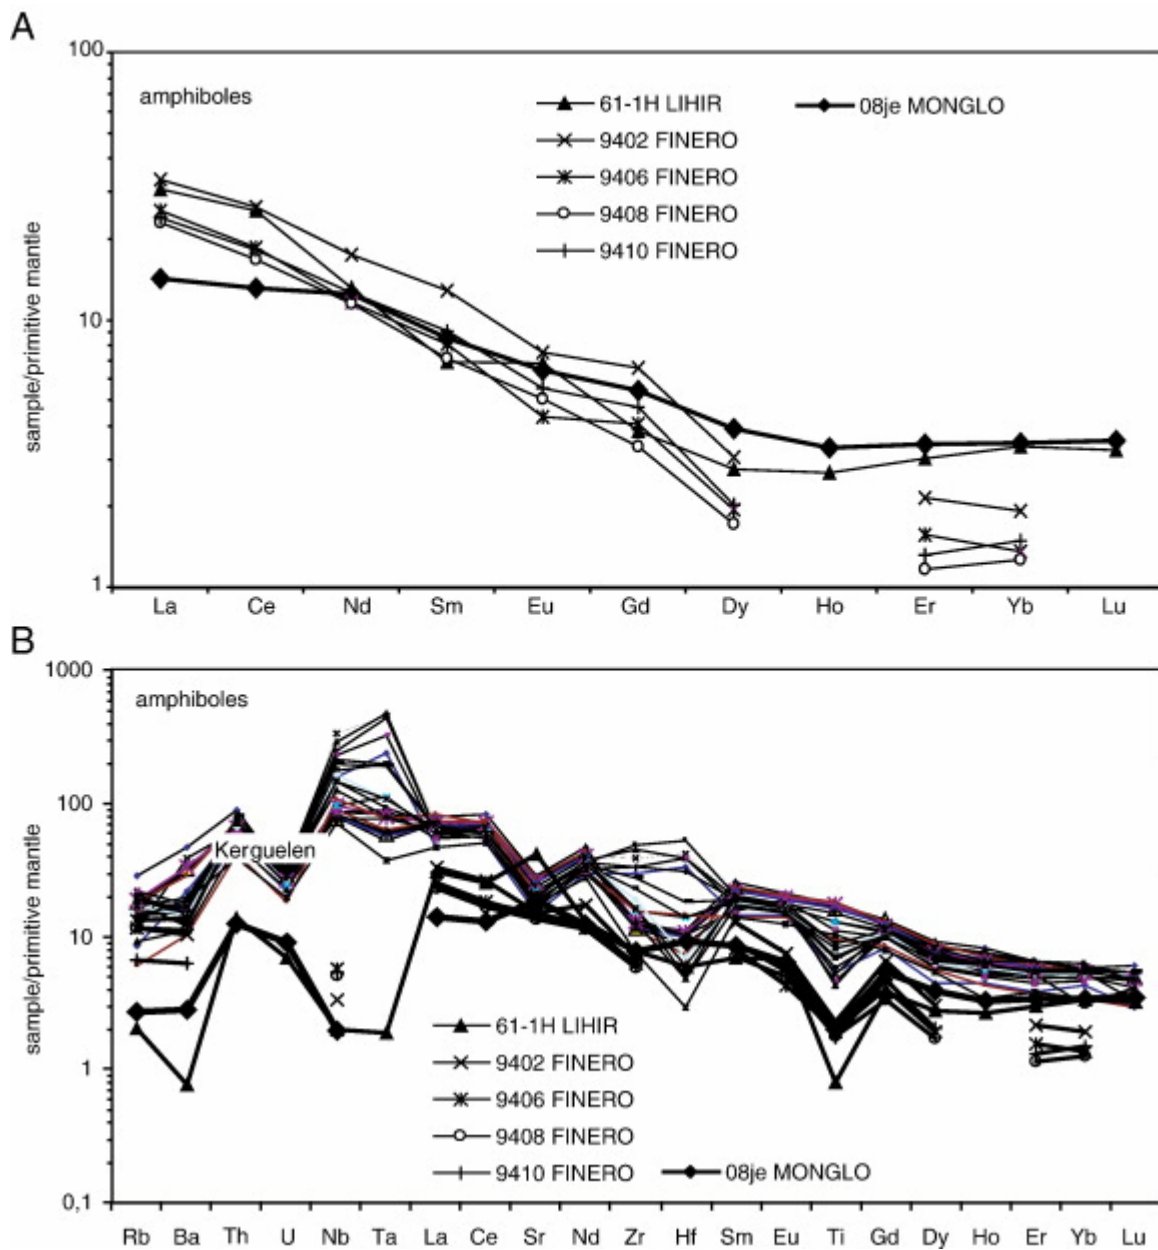

Fig. 7. Primitive mantle-normalized REE patterns (A) and incompatible trace element patterns (B) for amphiboles of Monglo dunite xenolith 08je compared to that of amphiboles in spinel peridotite xenoliths from Lihir Island (samples 61-1h, Papua New Guinea, Grégoire et al., 2001) those of amphiboles from peridotites from the Finero massif (samples 9402, 9406, 9408 and 94010, Italian alps, Coltorti et al., 2007) and those of amphiboles from the mantle xenoliths from the Kerguelen Islands ([Grégoire et al., 200] and [Moine et al., 2001]). Amphiboles from Lihir and Finero are Subduction mantle amphiboles (S-type of Coltorti et al., 2007) while those of Kerguelen are typical Intraplate mantle amphiboles (I-type of Coltorti et al., 2007). Normalizing values after McDonough and Sun (1995).

Fig. 8. Primitive mantle-normalized REE patterns (A) and incompatible trace element patterns (B) for the theoretical liquid in equilibrium with cpx of the Monglo dunite 01c01 (big diamonds, see Section 5.2 for the method of calculation) compared with the REE and TE contents of some basaltic rocks from the Luzon Arc (data from [Bau and Knittel, 1993], [Yumul et al., 2000], [Schiano et al., 1995], [Sajona et al., 1994], [Sajona et al., 1996], [Sajona et al., 1997], [Sajona et al., 2000a], [Sajona et al., 2000b], [Miklius et al., 1991] and [Pallister et al., 1996]). Normalizing values after McDonough and Sun (1995).

Tables

Table 1. : Averaged major element compositions of the minerals of the Monglo spinel dunites
