Abstract:

Chloride ingress and carbonation cause corrosion of reinforced concrete (RC) structures affecting its operational life. Experimental evidence indicates that these deterioration processes are highly influenced by CO_2 emissions and climatic conditions in the surrounding environment −i.e. temperature, humidity, etc. Since studies on global warming announce changes in climate, the impact of changing climate on RC durability should also be considered. This paper links RC deterioration mechanisms to CO_2 emissions and global warming. Based on various studies on climate change, models for estimating the effect of CO_2 emissions and temperature/humidity changes due to global warming are described. Furthermore, various scenarios of global warming that can be used to assess the effect of climate change in structural reliability are proposed. The proposed approach is then illustrated with a numerical example that calculates the probability of failure of a RC bridge beam for future climate scenarios. The paper then outlines some adaptation strategies, particularly focusing on the needs for risk-based selection of optimal adaptation measures.

Keywords: corrosion; reinforced concrete; chloride ingress; carbonation; global warming; reliability.

1. Introduction

Reinforced concrete (RC) structures are subjected to environmental actions affecting their performance, serviceability and safety. Among these actions, chloride ingress and carbonation lead to corrosion of reinforcing bars that reduces the service life of RC structures. Experimental evidence indicates that carbonation and chloride ingress are

highly influenced by environmental and climatic conditions of the surrounding environment –i.e. atmospheric CO_2 concentration, temperature, and humidity [1]. According to the International Panel of Climate Change (IPCC), the uncertainty of climate projections is high. The annual carbon dioxide concentration growth rate has increased from 1.4 ppm per year during the period 1960–2005 to 1.9 ppm per year during the period 1995–2005 [2]. Following the current patterns, studies have estimated that environmental CO_2 concentration could increase from 379 ppm in 2005 over 1000 ppm by the year 2100 [2]. The changes in environmental temperature, relative humidity and carbon dioxide concentration can increase corrosion risks resulting in more widespread corrosion damage and loss of structural safety. Consequently, the effect of atmospheric CO_2 concentration change and global warming on both chloride ingress and carbonation should be considered the long-term management of RC structures.

Climate change could affect directly or indirectly human communities and ecosystems in different ways – e.g., sea-level rise, increase in frequency and/or intensity of many extreme climate events, more frequent heat waves, increases in rainfall, etc. The impact of climate change on the performance of structures is becoming an important research issue from an engineering point of view. Moreover, risk-based methods are highly suited to assess the cost-effectiveness of climate adaptation measures. For instance, Bjarnadottir *et al*. [3] proposed a framework to refine hurricane risk assessment considering the impacts climate change on hurricane intensity and/or frequency. For RC structures, Bastidas-Arteaga *et al*. [4] proposed a stochastic approach to study the influence of global warming on chloride ingress, but this study only focused on the effect of climate change on the corrosion initiation stage. Stewart and Peng [5] carried out a preliminary risk and cost-benefit study on adaptation measures to mitigate the effects of carbonation of RC structures. Recent work also focused on the assessment of climate change on the durability of concrete structures in specific locations. Stewart *et al*. [6,7] and Wang *et al*. [8] studied the impact of climatic change on corrosion-induced damage in Australia. They proposed a probabilistic approach to assess corrosion damage (cracking and spalling) taking into account the influence of climate change on areas characterized by different geographical conditions. Talukdar *et al*. [9] estimated the effects of climate change on carbonation in Canadian cities (Toronto and Vancuver). They found potential increases in carbonation depths over 100 years of approximately 45%. However, this work did not consider the uncertainties related to climate, materials and models, nor did it predict the effect of carbonation on damage and safety of concrete infrastructure.

Within this context, the objective of this paper is to describe a new methodology for estimating the effect of increasing CO_2 concentrations and global warming induced changes in temperature and humidity on the durability and structural safety of RC structures. The first part of the paper presents models of chloride ingress and carbonation that could be used towards this aim. The following section focuses on modelling of effects of global warming on the environmental actions that affect the rates of chloride penetration and carbonation and RC corrosion. This section also includes the projected changes in temperature and humidity in relation to global warming scenarios. The paper then illustrates the effects of global warming on the structural reliability

(collapse limit state) of a RC bridge girder under chloride penetration. The final part of the study outlines some adaptation strategies for design and repair of RC structures accounting for climate change. The results presented in this study are based on the projections of global warming found in the literature [2,10–12]. In the regard, the conclusions outlined herein are not general. Instead, they should be interpreted as overall tendencies for given climate change scenarios.

2. Time-dependent performance of corroding RC structures

The assessment of corrosion effects on RC structures is a difficult task because several deterioration mechanisms interact in the process; ingress of the corroding agent –i.e., chlorides or carbon dioxide, corrosion of reinforcing steel and concrete cover cracking. The ingress of the corroding agent induces corrosion of the reinforcing bars. Corrosion reduces the structural capacity and the accumulation of corrosion products in the steel/concrete interface generates concrete cover cracking. The corrosion process is divided into two stages namely 'corrosion initiation' and 'corrosion propagation'.

2.1. Time to corrosion initiation induced by chloride ingress

The adopted chloride ingress model considers the interaction between three physical processes: *chloride ingress*, *moisture diffusion* and *heat transfer*. Each phenomenon is represented by a partial differential equation (PDE) expressed in the following general form [13]:

$$\zeta \frac{\partial \psi}{\partial t} = \underbrace{\operatorname{div} J}_{\text{diffusion}} + \underbrace{\operatorname{div} J'}_{\text{convection}} \tag{1}$$

where ς represents the studied parameter, t is the time and the correspondence between ψ, J, J' and the terms for the physical problem is presented in Table 1.

For chloride ingress, C_{fc} is the concentration of free chlorides, h is the relative humidity and D_c^* and D_h^* represent the apparent chloride and humidity diffusion coefficients, respectively:

$$D_c^* = D_{c,ref} \frac{f_1(T)f_2(t)f_3(h)}{1 + (1/w_e)(\partial C_{bc}/\partial C_{fc})} \tag{2}$$

$$D_h^* = D_{h,ref} \frac{g_1(h)g_2(T)g_3(t_e)}{1 + (1/w_e)(\partial C_{bc}/\partial C_{fc})} \tag{3}$$

where $D_{c,ref}$ and $D_{h,ref}$ are reference diffusion coefficients measured to standard conditions [1], w_e is the evaporable water content, and f_i and g_i are correction functions to account for the effects of temperature, relative humidity, aging and degree of hydration of concrete. These functions are detailed in [13]. The term $\partial C_{bc}/\partial C_{fc}$ represents the binding capacity of the cementitious system which relates the free and bound chlorides concentration at equilibrium. A Langmuir isotherm is used in this

work.

For moisture diffusion, the humidity diffusion coefficient D_h is estimated by accounting for the influence of the parameters presented in eq. (3). The term $\partial w_e/\partial h$ (Table 1) represents the moisture capacity which relates the amount of free water, w_e, and the pore relative humidity, h. For a given temperature this relationship has been determined experimentally by adsorption isotherms. According to the Brunauer-Skalny-Bodor (BSB) model, the adsorption isotherm depends on temperature, water/cement ratio, w/c, and the degree of the hydration attained in the concrete, t_e. This work adopts the BSB model to represent the moisture capacity.

Finally, for heat transfer (Table 1) ρ_c is the concrete density, c_q is the concrete specific heat capacity, λ is the thermal conductivity of concrete, and T is the temperature inside the concrete after time t.

The boundary conditions at the exposed surfaces consider the flux of ψ crossing the concrete surface, q'^s_ψ (Robin boundary condition) [1]:

$$q^s_\psi = \underbrace{B_\psi(\psi^s - \psi_{env})}_{\text{diffusion}} + \underbrace{\psi_{env}q'^s_\psi}_{\text{convection}} \tag{4}$$

where B_ψ is the surface transfer coefficient, ψ^s is the value of ψ at the exposed surface and ψ_{env} represents the value of ψ in the surrounding environment for each physical problem. The terms in eq. (4) are also presented in Table 1. By fitting experimental data, Saetta et al. [1] reported that BC_{fc} varies between 1 and 6 m/s. Typical values of B_h are in the range of 2.43-4.17×10^{-7} m/s [14]. Finally, Khan et al. [15] observed that B_T fluctuates between 6.2 and 9.3 W/(m^2°C).

The flow of chlorides into concrete is estimated by solving simultaneously the system of equations described by eq. (1) and Table 1. The numerical approach used to solve the coupled system of PDEs combines a finite element formulation with finite difference to estimate the spatial and temporal variation of C_{fc}, h and T. Then, the time to corrosion initiation, t_{ini}, is estimated by comparing the chloride concentration at the cover depth, c_t, with a threshold concentration for corrosion initiation C_{th}.

2.2. Time to corrosion initiation induced by carbonation

The carbonation depth (x_c in cm) may be predicted from **Erreur ! Source du renvoi introuvable.**, but corrected to allow for k_{urban} as:

$$x_c(t) = \sqrt{\frac{2D_{CO_2}(t)}{a}k_{urban}C_{CO_2}t}\left(\frac{t_o}{t}\right)^{n_m}$$

$$D_{CO_2}(t) = D_1 t^{-n_d} \qquad a = 0.75 C_e C_a O \alpha_H \frac{M_{CO_2}}{M_{C_aO}} \tag{5}$$

where C_{CO_2} is the mass concentration of ambient CO_2 (10^{-3}kg/m^3); k_{urban} is a factor to account for increased CO_2 levels in urban environments; $D_{CO_2}(t)$ is a time-dependent CO_2 diffusion coefficient in concrete; D_1 is CO_2 diffusion coefficient after one year; n_d

4

is the age factor t_0 is one year; C_e is cement content (kg/m^3); C_aO=0.65; α_H is a degree of hydration; M_{CaO}=56 g/mol and M_{CO_2}=44 g/mol. The age factor for microclimatic conditions (n_m) associated with the frequency of wetting and drying cycles is n_m=0 for sheltered outdoor conditions.

While eq. (5) was used by Yoon *et al.* [16] to predict carbonation depths for increases in CO_2 concentrations it needs to be recognised that eq. (5) is a point-in-time predictive model –i.e., the carbonation depth at time t assumes that C_{CO_2} is constant for all times up to time t. This will overestimate carbonation depth as CO_2 concentration will be gradually increasing with time up to the peak value. Stewart *et al.* (2002) considered this phenomenon and calculated carbonation depths due to enhanced greenhouse CO_2 conditions using the average CO_2 concentration over the time period, and not the peak value at time t –i.e., $C_{CO_2}(t)$. As such, eq. (5) can be rewritten as [6]:

$$x_c(t) \simeq \sqrt{\frac{2f_T(t)D_{CO_2}(t)}{a} k_{urban} \int_1^t C_{CO_2}(t)dt} \left(\frac{1}{t}\right)^{n_m} \tag{6}$$

where $f_T(t)$ considers the effect of temperature on carbonation using the Arrhenius Law [16,17]. A higher temperature will cause an increase in diffusion coefficient leading to increased carbonation depths. To be sure, Eqs. (5) or (6) are approximations, and there is a need for an improved carbonation model that considers the time-dependent effect of CO_2 concentration and other parameters such as temperature or humidity.

2.3. Corrosion propagation

After corrosion initiation, the diameter reduction of reinforcing bars induced by corrosion can be estimated in terms of a change in the volumetric rate by using Faraday's law:

$$d_u(t) = d_0 - 0.0232 \int_{t_{ini}}^t i_{corr}(t)dt$$

$$p(t) = 0.0116\alpha \int_{t_{ini}}^t i_{corr}(t)dt \tag{7}$$

where $d_u(t)$ is the residual diameter of the reinforcing bar at time t for uniform corrosion in mm, d_0 is the initial diameter of the bar in mm, and $p(t)$ is the pit depth at time t in mm, α is the ratio between pitting and uniform corrosion depths, and $i_{corr}(t)$ is the time-variant corrosion rate (μA/cm^2). The remaining cross-sectional area of steel for pitting corrosion is computed herein considering the relationships proposed by Val and Melchers [18]. Given the complexity of the corrosion process, i_{corr} depends on many factors such as concrete pH and availability of oxygen, and water in the corrosion cell. For instance, the optimum relative humidity for corrosion is 70-80%. This study considers the following time-variant corrosion rate model that takes into account the effect of temperature changes [17,19]:

$$i_{corr}(t) = i_{corr,20}[1 + K_c(T(t) - 20)]$$ (8)

where $i_{corr,20}$ is the corrosion rate at 20 ºC, $T(t)$ is the temperature at time t (in ºC) and K_c is a factor that depends on the value of $T(t)$. For instance, $K_c = 0.025$ if $T(t) < 20$ºC or $K_c = 0.073$ if $T(t) > 20$ºC. Corrosion rates are obtained from various sources [20]. For more details of carbonation-induced corrosion due to a changing climate see [5,6].

The LIFECON project proposes a more realistic model for corrosion rate that accounts for the actual concrete resistivity, the influence of chloride content, the galvanic effects and the availability of oxygen [21]. Given that the quantification of various parameters of such a model is partly missing, this work used the DuraCrete model to avoid including more model uncertainties into the problem. However, once more information becomes available, this model could improve the assessment of climate change effects on the corrosion propagation because it includes, among others, the effect of relative humidity variations.

3. Modelling global warming actions

3.1. Effects on climate: temperature and humidity

As mentioned previously, chloride penetration and carbonation are governed by diffusion coefficients that depend, among other factors, on the surrounding humidity and temperature. Therefore, it is necessary to implement a comprehensive model of weather (humidity and temperature). The basic science of weather modelling, including the greenhouse effect, is well understood and has been widely discussed. Nevertheless, given the difficulties of integrating a fully coupled model of weather with chloride ingress and carbonation phenomena, a simplified model of climate is presented in this section. It accounts for the following aspects:

- influence of global warming,
- seasonal variations, and
- random nature of weather within a season.

The change of temperature and humidity produced by global warming for the upcoming years is modelled by a linear time-variant function. By denoting ϕ as the weather parameter (humidity or temperature), the annual mean value of ϕ for a period of analysis t_a (i.e., $t_a = 100$ years) is:

$$\bar{\phi}(t) = \phi_0 + \left(\frac{\phi_{t_a} - \phi_0}{t_a}\right) t$$ (9)

where ϕ_0 and ϕ_a are the values of the annual means of humidity or temperature at the beginning of the analysis ($t = 0$ yr) and at the end of the reference period ($t = t_a$ yr), respectively. To take seasonal variations of humidity and temperature into consideration, the model divides the year into two seasons: hot and cold for temperature, and wet and dry for humidity. Actual forecasts of global warming also

indicate that the droughts increase the length of hot (or wet) seasons, L_h, with respect to the length of cold (or dry) seasons, L_c [2]. By defining R_0 as the normalized duration of the cold (or dry) season for $t=0$, i.e. $R_0=L_c/(1 \text{ year})$, and R_{t_a} as the normalized duration of the cold or dry season for $t=t_a$ (L_c in yr); it is possible to linearly estimate the normalized duration of the cold or dry season R for a given t:

$$R(t) = R_0 + \left(\frac{R_{t_a} - R_0}{t_a} \right) \lfloor t \rfloor \tag{10}$$

where $\lfloor t \rfloor$ represents the floor function. Thus by using a sinusoidal formulation to simulate the seasonal variation of ϕ around the linear trend (eq. (9), the seasonal mean of ϕ for hot of wet seasons is:

$$\bar{\kappa}(t) = \bar{\phi}(t) + \frac{\phi_{max} - \phi_{min}}{2} \sin \left(\frac{t - \lfloor t \rfloor}{1 - R(t)} \pi \right) \tag{11}$$

and for cold or dry seasons:

$$\bar{\kappa}(t) = \bar{\phi}(t) - \frac{\phi_{max} - \phi_{min}}{2} \sin \left(\frac{t - \lfloor t \rfloor}{1 - R(t)} \pi \right) \tag{12}$$

where ϕ_{max} and ϕ_{min} are respectively the maximum and minimum values taken by ϕ during one year and t is expressed in years.

To further improve the predictability of the assessments, it is important to implement a model that reproduces realistically temperature and humidity. Therefore, stochastic processes were used to represent the random nature of the weather parameters within a season. Taking into account the simplicity of the implementation and the computational time, the Karhunen-Loève expansion is appropriate to represent the weather variables. Let $\kappa(t, \theta)$ be a random process, which is a function of time t and defined over the domain $\mathbf{D}$ with θ belonging to the space of random events $\mathbf{\Omega}$; $\kappa(t, \theta)$ can thus be expanded as follows [22]:

$$\kappa(t, \theta) \simeq \bar{\kappa}(t) + \sum_{i=1}^{n_{kl}} \sqrt{\lambda_i} \xi_i(\theta) f_i(t) \tag{13}$$

where $\bar{\kappa}$ is the mean of the process (eqs. (11) and (12)), $\xi_i(\theta)$ is a set of normal random variables, n_{KL} is the number of terms of the truncated discretization, $f_i(t)$ are a complete set of deterministic orthogonal functions, and λ_i are the eigenvalues of the covariance function $C(t_1,t_2)$. Since closed-form solutions for $f_i(t)$ and λ_i are obtained for an exponential covariance [22], this study assumes that the processes of temperature and humidity have this kind of covariance.

Figure 1 presents a realisation of the stochastic process representing temperature, T, where the parameters for the time-variant mean (eqs. 8 to 11) are $T_0 = 5°C$, $T_{t_a} = 7.5°C$, $T_{min} = -10°C$, $T_{max} = 20°C$, $t_a = 100$ years, $R_0 = 50\%$, and $R_{t_a} = 40\%$. From the comparison between time-variant and stochastic models it is important to

highlight that although the stochastic realization follows the tendency of the time-variant mean, it includes the appearance of extreme values during the exposure time. This behaviour has been observed for real exposure conditions, and may contribute to higher corrosion damage.

This climate model can be used to represent the temperature or relative humidity for a given location. However, on real structures, structural components could be exposed to different climate exposures (solar radiation, wind, etc.) that will also affect deterioration. Although a comprehensive evaluation of climate change effects for a real structure should account for these microclimatic variations, this study focuses on the study of various exposure conditions and climate change scenarios for single components.

3.2. Increase of carbon dioxide emissions

The increase of actual atmospheric CO_2 concentration is difficult to model because it depends on several factors that differ for a particular problem. For instance, Stewart *et al* [23] found that the environmental CO_2 concentration in an urban environment could be approximately 5 – 10 % higher than CO_2 concentrations in a rural environment. CO_2 concentration in urban environments also depends on different factors such as: combustion of fossil fuels from traffic, domestic heating, power generation, etc. [5]. On the other hand, future carbon dioxide emissions will be determined by different socio-technical and political factors such as: population growth, economy, use of clean technology, etc. To account for these factors, the IPCC [2] defined four scenarios families of global warming (i.e., A1, A2, B1 and B2).

Figure 2 presents a projection from 1990 of atmospheric carbon dioxide concentrations for various global warming scenarios. This projection is based on the Model for Assessment of Greenhouse-gas Induced Climate Change [24]. The scenario A1F1 assumes a rapid economic growth, a stabilization of population growth in the mid-century, a rapid introduction of clean technologies and an intensive introduction of fossil sources of energy. The scenario A1B has similar assumptions excepting that there is a balance between consumption of fossil and non-fossil sources of energy. The values presented in Figure 2 show the IPCC predicted mean and 10th and 90th percentiles of CO_2 concentration to 2100, which can be used in eq. (5) for lifetime durability assessment for RC structures subject to carbonation.

3.3. Climate scenarios of global warming

This analysis defines three possible scenarios of global warming: *without*, *expected* and *pessimistic* global warming. The characteristics of the selected scenarios gather the information currently available and make consistent assumptions when needed [2,10–12]. A complete description of these considerations is given in [4]. The most important factors considered in such a study are: carbon dioxide, methane and nitrous oxide emissions; global population growth; introduction of new and clean technologies leading to the reduction of CO_2 emissions; and use of fossil sources of energy. Thus,

each scenario is defined in terms of:

- the difference between the annual means of temperature for the initial year $T(t_0)$ and the year of the end of the forecast $T(t_a)$, ΔT,
- the difference between the annual mean of relative humidity for $h(t_0)$ and $h(t_a)$, Δh, and
- the difference between the normalized durations of cold seasons for $R(t_0)$ and $R(t_a)$, ΔR.

By taking as reference a period of analysis of 100 years –i.e., $t_a = 100$ yr, the features and the values of ΔT, Δh and ΔR for each scenario are given in Table 2.

4. Numerical example

4.1. Problem description

This example evaluates the influence of realistic environmental conditions including global warming on the structural reliability of a simply supported RC girder placed in various chloride-contaminated environments. This girder has a span of 10 m and is subjected to a point (concentrated) wheel load placed in the middle of the span. Figure 3 presents the characteristics of the cross-sectional section that has been designed according to Eurocode 2 [25]. Its material design properties are described in Table 3 and the climatic conditions are defined by:

- two environments: oceanic and tropical (Table 4);
- three scenarios of global warming: without, expected and pessimistic (Table 2); and
- three levels of corrosion aggressiveness: low, moderate and high (Table 5).

The time to corrosion initiation considers flow of chlorides in one dimension where the Langmuir isotherm is used to account for chloride binding. The constants of the isotherm are α_L=0.1185 and β_L=0.09.

4.2. Probability of failure

The integration of the deterioration models presented in section 2 into a suitable probabilistic framework is necessary to perform efficient probabilistic lifetime assessments and reliability analysis. The cumulative distribution function (CDF) of the time to failure, t_f, is:

$$F_{t_f}(t) = \Pr\{t_f \leq t\} = \int_{t_f \leq t} f(\underline{\mathbf{x}})d\underline{\mathbf{x}} \tag{14}$$

where $\underline{\mathbf{x}}$ is the vector of random variables to be taken into account, and $f(\underline{\mathbf{x}})$ is the joint probability density function (PDF) of $\underline{\mathbf{x}}$. The cumulative failure probability, p_f, is then estimated by integrating the PDF of $\underline{\mathbf{x}}$ over the failure domain as:

$$p_f = \int_{g(\underline{x},t) \leq 0} f(\underline{x})d\underline{x} \tag{15}$$

where $g(\underline{x}, t)$ is the limit state function. Defining failure in terms of the limit state of bending, $g(\underline{x}, t)$ becomes:

$$g(\underline{x}, t) = M_f(A_s(t), \underline{x}) - M_e(P, \underline{x}) \tag{16}$$

where $A_s(t)$ is the residual cross-sectional area of reinforcement at time t, P is the applied load, $\underline{x}$ is the vector of random variables (i.e. concrete compressive strength, f'_c, yield stress, f_y, etc.), $M_f(A_s(t), \underline{x})$ is the bending moment capacity, and $M_e(P, \underline{x})$ is the bending moment due to the load P.

Closed-form solutions for both the CDF of the time to failure and the failure probability are very difficult to obtain. Therefore, Monte Carlo simulations and Latin hypercube sampling are used herein to deal with this problem. The probabilistic models used to estimate both failure probability and PDF of the time to failure are presented in Table 6. It is assumed that all the random variables are statistically independent. Probabilistic loading P is modelled by a random wheel load placed at the middle of the span.

For illustrative purposes, this example focused on the study of the effects of climate change under several environmental conditions defining failure only in terms of the limit state of bending. The study of the influence of other failure modes is beyond the scope of the paper. However, the results of the evaluation of the effects of climate change could change when the limit state function is defined in terms of other failure modes [4,6–8]. Therefore, although similar trends could be obtained for other failure modes, it is important to highlight that the conclusions of section 4.3 are only valid for the limit state function presented by eq. (16).

4.3. Results

The effect of three types of weather models are considered:

1. *Constant*: temperature and humidity are constant within any one year and adopts its annual mean value for modelling –e.g, from Table 4, $T = 15^{\circ}C$ and $h = 0.7$.
2. *Time-variant*: uses eqs. (11) and (12) to consider the seasonal mean variations of temperature and humidity.
3. *Stochastic:* accounts for the randomness of temperature and humidity within a season (eq. (13)).

The effect of weather models on the probability of failure is presented in Figure 4. These curves, obtained for the oceanic environment and the high level of corrosion aggressiveness, but do not consider the effect of global warming. In general, the failure probability is highly dependent on the type of weather model. Constant and time-variant models underestimate failure probabilities. For instance, a constant level of failure probability (i.e., p_f=0.5) is reached at 62, 77 and 120 years for stochastic, time-variant

and constant models, respectively. The time to failure is highly dependent on the time to corrosion initiation which is influenced by the type of weather model. Therefore, the selection of an appropriate weather model becomes a paramount issue in the computation of failure probability. These results support the use of a comprehensive model of chloride ingress including realistic weather models for an optimum lifetime assessment.

Figure 5 shows the failure probability of the beam for the tropical and the oceanic environments, and the three levels of corrosion aggressiveness for the stochastic weather model ignoring global warming. It is observed that the failure probability increases, in all cases, when the level of corrosion aggressiveness is higher. This increment is caused by higher concentrations of chlorides and corrosion rates in aggressive environments. If failure probabilities are evaluated for a lifecycle length of 50 years, the structural reliabilities are very low for the high level of corrosion aggressiveness. By considering that the failure probability should be lower than a critical value to ensure a safety level –i.e., $p_f < p_{ft} = 10^{-4}$, the studied structural configuration only guarantees this condition for moderate and low levels of aggressiveness. These results are not surprising because in real structures close to the sea as ports or quays, appreciable levels of deterioration have been reported after only 15 or 20 years of exposure. The results are similar for both environments. However, the failure probabilities are lower for the oceanic environment where the lower temperature and humidity delay corrosion initiation. This behaviour indicates that a sophisticated model of chloride ingress calibrated with experimental observations and monitored with inspections should be included in the management of structures to assure appropriate levels of serviceability and safety during its lifecycle.

The effects of weather and global warming on the PDF of time to failure are then evaluated. The PDFs for all the studied cases were adjusted from the Monte Carlo results where the selection criterion was the Kolmogorov-Smirnov test with a level of significance of 5%. For all cases, the best fitting corresponds to lognormal distributions. Tables 7 and 8 present the computed mean and standard deviation of the time to failure for the studied cases, for three climate scenarios using the stochastic weather model. It is observed that the mean time to failure decreases for more aggressive environments. The mean time to failure is lower for tropical than for oceanic environments. This behaviour seems logical because tropical environments are characterized by higher temperature and humidity that accelerate chloride ingress reducing corrosion initiation time. By taking as reference the scenarios without global warming, it is also noted that the effect of global warming is more important for structures located in oceanic environments. While for the tropical environment global warming induced reductions varying from 1.7% to 19.9% in the mean time to failure, for the oceanic environment this reduction ranges between 3% and 31%. It can be concluded that global warming has more influence in environments where humidity and temperature are characterized by important seasonal variations.

This example showed that climate change could lead to considerable reduction to the predicted time to failure. Other works have shown that climate change can

increase damage risks by up to 460% for carbonation-induced corrosion, and up to 15% for chloride-induced corrosion [4,8].

5. Adaptation strategies

Climate adaptation in terms of the enhancement of adaptive capacity can be done by developing new technologies and materials to counter the impact of increasing corrosion risk under a changing climate. On the other hand, there is a wide range of existing and 'low-tech' options that can enhance the durability of concrete structures and these can be applied to reduce the adverse affects of climate change. The design options generally include the selection of cover, concrete mix, surface coating barriers, extraction, and cathodic protection. In addition to reducing environmental exposure as much as possible, practical adaptation solutions in a new design may come from increasing cover and strength grade, or any approaches that reduce material diffusion coefficient without compromising the reliability and serviceability of concrete. Adaptation measures for new and existing concrete structures may include:

(1) Surface treatments,
(2) Realkanization,
(3) Extra design cover,
(4) Increase concrete durability,
(5) Stainless or galvanised steel reinforcement,
(6) Corrosion inhibitors,
(7) Cathodic protection, and
(8) Replace existing cover with new concrete.

The time of application is highly variable and dependent on extent and location of corrosion damage. Some adaptation strategies will be applied at time of construction (coatings/surface treatments, reinforcement), and others at time of corrosion initiation (realkanization, chloride extraction). Clearly, it is preferable to use adaptation strategies that are implemented during design and construction rather than in-service (e.g., when corrosion damage occurs) as the latter will be much more costly in terms of direct costs and inconvenience/user delays and other indirect costs (e.g., Stewart *et al.* [7]).

These adaptation strategies will have varying degrees of effectiveness and cost. Some will require regular maintenance over the life of the structure, such as surface treatments, which will increase their lifecycle cost. Given that there are many millions of new and existing concrete infrastructure in many countries the cost of adaptation can be immense. For this reason, a risk-based approach is needed to assess the optimal level, if any, of adaptation measures. This includes the cost, location, timing and extent of adaptation measures.

The increase in cover thickness can increase the time of carbonation and chloride ingress to reach concrete reinforcement and in turn delay carbonation and chloride-induced corrosion. It is therefore one of the most obvious and simplest adaptation options in the design of concrete infrastructure under a changing climate to

maintain structural durability and serviceability. While the change of cover is considered as the most straightforward design approach to reduce the impact of changing climate, other options may also include the selection or design of concrete materials to reduce the diffusion coefficient of deleterious substances –i.e. slow the ingress of those substances, and hence delay corrosion of concrete reinforcement. In practice, selection of a higher strength grade of concrete is one approach to reduce the diffusion coefficient, in addition to enhancing its mechanical properties.

Stewart and Peng [5] have conducted a preliminary lifecycle cost assessment to assess the cost-effectiveness of increasing design cover as an adaptation measure to mitigate the effects of carbonation of concrete. The lifecycle cost analysis considered costs associated with extra design cover and expected maintenance/repairs for typical RC structures and elements over the next 100 years considering several IPCC atmospheric CO_2 emission scenarios. The preliminary analysis found that lifecycle costs for the current situation ('do nothing' – use existing covers) are lower than lifecycle costs for proposed increases in design cover. This suggests that although enhanced greenhouse conditions will lead to increased carbonation-induced corrosion of RC structures it may not be cost-effective to increase design covers. However, a more detailed assessment of risks, costs, benefits of adaptation measures and environmental impact may reveal a different conclusion. What is important is the need to estimate time-dependent changes in damage risks, the effectiveness and cost of one or more adaptation measures, costs of repairing damage, and other criteria needed to assess the optimal level of adaptation measures both now and into the future.

6. Conclusions

This paper presented some considerations to assess the effects of global warming on the durability of corroding RC structures subjected to chloride ingress or carbonation. The first part of this paper described the deterioration models that can be used for modelling this interaction. Afterwards, the discussion focused on modelling the effects of global warming on the environmental factors that could alter the kinematics of the deterioration process (temperature, humidity and CO_2 concentrations). The proposed methodology is illustrated with a numerical example that studies the effects of climate change on the structural reliability and time to failure of a RC bridge girder placed in a chloride-contaminated environment. The results showed that global warming can reduce the time to failure by up to 31%, or shorten service life by up to 15 years for moderate levels of aggressiveness. The final part of the paper outlined different adaptation strategies that can be used to mitigate the effect of deterioration processes and global warming on structural safety. It is concluded that an optimal adaptation strategy should be selected by considering its risks, costs, benefits and environmental impact.
