## **Abstract**

The hardened ordinary Portland cement (OPC) surface layer of concrete which was glazed using a CO<sub>2</sub> and a high power diode laser (see Part I of this paper) has been tested in order to determine the mechanical, chemical and physical characteristics of the glazes. The work showed that the generation of the surface glazes resulted in improved mechanical, chemical and physical properties over the untreated OPC surface of concrete. However, differences in the performance of the CO<sub>2</sub> and HPDL generated glazes were observed. These are believed to be due to the differences in the morphology and microstructure of the glazes generated as a result of the differing beam absorption characteristics of the two lasers. Life assessment testing revealed that the laser glazed OPC surfaces effected an increase in actual wear life of 1.3 to 17.7 times over the untreated OPC surface of concrete depending upon the corrosive environment.

*Keywords:* CO<sub>2</sub> laser; High power diode laser; Concrete; Cement; Surface glazing; Properties

## **1. Introduction**

Building and civil engineers alike employ concrete in a broad area of applications. Over time, however, and as a direct consequence of the operating environment the concrete becomes corroded and/or contaminated. This ultimately necessitates the arduous and costly undertaking of repairing or replacing the affected concrete either by physical or mechanical means. Clearly, any means by which the life of the concrete can be extended would be of great interest to engineers.

As has been demonstrated in Part I of this paper, both the CO<sub>2</sub> laser and the high power diode laser (HPDL) are feasible tools to produce a glaze on the hardened ordinary Portland cement (OPC) surface of concrete. However, marked differences in the characteristics of the glazes generated on the OPC surface of concrete when treated with CO<sub>2</sub> laser and HPDL radiation were clearly apparent. This part of the paper reports on the comparative testing of the CO<sub>2</sub> and HPDL generated glazes in terms of their mechanical, chemical and physical properties, as well as a comparison with the untreated OPC surface properties. Mechanical tests were conducted to determine such properties as pull-off (bond) strength, rupture strength, wear resistance and absorptivity to water. Additionally, chemical tests were carried out to examine the corrosion resistance of the laser glazed and untreated OPC with regard to acid (nitric acid) alkali (sodium hydroxide) and common industrial detergent. Life assessment testing of the laser glazed and untreated OPC was also carried out.

## **2. Experimental procedures and results**

Current British and international standards in relation to concrete and coated concrete are concerned only with water sorptivity and compressive strength. No British or international standards exist regarding the testing of glazed concrete. It was therefore generally not possible to test the CO<sub>2</sub> and HPDL generated glazes in strict accordance with established tests. As such, wherever possible tests based on current standards or the work of others were developed to investigate specific aspects of particular relevance to the laser generated glazes. These aspects were: the pull-off strength; the surface roughness; the rupture strength; the wear resistance and the corrosion resistance.

### *2.1. Pull-off strength*

To determine the strength of the bond between the CO<sub>2</sub> and HPDL generated glazes on the OPC surface and the concrete substrate itself, pull-off tests were conducted based on the work of Bungey et al. [1] and Carino [2]. For experimental convenience the concrete was prepared as relatively small area samples (25 mm x 25 mm). High tensile aluminium test dollies were then attached onto both the glazed surface, and to the axially opposite concrete substrate surface, using Araldite epoxy and left to cure for 24 hours. The diameter of the test dollies was 12 mm. In order to ensure axial accuracy (essential for true results) the test dollies were set in position using identical V-blocks. The samples were placed into an Instron 4507 tensile/compressive test rig by mounting the test dollies into the jaws of the rig. A tensile force was then applied until sample failure, with the force being simultaneously recorded.

As Fig. 1 shows, the results obtained varied markedly with both changes in the laser operating parameters and, perhaps more importantly, with the laser used. A post-test analysis of both the CO<sub>2</sub> and HPDL generated surface glazes on the OPC surface revealed that the material failed well below the laser treated surface, within the heat affected zone (HAZ). As is evident from Fig. 1, when using laser operating parameters that produced good quality glazes with both lasers (1.5 kW cm<sup>-2</sup> power density, 480 mm min<sup>-1</sup> traverse speed), the average maximum pull-off force required for the CO<sub>2</sub> laser generated glaze was recorded as 40.3 N, whilst the for the HPDL generated glaze the force required was 235.6 N. This compares with 636.8 N for the untreated OPC surface of concrete.

## *2.2. Rupture strength*

In order to determine the rupture strength of the CO<sub>2</sub> and HPDL generated OPC glazes test samples were prepared as described above. The samples were placed onto the sample stage of the Instron 4507 tensile/compressive test rig and then subjected to a compressive rupture force until the OPC glazes failed (cracked), with the energy being simultaneously recorded. The rupture force was applied by means of a high tensile steel indenter with a 1 mm radius point. The results of the tests revealed that the average rupture strength of the CO<sub>2</sub> and HPDL generated OPC glazes were very similar, only 0.82 and 0.8 J respectively. In contrast, the rupture strength of the untreated OPC surface was some 4.3 J. This is perhaps to be expected as the OPC surface has been partially (CO<sub>2</sub> laser) and fully (HPDL) vitrified, effectively generating a glass.

## *2.3. Water absorptivity testing*

In order to test the absorptivity of the CO<sub>2</sub> and HPDL generated OPC glazes, a series of comparative experiments with the untreated OPC surface were conducted in terms of water absorptivity. The tests were conducted in accordance with the standard procedure employed by Hall et al. [3] and Wilson et al [4]. For the experiments the laser treated and untreated OPC samples were cut into smaller pieces (25 mm x 25 mm). The samples were then dried to a constant weight in an air oven at 65°C to ensure all the pores were free of water. The OPC laser glazes and the untreated OPC surfaces were then immersed in water and weighed at regular intervals. The side faces of the three samples were shielded from the water by means of an Araldite coating. In order to determine the absorptivity of the OPC laser glazes and the untreated OPC surface,  $i$  was plotted against the square root of time so as to give a straight line, as shown in Fig. 2.  $i$  is defined as

$$i = \frac{1000\Delta m}{A} \quad (1)$$

where  $\Delta m$  is the cumulative change in mass with time and  $A$  is the immersed surface area. The sorptivity,  $s$ , of the laser generated OPC glazes and the untreated OPC surface is simply the gradient of this line.

As one can see from Fig. 2, the sorptivity of the untreated OPC surface was a typical 0.096 mm min<sup>-1/2</sup>, compared with 0.047 mm min<sup>-1/2</sup> and 0.043 mm min<sup>-1/2</sup> for the CO<sub>2</sub> and the HPDL glazed OPC surfaces respectively. It is therefore reasonable to conclude from this that both the laser generated glazes provided approximately twice as much resistance to water absorption than the untreated OPC surface. In addition, it is a distinct possibility that the HAZ, which was identified as being composed of CaO resulting from the dehydration of the Ca(OH)<sub>2</sub>, may, once re-hydrated, act as a barrier towards liquids such as water. In this way the HAZ may therefore augment the resistance of the laser glazed OPC surface to water absorption.

#### 2.4. Wear life characteristics

Generally, the wear resistance of a material is primarily determined by the hardness of the material in comparison with that of other materials with which it subsequently comes into contact with [5]. However, wear resistance does not always increase with hardness [6]. Tests were therefore conducted in accordance with the procedure detailed by Petitbon et al. [7] and Lawrence et al. [8] to determine the exact difference in the wear resistance characteristics between the CO<sub>2</sub> and HPDL generated OPC glazes, as well as those of the untreated OPC surface. For experimental purposes the OPC was cut

into smaller pieces (25 mm x 25 mm), with half of the samples then being laser treated. All the samples were then weighed and subjected to a friction force for a total of 8 h, being removed from the machine and weighed at two hourly intervals.

Fig. 3 shows the relationship between weight loss and the friction time for the laser generated OPC glazes and the untreated OPC. As one can see, the wear resistance of the HPDL generated OPC glaze is fractionally greater than that of the CO<sub>2</sub> laser generated OPC glaze. However, both the OPC laser glazes displayed a significant increase in wear resistance over the untreated OPC surface, with the weight loss being approximately 2 times lower after 4 h, and 3 times lower after 8 h.

### *2.5. Corrosion resistance*

Concrete surfaces are often subjected to corrosive substances, either as part of the normal service environment and/or as a result of routine cleaning. Therefore, corrosion resistance tests based upon BS 6431 [9] were conducted using nitric acid, sodium hydroxide and Premier Products MP9 detergent cleaner. The experiments were carried out by dropping small amounts of the corrosive agents on to the surface of the CO<sub>2</sub> and HPDL glazed OPC surfaces, as well as the untreated OPC surface of the concrete, at hourly intervals for four hours. The reagents were applied in the concentration ratios of 80%, 60%, 40%, 20% and 10%. The samples were then examined optically, as well as being mechanically tested in terms of compressive strength and wear. High concentrations of the various corrosive agents were used principally to accelerate the tests. However, in practice 60% nitric acid is used within the nuclear processing industry as a solvent for nuclear fuels [10].

All three substances in the concentrations 80%, 60% and 40% were seen to immediately attack the untreated OPC surface, with the nitric acid and sodium hydroxide attacking with greater severity than the detergent. On the other hand, both the CO<sub>2</sub> and HPDL glazed surfaces displayed no discernible microstructural changes or signs of devitrification due to corrosion.

Tests conducted according to ASTM C579-91 [11] revealed that exposure of the untreated OPC surface to the reagents had a significant effect on the compressive strength and the wear resistance of the OPC. Exposure of the OPC to nitric acid and sodium hydroxide in the concentrations 40-80% resulted in an average loss of compressive strength of approximately 19-37%. In the case of the detergent a discernible loss in compressive strength only occurred with concentrations above 40%. Here the average loss in compressive strength for concentrations in the range 60-80% was approximately 17%. This compares with no discernible difference in either the wear resistance or the

compressive strength of the laser glazed OPC surfaces. Similarly, the wear resistance of the untreated OPC surface when exposed to the reagents with an 80% concentration was significantly affected, particularly through interaction with the nitric acid and the sodium hydroxide. Here the weight loss was approximately 5 times higher than for the unexposed OPC after 4 h, and approximately 11 times higher after 8 h for the nitric acid. In the case of the detergent the weight loss was marginal after both 4 and 8 h.

### 3. Discussion

As the results of the mechanical and chemical tests show, the CO<sub>2</sub> and HPDL generated OPC glazes out performed the untreated OPC surface in many of the test areas. This was especially true in the case of chemical resistance, where both of the OPC laser glazes proved to be resistant to both in the time of the experiments. This marked variation in corrosion resistance can be ascribed to the difference in structure of the laser generated OPC glazes and the untreated OPC. Whereas the HPDL generated OPC glaze is of a fully amorphous nature, and the CO<sub>2</sub> laser OPC glaze is of a semi-amorphous nature, the untreated OPC is comprised of a porous polycrystalline structure. Thus the untreated OPC is readily attacked by acids, whilst the amorphous structure of both OPC laser glazes ensures an increase in acid resistance [12].

The superior mechanical and chemical performance of the laser generated OPC glazes over the untreated OPC suggests that the life characteristics of the glazes may also be superior to those of untreated OPC. Yet in any practical analysis of the wear life of materials, the in-situ relative thicknesses of the materials must be considered. Consequently the laser generated OPC glazes and the untreated OPC layer on concrete must be taken into consideration in any calculations in order to give a true interpretation of the actual life characteristics. Thus the increase in wear life can be given by

$$\text{Increase in wear life} = \frac{\text{Laser glaze wear life}}{\text{Untreated OPC wear life}} \quad (2)$$

where,

$$\text{Wear life} = \frac{\text{Density} \cdot \text{Thickness (mg.cm}^{-3}\cdot\text{cm)}}{\text{Wear rate (mg.cm}^{-2}\cdot\text{h}^{-1})} \quad (2a)$$

Table 1 summarises the wear rate details and the nominal life increase of both the CO<sub>2</sub> and HPDL generated OPC glazes over the untreated OPC surface. As Table 1 shows, the laser generated OPC

glazes gave an increase in actual life over the untreated OPC surface regardless of the environment. Nonetheless, as one can see from Table 1 the increase in actual life of the laser generated OPC glazes over the untreated OPC surface varies considerably depending upon the working environment. However, arguably the most common working environment for an OPC surface would involve some contact with at least detergent acids, therefore significant economic savings may be yielded since a OPC surface glazed with either laser lasts around 2.5-times longer than one which is unglazed. Furthermore, as Fig. 3 and Table 1 both show clearly, the wear rate and the wear life of the HPDL generated glaze was, although similar in value, consistently higher than that of the CO<sub>2</sub> laser generated glaze. This is believed to be due to the effects of the greater occurrence of porosities, in particular the 'knife edge' porosities discussed in Part I of this paper, which are prone to excessive wear. Consequently, the wear rate of the CO<sub>2</sub> laser glaze will therefore be somewhat higher than that of the HPDL glaze.

Of great importance is the resistance to water absorption afforded the concrete as a result of laser glazing with both the CO<sub>2</sub> and the HPDL. As Fig. 2 suggests, the CO<sub>2</sub> laser glaze offered slightly less resistance to water absorption than the HPDL glaze. Again, this is likely to be due to the greater prevalence of not only porosities, but cracks, in the CO<sub>2</sub> laser glaze which will inherently allow more water to permeate through the glaze and be absorbed by the concrete.

As is evident from Fig. 1, surface glazing of the OPC with either laser effected a considerable decrease in the pull-off strength in comparison with the untreated OPC surface of the concrete. However, a significant difference between the required pull-off force of the CO<sub>2</sub> and the HPDL glazed surfaces was apparent, 40.3 N compared with 235.6 N respectively. This marked difference can perhaps be attributed to the fact that the HAZ generated on the OPC after CO<sub>2</sub> laser glazing was much larger than that generated as a result of HPDL glazing (see Part I of this paper). Thus, a larger dehydrated and CaO rich area is generated which is therefore inherently weaker.

#### **4. Conclusion**

A comparative study of the mechanical, chemical and physical properties of the surface glaze generated on hardened ordinary Portland cement (OPC) paste by means of CO<sub>2</sub> and a high power diode laser (HPDL) radiation has been conducted. Furthermore, the performance of both laser generated glazes has been compared with that of the untreated OPC surface. It was found that: (i) The

required pull-off force after laser glazing was reduced from 636.8 N to 235.6 N after HPDL glazing and 40.3 N after CO<sub>2</sub> laser glazing. The general reduction in required pull-off force after laser glazing is believed to be due to the inherent generation of a heat affected zone (HAZ) comprising mainly of weaker CaO. Similarly, the marked difference between the pull-off strength of the CO<sub>2</sub> and HPDL glaze can be attributed to the fact that the HAZ after HPDL glazing was much smaller than that of the CO<sub>2</sub> laser glaze. (ii) The average rupture strength of the CO<sub>2</sub> and HPDL generated OPC glazes were very similar, 0.82 and 0.8 J respectively, whilst the rupture strength of the untreated OPC surface was some 4.3 J. This is because laser glazing of the OPC surface has resulted in partial (CO<sub>2</sub> laser) and full (HPDL) vitrification, effectively generating a glass. (iii) Laser glazing of the OPC surface afforded the concrete approximately twice as much resistance to water absorptivity than the untreated surface, 0.096 mm min<sup>-1/2</sup> compared with 0.047 mm min<sup>-1/2</sup> and 0.043 mm min<sup>-1/2</sup> for the CO<sub>2</sub> and the HPDL glazes respectively. The slightly higher water absorptivity of the CO<sub>2</sub> laser glaze is likely to be due to the greater prevalence of porosities and cracks in the CO<sub>2</sub> laser glaze; which will inherently allow more water to permeate through the glaze and be absorbed by the concrete. (iv) Life assessment testing revealed that surface glazing of the OPC with both the CO<sub>2</sub> and the HPDL effected an increase in wear life of 1.3 to 17.7 times over an untreated OPC surface, depending upon the corrosive environment. The wear life and the wear rate of the HPDL glaze was consistently higher than that of the CO<sub>2</sub> laser glaze. (v) Both the CO<sub>2</sub> and HPDL glazed OPC surfaces displayed no discernible microstructural changes or signs of devitrification resulting from exposure to corrosive agents. In contrast, the corrosive agents were seen to immediately attack the untreated OPC surface. Clearly, the economic and material benefits to be gained from the deployment of such an effective and efficient coating on OPC could be significant.
