Abstract

This work aims to develop an orthogonal cutting model for surface integrity prediction, which incorporates a new constitutive model of Oxygen Free High Conductivity (OFHC) copper. It accounts for the effects of the state of stress on the flow stress evolution up to fracture. Moreover, since surface integrity parameters are sensitive to the microstructure of the work material, this constitutive model highlights also the recrystallization effects on the flow stress. Orthogonal cutting model is validated using experimental designed cutting tests. More accurate predictions were obtained using this new constitutive model comparing to the classical Johnson-Cook model.

1. Introduction

Efforts on numerical modeling and simulation of metal cutting operations continue to increase due to the growing need for predicting the machining performance. However, the effectiveness of the numerical models to predict the machining performance depends on how accurately these models can represent the actual metal cutting process [1]. Several factors will influence accuracy of such models, including the incorrect description of the work material behavior in metal cutting. In the case of surface integrity, they are very sensitive to the energy required for separating the material from the workpiece to form the chip (energy of plastic deformation and fracture) [2]. Therefore, an improper modeling of the flow stress and fracture in metal cutting simulations leads to a high dispersion among the simulated results. Within the CIRP Working Group on “Surface Integrity and Functional Performance of Components”, a benchmark study was conducted to evaluate the effectiveness of the current numerical predictive models for machining performance, including surface integrity [1, 2]. The predicted results clearly show a high dispersion among them, being this dispersion higher for the surface integrity.

The objective of this work is to propose a consolidated physical modelling approach for predicting surface integrity induced by machining OFHC copper. This approach incorporates a new constitutive model that accounts for the effects of the state of stress and microstructure on the flow stress. Moreover, it incorporates a physical-based model for microstructure prediction induced by machining.

2. Consolidated physical modeling (CPM)

This study concerns annealed (2h at 450°C) OFHC copper, a monophasic material with an average grain size \(d_0\) of 62 \(\mu m\), and an initial dislocation density \(\rho_0\) of \(4.2 \times 10^{13} m^{-2}\).
2.1. Material constitutive model

The proposed material constitutive model takes into consideration the most relevant phenomena influencing the material behavior. It was inspired from phenomenological models (including the Johnson-Cook constitutive model [3]) taking into account the strain hardening, the strain rate, the temperature [3], the microstructural transformation [4], and the state of stress effects [5]. The flow stress (\( \sigma \)) is expressed by the following equation (Eq. 1).

\[
\sigma = \left[ A + B e^\varepsilon \right] \times \left[ 1 + C \ln \left( \frac{\dot{\varepsilon}}{\varepsilon_0} \right) \right] \times \left[ 1 - \left( \frac{T - T_{\text{room}}}{T_{\text{room}} - T_m} \right)^n \right] \times \left[ 1 - c_4 (\eta - \eta_0) \right] \times \left[ 1 - \gamma (\varepsilon - \varepsilon_0) \right] \times \left[ 1 - \gamma (\varepsilon - \varepsilon_0) \right] \times \left[ 1 - \gamma (\varepsilon - \varepsilon_0) \right]
\]

(1)

Its particularity comes from the proposed \( H(\varepsilon, \dot{\varepsilon}, T) \) function (Eq. 2) introducing the microstructural effect, especially dynamic recrystallization. This function couples the effect of strain, strain-rate and temperature as three of them influence this phenomenon. Indeed, it is activated by the (u) function (Eq. 3) only in case the strain exceeds the recrystallization strain threshold \( (\varepsilon_0) \), calculated using the equation proposed by Liu et al. [6] for OFHC copper (Eq. 6).

\[
H(\varepsilon, \dot{\varepsilon}, T) = \frac{1}{1 - H(\varepsilon, \dot{\varepsilon}) = \varepsilon_0 \times u(\varepsilon, \dot{\varepsilon}, T)}
\]

(2)

\[
u(\varepsilon, \dot{\varepsilon}, T) = \begin{cases} 0 \text{ when } \varepsilon < \varepsilon_0 \\ 1 \text{ when } \varepsilon \geq \varepsilon_0 \end{cases}
\]

(3)

\[
\dot{H}(\varepsilon, \dot{\varepsilon}) = \frac{\dot{H}(\varepsilon, \dot{\varepsilon}) = \dot{H}(\varepsilon, \dot{\varepsilon}) = \dot{H}(\varepsilon, \dot{\varepsilon}) = \dot{H}(\varepsilon, \dot{\varepsilon}) = \dot{H}(\varepsilon)}{\varepsilon_0 \times \varepsilon_0 \times \varepsilon_0 \times \varepsilon_0 \times \varepsilon_0 \times \varepsilon_0}
\]

(4)

\[
\varepsilon_0 (\dot{\varepsilon}, T) = c_0 \ln (\varepsilon / \varepsilon_0) + c_1 \times \exp (\varepsilon / \varepsilon_0)
\]

(5)

Concerning to the state of stress effect, only the triaxiality parameter \( (\eta) \) (the ratio between the hydrostatic stress and von Mises equivalent stress) is considered. The proposed constitutive model coefficients of Eq.1 (A, B, C, n, m, h, i=0…2) and \( (c_0) \) are identified basing on material characterization tests described as follows. Three kinds of mechanical tests were performed. To identify the constants corresponding to the strain hardening effect, uniaxial compression tests were led on cylindrical specimens with a Gleeble machine at low strain rates \( (0.1 \text{ s}^{-1}, 1 \text{ s}^{-1} \text{ and } 10 \text{ s}^{-1}) \) at 20°C, 200°C, 400°C and 600°C. For the constants corresponding to the strain-rate effect, split Hopkinson pressure bars tests were led on cylindrical specimens at high strain-rates \( (700 \text{ s}^{-1}, 1600 \text{ s}^{-1} \text{ and } 2000 \text{ s}^{-1}) \) at 27°C, 500°C and 650°C. Several temperature levels were used to identify the thermal softening coefficients, as well as those coefficients related to the microstructural transformation effect. As far as the state of stress effect is concerned, uniaxial compressive (cylindrical specimens [5]) and tensile tests (flat grooved specimens) were performed to evaluate the influence of different stress triaxiality values on the flow stress. Using a hybrid experimental-numerical procedure described in [5], the \( (c_0) \) was identified. All the coefficients are in Table 1.

2.2. Microstructure prediction model

The microstructure parameters are predicted using the dislocation density based model proposed by Estrin and Klim [7]. It aims to calculate the total dislocation density \( (\rho_{\text{total}}) \) evolution and grain size \( (d) \). It makes a distinction between the two kinds of dislocations densities: those in the walls \( (\rho_{\text{wall}}) \) and those in the cells interiors \( (\rho_{\text{cell}}) \). Knowing the volume fraction of the walls \( (f) \) given by Eq. 7, the total dislocation density can be calculated using Eq. 8:

\[
f = f_o + (f - f_o) \times \exp (-\frac{\gamma}{\gamma_o})
\]

(7)

\[
\rho_{\text{wall}} = f \times \rho_{\text{cell}} + \left(1 - f\right) \times \rho_{\text{cell}}
\]

(8)

\[
d = \frac{\beta}{\sqrt{b \cdot d \cdot f}} + \frac{1}{\sqrt{b \cdot d \cdot f}} \times \frac{\sqrt{b \cdot d \cdot f}}{k_o \left(\frac{\gamma}{\gamma_o}\right)^{\frac{1}{k}}}
\]

(9)

\[
d = \frac{\alpha \times \left(\frac{\beta}{\sqrt{b \cdot d \cdot f}} \times \frac{1}{\sqrt{b \cdot d \cdot f}} \times \frac{\sqrt{b \cdot d \cdot f}}{k_o \left(\frac{\gamma}{\gamma_o}\right)^{\frac{1}{k}}}\right) \times \rho_{\text{cell}}}{\rho_{\text{cell}}}
\]

(10)

where \( (f_o) \) and \( (f) \) are initial and saturation values of (f), equal to 0.077 and 0.25 respectively. Moreover, \( (\gamma_o) \) is the variation of (f) with the resolved shear strain \( (\gamma) \) which is equal to 3.2 s^{-1}. Dislocation densities in the cells and in the walls are governed by Eq. 9 and Eq. 10 basing on the reactions that are susceptible to occur due to density dislocation nucleation, annihilation and interaction. Their description and the values of the used parameters for OFHC copper are detailed in the reference [7].

In order to calculate the grain refinement on the machined surface, the average grain size \( (d) \) is assumed to evolve linearly with the inverse of the square root of the total dislocation density \( (\rho_{\text{total}}) \), as shows Eq. 11. The value of the parameter \( (K) \) is identified knowing initial grain size \( (d_0) \) of the bulk material and its initial dislocation density \( (\rho_0) \).

\[
d = \frac{K}{\sqrt{\rho_{\text{total}}}}
\]

(11)

As the micro-hardness Vickers (HV) is correlated to grain size, it is possible to predict it using the equation (Eq. 12) proposed by Rotella and Umbrello [8], with \( (c_{\text{hv1}}) \) and \( (c_{\text{hv2}}) \) two constants equal to 77 and 18 \mu m^{-1} respectively.
In order to evaluate the proposed CPM approach to predict surface integrity parameters, an orthogonal cutting model was developed and validated using experimental cutting tests data. The tool is made of carbide with a rake angle ($\gamma$) of 30°, a flank angle ($\alpha$) of 10°, and a cutting edge radius of (r_e) of 10±2 μm. The cutting speed ($v_c$) was 90 m/min, the uncut chip thickness (h) was 0.2 mm and the width of cut was 4 mm.

3.1. Orthogonal cutting model

A numerical model based on the Arbitrary Lagrangian-Eulerian (ALE) formulation was developed and applied to simulate the surface integrity induced by orthogonal cutting of OFHC copper. A coupled temperature displacement analysis was performed using the FEA software ABAQUS/Explicit. To model the flow stress behavior and the microstructure evolution of OFHC copper, a user subroutine VUMAT was developed to integrate the CPM approach described in §2 in the numerical simulations. The elastic and thermal properties of the work material were obtained from experimental tests on the same work material as those used in the machining tests. The tool was modelled as elastic and its thermal and elastic properties were obtained from literature [9]. Concerning to the chip-chip and the tool-workpiece contacts, they were modelled using the Zorev’s model [10], being the friction coefficient ($\mu$) obtained from literature [9]. Concerning to the chip compression ratio ($CR$), predictions are in good agreement with the experimental values (measured $CR$ value is 2.25+0.15, while the simulated ones are 2.62 for the new model and 2.08 for the J–C model).

As far as surface integrity is concerned, residual stresses and grain size distributions at surface and subsurface were evaluated. Micrographic analysis (Fig. 1a) has revealed an average grain size (d) at the machined surface of 6±5 μm and a refined layer thickness of about 100±10 μm (Fig. 1b).

Results issued from both models (Fig. 2) are in good agreement with the experimental concerning the grain size at the top surface (4 μm for the J–C model and 2 μm for the new model). Nevertheless, a slight improvement is seen in the affected layer thickness prediction when the new model is used (64 μm for the J–C model and 97 μm for the new one). It should be pointed out that due to the effect of the etchant used for grains revelation, the experimentally measured grain size value should correspond to a depth of few microns under the machined surface, which seems in accordance with simulations.

The accuracy of the micro-hardness model was also tested. According to the results (Fig. 3), it fits well the hardness trend while simulating with both J–C and the new models. Nevertheless, the impact of the material model modification is more noticeable in the residual stresses prediction. In fact, Fig. 4 and Fig. 5 show that the proposed model gives better prediction of the residual stresses than the J–C model, although a gap is still prevailing between the
numerical simulations and the experimental measurements, in particular for depths higher than 300 µm.

In fact, an enhancement is seen in simulations results concerning cutting forces, chip compression ratio, average grain size, micro-hardness and residual stresses predictions. Nevertheless, more enhancements should be done on this proposed model in order to obtain better predictions.

Fig. 5. Experimental and predicted residual stresses in transversal direction ($\sigma_T$).
