Abstract

The tower is located on a promontory on the south-western Gulf of Cagliari, near to the Coltellazzo island and the archaeological Punic-Roman of Nora.

The first military settlement was probably present since the beginning of the fourteenth century. Surely the tower was active since 1607. Jorge Aleo (1680) mentions, calling Fortalleza Coltellaz. In the eighteenth century the building was engulfed in a fort, built in a period of six years (1722-1728) by engineer the Piedmont Antonio Felix de Vincenti. Later (in the nineteenth century) further work was carried out until the tower became a lighthouse.

The tower was considered a tower de armas or vigorous, or for heavy defense, with a garrison of men under a commander. Being a watch tower, is in sight of the towers of Cala d'Ostia, San Macario and the Diavolo. The tower has a structure of a truncated cone, with a height of about 11 meters high and 12 meters in diameter at the base. Inside it has a double ribbed vaulted dome, supported by a central pillar.

The aim of this research is were studying mortars and geomaterials used of the ashlar, for define: i) composition of ancient mortars with ratio binder/aggregate; ii) provenance of the raw materials used in the mixture of mortars; iii) alteration processes in progress on mortars and on geomaterials used in masonry.

Through the analysis of the physical-mechanical properties, important evidences of chemical and physical decay were highlighted in the mortar of the plasters coating the tower and also in bedding mortars of ashlar of masonry. In some areas, where they are concentrated processes of physical disintegration, also as a result of dissolution of the carbonate matrix of the mortar, show scarce resistance physical-mechanical with consequent detachment from the masonry.

Keywords: Fortification, Physical decay, Chemical alteration, Nora, Geomaterials.

1. Introduction

The coastal tower of Coltellazzo (XVII cent.), (Fig. 1,2) situated into the Nora archaeological area, is a major maritime tower of southern Sardinia (Italy), as well as artifact of historical strategy for the island. The study of this monument is extremely useful for understanding its construction methods and the choice of geomaterials (stones and mortars) used for edification. All these information allow to direct a plan for possible restoration of the monument.

To perform the physical and petrographic characterization of geomaterials, several samples were collected from structure of tower. The sampling puts attention for the parts exposed or not to chemical and physical decay, due not only to different petrophysical characteristics of rocks, but also different micro-environmental conditions. In this article were analyzed different rock types and some constructive mortars, by applying different archaeometric study

techniques for mineralogic-petrographic and physical characterization. This article also contains geological and geomorphological information of area's building construction and the origin of the materials used.

2. Historical informations and architecture of monument

The Coltellazzo tower, built near the remains of the acropolis of Nora, became operational in 1607, although the existence of a previous military settlement reached by the beginning of the fourteenth century (Rassu, 2005). Jorge Aleo, in 1680, mentions the tower, calling it as Fortalleza Coltellaz (Fois, 1981). In the eighteenth century the building was engulfed in a fort, built between 1722 and 1728 by engineer Piedmont Antonio Felice de Vincenti (Mondaldo 1992). Additional work was carried out in the nineteenth century, when the tower was equipped with a beacon. The Coltellazzo tower is architecturally similar to the nearby tower of St. Macario with column and ridges to support

the vault. Coltellazzo tower is built on a hill of volcanic rock about 35 m high with a diameter of 14 meters (Mele, 2000). It has a conical shape with walls inclination of approximately 5°(fig. 3,4) The height of the tower was modified than the original article at the beginning of '900 to allow the realization of 4 meters high volume for a beacon station (Pillosu, 1957, 1959). This structure removed some characteristic architectural elements of the original terrace caused over time several settlements of the below structure (Rassu, 2000).

3. Materials e methods

3.1 Sampling

The preliminary sampling was done taking on the site samples for each lithology and all kinds of mortars (*i.e.*, bedding mortars of irregular stones and regular ashlars, plasters from outer surface of tower). They were taken 4 samples of granitoid rocks, 6 volcanic rocks (mainly with andesitic composition), 7 sedimentary rocks (*i.e.*, sandstone, conglomeratic rocks, etc.,

according to the particle size coarse, medium and fine), 4 samples of bedding mortars of the ashlars, 5 samples of plasters (3 of *arriccio/rinzaffo* layer and 2 of *finiture* layer) for a total of 26 samples. The sampling is occurred so as to uniformly cover the structure so as to identify any differences between samples related to different degree of alteration as function of exposure to weathering processes.

3.2 Methods

Petrographic determinations of mineralogical composition were carried out on polished thin sections by optical polarised microscopy Leitz Wetzlar. The physical tests were determined on specimens dried at $105 \pm 5^\circ\text{C}$ and after the dry solid mass (m_D) was determined. The solid phases volume (V_S) of powdered rock specimens (on 5-8 g and with particle size less than 0.063 mm) and the real volume (with $V_R = V_S + V_C$, where V_C is the volume of pores closed to helium) of the rock specimens were determined by helium Ultracycrometer 1000 (Quantachrome Instruments). Then, the wet solid mass (m_W) of the samples was determined after water absorption by immersion for ten days. Through a hydrostatic analytical balance, the bulk volume V_B (with $V_B = V_S + V_O + V_C$, where $V_O = (V_B - V_R)$ is the volume of open pores to helium) is calculated as:

$$V_B = [(m_W - m_{HY}) / r_W T_X] \cdot 100$$

where m_{HY} is the hydrostatic mass of the wet specimen and $r_W T_X$ is the water density at a temperature T_X . Total porosity (Φ_t), open porosity to water and helium (Φ_{H_2O} ; Φ_{He} , respectively), closed porosity to water and helium (Φ_{CH_2O} ; Φ_{CHe}), bulk density (ρ_B), real density (ρ_R), solid density (ρ_S) were computed as:

$$\Phi_t = [(V_B - V_S) / V_B] \cdot 100$$

$$\Phi_{H_2O} = \{[(m_W - m_D) / \rho_W T_X] / V_B\} \cdot 100$$

$$\Phi_{He} = [(V_B - V_R) / V_B] \cdot 100$$

$$\Phi_{CH_2O} = \Phi_t - \Phi_{H_2O}$$

$$\Phi_{CHe} = \Phi_t - \Phi_{He}$$

$$\rho_S = m_D / V_S$$

$$\rho_R = m_D / V_R$$

$$\rho_B = m_D / V_B$$

The weight imbibition coefficient (IC_W) and the saturation index (SI) were computed as:

$$IC_W = [(m_W - m_D) / m_D] \cdot 100$$

$$SI = (\Phi_{H_2O} / \Phi_{He}) = \{[(m_W - m_D) / \rho_W T_X] / V_O\} \cdot 100$$

4. Geological and geomorphological context

The area of the Pula-Sarroch plain, which is a coastal strip of the campidanese graben (Cherchi and Montadert, 1982), consisting of Paleozoic reliefs of eastern Sulcis. The yielding of these mountains has led to the formation of alluvial and slope deposits during the Quaternary glacial modeled along the fault surface to the east towards the sea, while downstream such deposits slope gently towards. The morphological differences are due to quaternary eustatic changes: the river terraces river to climate change. The elevations of the plain have no special heights but characterize the coastline with bays and headlands. The elevation in which Nora stands, from a geographical point of view, is originated from an ancient volcanic island connected to the mainland by a sandy pillow of modest size and shapes not particularly evident established through leveling of wind and waters.

The promontory on which the tower was built, presents a substrate made up of volcanic rocks formed by andesitic lavas and volcanic gray purple breccias belong to Oligo-Miocene volcanic cycle occurs in Sardinia between 32-11 Ma (Beccaluva et al., 1985, 1989). La Marmora (1840), who studied this area, described volcanic rocks alternating with beddings lithologically more compact defined respectively "conglomerates" and "lava". It has also highlighted the presence of zeolites and veins of calcium carbonate and quartz. In addition to various volcanic rock types found in the Nora area it is reported also the presence of Paleozoic granitoids, sandstones and clays of Cixerri fluvial-deltaic formation and quaternary marine and continental deposits.

5. Petrographic characterization

5.1 Distribution of lithologies on tower

The structure of the tower in the basal part (stepped area) consists of a series of three steps

made through the use of a 80% of blocks of andesite with size up to 50 cm, 15% of sedimentary rocks in blocks up to 30 cm and 5% of granitoids with predominantly sub-spherical forms probably attributable to fluvial blocks. In sloping walls used lithologies are the same than the basement but there is a higher frequency of use of sandstone (80% of the blocks) 15% volcanic rock and a 5% of granitoids. It should be specified that in the sloping walls there is the presence of a first row (fig. 5) of square and worked sandstone blocks (side about 40 cm) coming probably from the dismantling of an earlier building in the neighboring area of Nora. Over the first row until the light room instead it detects a chaotic presence of irregular stone blocks dimensionally and unworked whose size is about 1/5 of the sandstone blocks of the first row (fig. 6).

Fig. 5- First row of sandstone block

5.2 Physical and petrographic characteristics

The Oligo-Miocenic volcanic rocks used for the tower mainly consist in two facies. A first have mainly dacitic composition with porphyritic structure (I.P.=8-12%) with opaque crystals, plagioclase, orthopyroxenes, amphiboles, and \pm quarzo, \pm biotite in groundmass. This facies shows porosity value range from 18-20% in samples not altered to 20-26% in samples more altered, with values around 35% in the samples with strong physical decay by weathering. The bulk density varies from 2 to 2,1 g/cm³.

The Oligo-Miocenic volcanic rocks of Sardinia were widely used in Roman period for make tools (Antonelli et al., 2014) or for construction

materials. For example, are used for cavea of the Roman theatre of Nora (Melis and Columbu, 1998), near to the tower, extracting from volcanic structure of "Su Casteddu", north of Pula city.

Fig. 6- Andesites, granitoid rocks and sandstones in a external wall

A second volcanic facies consists in andesites, lati-andesites, with opaque phenocrysts, plagioclase, orthopyroxenes, amphiboles (Marchi et al., 2002). These rocks have a lower porosity (ranging within 10-20%) and so greater bulk density ($>2,1$ g/cm³).

The sedimentary rocks show silico-clastic component with a particle size ranging from conglomerates to siltstones. The siltstones are reddish-purple and they come from a continental local formation (Cixerri). The basis of this formation was referred to the Middle Lutetian for the discovery of Carophyta and associations pollen (Pittau, 1979). Sandstones and conglomerates show quartz, feldspar, litic and andesitic clasts up to 1 cm of diameter. Often they have plane parallel layers and crossed lamination. The lithologies are represented by a high marine fossil content (fig. 7) (Ulzega & Ozer 1982). These rocks are derived from the Sardinian Tyrrhenian dock (Carmigniani et al., 1982) outcropping in different parts of the Nora area. These sedimentary rocks show greater primary porosity and variable secondary porosity, due to alteration processes of "cement" matrix.

The granitoid rocks instead consist in pink leucogranite with grit from fine to medium, for the presence of large pink crystals of potassium

feldspar and quartz. This rock is present in the high mountains northwest of Nora and belongs to the Hercynian basement. It arrives in the territory of Nora through some major rivers like Rio Pula and Rio Piscinamanna. The granitoid rocks, when not altered, have a low porosity (<10%).

Fig. 7- Macrofossils in tyrrhenian sandstones

Fig. 8- Andesitic stones into bedding mortars

Original mortars in Coltellazzo tower are difficult to identify because of the massive presence of modern mortars used in recent restoration. In addition to Portland cement (Fig. 11) were used at least 3 types of modern restoration mortars. However the original mortars were sampled and divided into three main types: 1) ashlar bedding mortars (Fig. 8), 2) arriccio/rinzaffo layer plasters, 3) finiture layer plasters (Fig. 9). All the mortars have exclusively a binder with lime composition with occasionally presence of lime-lumps. However, the mortars show a medium-high degree of

cohesion. The mortar aggregate consists mainly of quartz and feldspar crystals, and andesitic clasts with variable size that in the bedding mortars arrive to about 15 mm. Binder/aggregate ratio of ashlar bedding mortars sampled is variable (range: 0,3-0,7). In the plaster the binder/aggregate ratio is approximately 0,4-0,8.

6. Discussion and conclusions

The petrographic analysis of the materials of the Coltellazzo tower show that the lithologies used come from local geological formations as often happens in the construction of historical buildings like this. The rocks used have very different compositions. So, the variable intrinsic petrophysical characteristics of the rocks (as their porosity and the degree of cohesion) affect on their decay, determining in time different macroscopic forms of alteration, that in the case of Coltellazzo tower, considered the distance to the sea (20 m) are more evident.

In sandstones and conglomeratic rocks we have decohesion processes of sediment due also to dissolution of carbonate matrix, with consequently alveolation processes, mainly in the side exposed to the prevailing wind.

In the volcanic rocks with dacitic composition in some cases are detected instead advanced stages of physical decay with processes of exfoliation and flaking, often due to hydric dilatation of these rocks (Columbu et al., 2014).

The granitoid rocks and andesites present no particular problem to decay. In volcanic rocks with andesitic composition, is present

occasionally exfoliation often sub-concentric to the outer surface of the ashlar, in part resulting from a pre-existing alteration. This alteration, due to marine aerosol and consequently to frequent cyclic salt crystallization-solubilization, is present mainly to the side exposed to the sea. On the side exposed to the north, are present biological patina (e.g., mosses, etc.).

The mortars of squared ashlars and irregular stone positioned in the first rows of the basal tower (mainly represented by reusing blocks of sandstone from the Punic-Roman site of Nora) are mostly a composition of lime, we do not find the presence aggregate pozzolanic. Where are the missing plaster (south side towards the sea, you can see these mortars only in depth between the segments, due to an obvious alteration.

The mortars of plaster are on the sides towards the north, while the south side, we observe various areas where missing. In this area these mortars are profoundly altered, with frequent detachment both the finishing layer, and the underlying layer of arriccio. It is evident the numerous restoration with the application of mortars recent age cement based, that certainly worsen the state of degradation generally present in the tower.
