Gamma-glutamyltransferase fractions

Vulnerable plaque

ABSTRACT

Objective: The atherosclerotic plaque that is vulnerable to rupture and to superimposed thrombosis is mainly represented by a thin-cap fibroatheroma with or without ulceration/thrombosis and inflammatory infiltrates. Total serum gamma-glutamyltransferase (GGT) activity is an independent predictor for cardiovascular events. Four GGT fractions have been identified in plasma and only one of them (b-GGT) in atherosclerotic plaques, but the possible role of GGT in plaque pathophysiology has not been assessed yet. We investigated the relationships between plaque b-GGT activity and the histological features of plaque vulnerability. **Methods and results:** Plaque GGT activity was investigated in 65 patients undergoing carotid endarterectomy; plaques were histologically characterized and immunostained for GGT. Intra-plaque total and fractional GGT activity was determined by a cost-effective test of molecular size exclusion chromatography, and compared with histological markers of plaque vulnerability. Plaque cholesterol content was also measured by chromatography. b-GGT was the only fraction detected within the atherosclerotic plaques and intra-plaque b-GGT activity correlated to plaque cholesterol content ($r = 0.667, P < 0.0001$), plasma b-GGT and f-GGT fractions ($r = 0.249; r = 0.298$, both $P < 0.05$). Higher b-GGT activity was found in thin-cap fibroatheromas and it was associated to histological markers of vulnerable plaques, i.e., larger necrotic areas, greater macrophage infiltration and higher cholesterol content ($P < 0.05$). **Conclusions:** intra-plaque b-GGT activity correlates with the histological markers of vulnerable plaque and with plasma b-GGT in human carotid atherosclerosis; these data support the possible role of b-GGT in clinically significant atherosclerotic disease.

1. Introduction

Cardiovascular diseases are leading causes of death, the social and economic burden of atherosclerosis increasing in the last decades together with population ageing [1]. Atherosclerosis is a progressive disease; cellular and molecular alterations within the arterial wall lead to lumen narrowing and/or to plaque rupture with

superimposed acute thrombosis, such complicated plaques representing the antecedents for cardiovascular events [2–5].

The atherosclerotic plaques that are vulnerable to rupture and to thrombosis show well defined histological features [2,3,6–8]. Morbidity and mortality from atherosclerosis is largely due to vulnerable plaques, i.e., type IV–VI lesions according to the American Heart Association (AHA) classification, corresponding to thin-cap fibroatheromas with or without ulceration/fissuration showing a large necrotic core and abundant inflammatory infiltrates, mainly constituted by macrophages [9–11]. Conversely, stable lesions usually correspond to predominantly fibrous/fibrocalcific plaques and to thick-cap fibroatheromas with low or absent inflammation,

¹ AP, MFr, ME, and APA equally contributed to this work.

absent or small necrotic core, no ulceration/fissuration or thrombosis [8–12].

The evolution of the atherosclerotic plaque towards stabilization or vulnerability is not completely understood so far [13], the search for *in vivo* biomarkers of plaque instability and subsequent life-threatening complications representing a major challenge of modern medicine [14–18].

During the last decade, total serum gamma-glutamyltransferase (GGT) activity has been recognized as a risk factor for both coronary and cerebrovascular events in unselected populations [19,20] as well as in patients with diagnosed coronary artery disease [21]. Its predictive value is independent and additive, as compared to other established markers, and independent from liver disease or alcohol consumption [17,19,21].

As to the possible role of GGT in plaque instability, its active form has been previously shown to co-localize with inflammatory cell infiltrates and peroxidized low-density lipoprotein (LDL) in both coronary and carotid plaques [16,21,22]. The GGT activity has been hypothesized to exert a direct pro-oxidant activity, eliciting the production of reactive oxygen species from cystenylglycine (CysGly) moieties via its catalytic activity on extracellular glutathione [23–25], the occurrence of GGT-mediated redox reactions having been demonstrated within the plaque [26]. Recently, four plasma GGT fractions have been identified by molecular size exclusion chromatography, i.e., b-GGT, m-GGT and s-GGT (that very likely represent >2000, 940 and 140 kDa, respectively, lipoprotein-bound molecular masses) plus the 70 kDa free fraction f-GGT [27,28]; only the highest molecular weight fraction b-GGT, has been found within atherosclerotic plaques by our group [26].

The aim of this study is to evaluate the possible relationships between intra-plaque b-GGT content, localization and activity and the histological features of plaque vulnerability in carotid atherosclerosis; in order to better understand the pathophysiology of high-risk plaque formation. Plasma GGT fractions are also investigated in the same patients.

2. Materials and methods

2.1. Study population

We investigated 65 consecutive patients undergoing carotid endarterectomy at the General and Vascular Surgery (University Hospital, Pisa, Italy). Since endarterectomy is recommended in patients with severe carotid artery stenosis (>70%), even in absence of neurological symptoms, the major part of this cohort was constituted by asymptomatic patients ($n = 50$), while 15 patients showed neurological symptoms. The indication for endarterectomy was based on the recommendations published by the Asymptomatic Carotid Surgery Trial and on the European Carotid Surgery Trial and the North American Symptomatic Carotid Endarterectomy Trial [29–32].

In all cases, baseline data were obtained by clinical files, including history of vascular disease, cardiovascular risk factors and medication use. Patients were on appropriate therapy with lipid- and/or glucose-lowering drugs, anti-coagulant or antiplatelet agents, anti-hypertensive drugs, according to current guidelines. Carotid stenosis severity was evaluated by ultrasound analysis. Hypertension was defined as systolic blood pressure ≥ 140 mmHg and/or a diastolic pressure ≥ 90 mmHg, with or without anti-hypertensive treatment at the time of endarterectomy. Diabetes mellitus was diagnosed in patients with fasting blood glucose > 126 mg/dL, and/or current oral or insulin treatment. Dyslipidemia was diagnosed as total cholesterol level > 200 mg/dL (> 5.18 mmol/L) and/or serum triglycerides ≥ 150 mg/dL (> 1.70 mmol/L), and/or current statin/fibrate treatment.

The study was approved by the Institutional Ethics Committee, and conformed to the Declaration of Helsinki, and patients gave the informed consent.

Standard assay of all blood tests were simultaneously performed according to the standard clinical laboratory procedures by automated analysers, plasma high sensitivity C-reactive protein (hs-CRP) was determined on Synchron CX instrument (Beckman, USA).

2.2. Tissue sampling

Surgically excised carotid plaques were collected on ice and dissected into 5-mm segments. Adjacent segments having the greatest plaque area and representing the culprit lesion, were fixed in 10% buffered formalin or in 70% cold ethanol and paraffin-embedded for histological analyses, and frozen at -20°C after being rinsed in cold Dulbecco's phosphate buffer for biochemical investigations, respectively. In a sub-group of these patients ($N = 20$) with adequate plaque volume, a third segment of the plaque was frozen at -20°C in Optimal Cutting Temperature (OCT) medium.

Plaque fragmentation due to the surgical procedure was minimal, allowing histological analysis in all cases.

2.3. Histopathological investigations

Serial 3 μm paraffin sections were stained with haematoxylin-eosin and Masson's trichrome method. Immunohistochemistry was performed on adjacent paraffin-embedded sections. Macrophages were identified by immunoperoxidase staining by using a specific monoclonal antibody raised against CD68 antigen, and endothelial cells by the antibody against CD31 antigen (Dakopatts, Glostrup, Denmark); immunoreactions were visualized by 3-diaminobenzidine substrate. GGT immunostaining was performed by using a previously characterized polyclonal antibody directed against the heavy chain of human GGT antigen at the appropriate dilution (1:1600) [33].

GGT enzymatic activity was evaluated both on 5 μm OCT embedded cryostat sections and on serial 3 μm paraffin sections obtained from plaques fixed in ethanol. The histochemical reaction was performed by using the specific substrate gamma-glutamyl-4-methoxy-2-naphtylamide and the diazonium salt Fast Blue BB as a chromogen [34].

The tissue areas constituted by lipidic core, fibrous tissue, calcification or immunostained for CD68 were automatically measured by a grey scale detection method with a fixed threshold by a computer-based morphometry software (J-Image, NIH, Bethesda, Maryland; USA).

2.4. Histological characterization of plaques

The plaques were histologically classified according to the American Heart Association (AHA) scheme [2,3] and, for the aim of the study, were categorized as stable or vulnerable plaques [7,9]. The vulnerable plaques were defined by the presence of a thin cap fibroatheroma, i.e., a fibrous cap $< 165 \mu\text{m}$ thick, whereas the stable plaques corresponded to predominantly fibrous lesions with a fibrous cap $\geq 165 \mu\text{m}$ thick.

To investigate possible relationships between plaque histology and intra-plaque b-GGT, the plaque components were categorized according to the following scoring system: a) necrotic core, score 0 (absent), 1 (low, i.e., representing up to 25% of the total plaque area), 2 (medium, >25–50%) or 3 (high, >50%); b) fibrous tissue, score 1 (low, up to 30%), 2 (medium, >30–60%) or 3 (high, >60%); c) calcifications, score 0 (absent), 1 (low, up to 15%), 2 (medium,

>15–30%) or 3 (high, >30%); d) macrophage infiltration, score 0 (absent), 1 (low, up to 5%), 2 (medium, >5–10%) or 3 (high, >10%).

2.5. Homogenates of atherosclerotic lesions

Portions of plaque were snap-frozen in liquid nitrogen, mechanically disrupted and homogenized in 5% volume of cold hypotonic buffer (PBS diluted 10 folds) using a Potter homogenizer. Crude homogenates were centrifuged at 1000 g, 5 min, 4 °C and the supernatant was further centrifuged 10,000 g, 15 min, 4 °C, the final sample was then used for fractional GGT analysis.

2.6. Fractional GGT analysis

Fractional GGT analysis was performed as previously described [27,28] using an FPLC (fast protein liquid chromatography) system (AKTA purifier, GE Healthcare Europe, Milan, Italy) equipped with a gel-filtration column (Superose 6 HR 10/300 GL, GE Healthcare Europe) and a fluorescence detector (Jasco FP- 2020, Jasco Europe, Lecco, Italy). Plaque homogenates and plasma samples (0.02 ml) were injected in the gel-filtration column, after being filtered with a 0.45 µm polyvinylidene fluoride Millipore filter. GGT activity was measured using gamma-glutamyl-7-amido-4-methylcoumarin (Nova Chimica, Milan, Italy) as substrate (0.03 mmol/L, final concentration) and glycylglycine (5.4 mmol/L, final concentration) as acceptor of the transpeptidation reaction. The fluorescence detector operating at excitation/emission wavelengths of 380/440 nm detected the amino-4-methylcoumarin signal; the intensity of the fluorescence signal was expressed in arbitrary fluorescence units.

Under this reaction conditions, area under curve is proportional to GGT activity. Total area, between 10 and 25 mL elution volume, and fractional GGT area was calculated by a MatLab program (Version 7 MathWorks, Inc.) to resolve overlapping peaks; the curve fitting was conducted with a nonlinear least-squares minimization algorithm using four exponentially modified Gaussian (EMG) curves. The reaction was calibrated analysing plasma samples with known total GGT activity (standards). The slope of the calibration curve was used to convert total and fractional GGT area to U/L. The sum of fractional GGT activity represents on average the 99% of total GGT activity. A 4.5 mmol/L stock solution of gamma-glutamyl-7-amido-4-methylcoumarin was prepared in ethanol 40% v/v containing 0.01 N NaOH and stored at –20 °C. This solution was diluted 25-fold into 0.25 M Tris–HCl buffer pH 8.5 (25 °C) daily.

2.7. Cholesterol analysis by high-performance gel filtration chromatography

Distribution profile of the cholesterol in plaque homogenates was obtained by the fractional GGT analysis method, but a commercially available reagent for total cholesterol determination (GiesseDiagnostic, Rome, Italy) was used as post-injected reagent. Reaction product was detected by recording the absorbance at 510 nm.

2.8. Statistical analysis

Continuous variables are expressed as mean ± standard deviation (SD), or median (25th–75th percentile), as appropriate. Variables with known skewed distributions were natural logarithmically transformed before further analysis. Statistical analysis of data was performed by Student's *t*-test and Pearson's correlation analysis. A *P* value <0.05 was considered to indicate significance.

3. Results

3.1. Population characteristics

Study patients were elderly (age 73.5 ± 8.1 years, 46 males) and showed, as expected, a high prevalence of arterial hypertension (86%) and/or dyslipidemia (85%) with overweight in 43% patients, diabetes in 39%, concomitant ischaemic heart disease in 29%, current smoking habit in 22%. Detailed clinical and biohumoral characteristics of the study population, including values related with analysis of total and fractional plasma GGT activity are reported in Table 1.

3.2. Intra-plaque GGT and correlations with plasma GGT fractions

Plaque homogenates displayed GGT activity in all but one case, corresponding to an exclusively fibrous plaque without necrotic core.

Total GGT activity of plaque homogenates ranged between 7.6 and 126.4 mU/g tissue (43.8 ± 27.3). A unique distinct peak of b-GGT was identified at fractional GGT analysis (Fig. 1), with a mean activity of 15.4 ± 10.7 mU/g tissue (range 2.6–46.7 mU/g tissue).

Intra-plaque b-GGT activity was shown to correlate with intra-plaque total cholesterol content, as well as with plasma b- and f-GGT fractions, and fibrinogen (Table 2). No correlation was found between intra-plaque b-GGT and serum triglyceride, fasting glucose, leucocytes or hs-CRP (Table 2). No association was found between intra-plaque b-GGT levels and the extent of lumen narrowing at echo-Doppler examination (stenosis <80%, 13.8 ± 9.3 mU/g tissue; stenosis ≥80%: 15.8 ± 10.8 mU/g tissue; *P* = 0.4987).

A residual GGT activity within the plaques, without discrete peaks (Fig. 1), was detected (28.4 ± 17.6 mU/g tissue, range

s-GGT, U/L	9.20 (5.26–16.82)
f-GGT, U/L	13.21 (10.09–15.02)

Data are reported as median (25th–75th percentiles). BMI, body mass index; HDL, high density lipoprotein, LDL low density lipoprotein; AST, aspartate aminotransferase; ALT, alanine aminotransferase; ALP, alkaline phosphatase; GGT, gamma-glutamyltransferase; hs-CRP, high sensitivity C-reactive protein.

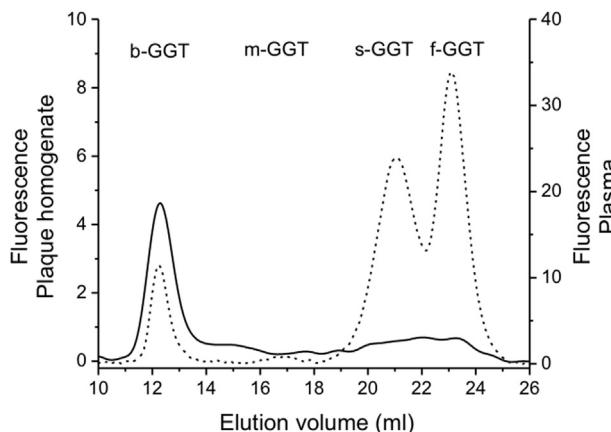

Fig. 1. Representative elution profile of GGT activity in plaque homogenate (continuous line) and plasma (dashed line) obtained from the same patient (C28). Elution profile was obtained by molecular exclusion chromatography, and GGT activity was detected by an on-line post-column reaction in presence of a fluorescent substrate, γ GluAMC [28].

4.1–79.7 mU/g tissue). It showed a significant correlation with intra-plaque cholesterol and plasma f-GGT fraction only (Table 2).

3.3. Plaque histology and GGT

The total mean area of the examined endarterectomy specimens was 65.67 ± 8.27 mm 2 . According to the AHA histological classification of atherosclerosis [2,3], 20 (32%), 10 (15%), and 1 plaques were defined as type Va, Vb, and Vc, respectively, whereas 12 (18%), 14, (22%), 3, (5%) and 5 (8%) were categorized as type VIa, VIb, VIc and VIabc, respectively. No type I–IV plaque was found.

A detailed histopathological characterization of vulnerability features is reported in Supplemental data Table 1. Thirty-four out of 41 vulnerable plaques (87%) were type VI according to AHA classification, 7 (13%) were type V, while all 24 stable plaques (100%) were type V lesions.

As expected, thin-cap fibroatheromas ($n = 41$, 63%) were characterized by large necrotic core and high macrophage infiltration (Fig. 2, panels A–C), whereas stable plaques ($n = 24$, 37%) showed a thick-cap fibroatheroma, small necrotic cores and light macrophage infiltration (Fig. 2, panels D–F) in all but one case with exclusively fibrous content and no necrotic core.

Table 2

Bivariate correlation analysis between intra-plaque b-GGT and residual GGT activity (mU/mg tissue), intra-plaque cholesterol content (mg/g tissue) and plasma analytes.

	Intra-plaque b-GGT		Intra-plaque residual GGT	
	r	P	r	P
Intra-plaque cholesterol	0.667	<0.0001	0.469	0.0003
hs-CRP	-0.084	0.5143	-0.018	0.8875
Fibrinogen	-0.281	0.0320	-0.327	0.0124
Leucocytes	0.080	0.5484	0.073	0.5840
Fasting glucose	0.058	0.6591	-0.025	0.8468
Triglycerides	0.027	0.8454	0.080	0.5649
Total GGT	0.242	0.0582	0.241	0.0553
b-GGT	0.249	0.0470	0.206	0.1033
m-GGT	0.203	0.1152	0.187	0.1390
s-GGT	0.169	0.1939	0.180	0.1543
f-GGT	0.298	0.0170	0.341	0.0058

Data are reported as Pearson correlation coefficients. hs-CRP, high sensitivity C-reactive protein; GGT, gamma-glutamyltransferase. Intra-plaque residual GGT activity was calculated as the difference between intra-plaque total GGT and b-GGT activity.

Immunohistochemical (Fig. 2) and histoenzymatic staining showed the presence of variable amounts of immunoreactive and catalytically active GGT, mainly localized to plaque areas corresponding to necrotic core, foamy macrophage-rich sites, and, to a lesser extent, to the endothelial lumen layer and/or to intra-plaque neoangiogenetic vessels (Supplemental Figs. 1 and 2).

As compared to thick-cap plaques, thin-cap fibroatheromas showed significantly higher ($P < 0.05$) intra-plaque GGT activity, both as b-GGT (16.8 ± 10.0 vs. 13.0 ± 11.7 mU/g tissue, Fig. 3) and residual GGT activity (31.4 ± 17.0 vs. 23.1 ± 17.8 mU/g tissue, Supplemental data Fig. 3) and higher cholesterol content (0.24 ± 0.21 vs. 0.13 ± 0.08 mg/g tissue, $P < 0.05$). As to the other histological features (Fig. 3), plaques with larger necrotic cores (score 3) showed a higher intra-plaque b-GGT activity as compared to those with small/medium necrotic core (scores 0–2; 17.2 ± 16.2 vs. 12.3 ± 10.4 mU/g tissue, $P < 0.036$). Plaque b-GGT activity was also higher in presence of a high vs. low macrophage infiltration (score 2–3 vs. score 0–1; 16.7 ± 11.0 vs. 11.1 ± 8.8 mU/g tissue, $P < 0.025$). Either fibrous component and calcium content were negatively associated with intra-plaque b-GGT activity, the lowest fibrous tissue score 1 corresponding to higher b-GGT activity as compared to higher fibrous scores (2–3; 16.8 ± 10.3 vs. 11.7 ± 11.3 mU/g tissue, $P < 0.023$), and the highest calcium content (scores 2–3) showing lower levels of b-GGT as compared to scores 0–1 (10.5 ± 10.4 vs. 17.4 ± 10.3 mU/g tissue, $P < 0.01$).

As to intra-plaque residual GGT activity, significant lower levels were found only in plaques with higher calcium content (21.9 ± 17.2 vs. 30.9 ± 17.3 mU/g tissue, $P < 0.05$), whereas no association was found with necrotic core, macrophage infiltration and fibrous component (Supplemental Fig. 3). Finally, no correlation was found between all above mentioned plaque histological features and hs-CRP circulating levels.

Plasma total and fractional GGT activity showed no statistically significant relationship with histological plaque features of instability (data not shown).

4. Discussion

This is the first study demonstrating that a specifically higher extent and activity of intra-plaque b-GGT is characteristic of plaques with the histological features of vulnerability, i.e., thin-cap fibroatheromas with large necrotic core and high macrophage infiltration [7,9] that have been previously shown to be associated with adverse clinical events on either *in vivo* (i.e., on carotid endarterectomies) and *post-mortem* studies [6,7,9]. Accordingly to the AHA histological classification of atherosclerosis, most vulnerable plaques (87%) of the present study corresponded to type VI complicated lesions [2,3]. Conversely, intra-plaque b-GGT was inversely correlated with fibrosis and microcalcifications, commonly observed in stable plaques in either carotid or coronary arteries [10,12].

Several clinical and population studies have shown that serum GGT activity independently predicts the risk of acute cardiovascular events associated with atherosclerosis, including stroke [19–21,35,36]. However, the relationship between plaque GGT activity and histological features of plaque vulnerability has never been previously established. GGT is the main determinant of the extracellular glutathione hydrolysis [37] that causes the release of the dipeptide CysGly. The reactive thiol of CysGly may cause the reduction of ferric Fe(III) to ferrous iron Fe(II), starting a redox-cycling process with subsequent production of the reactive oxygen species superoxide anion and hydrogen peroxide [37]. These reactions could take place in the necrotic core of the plaque, where both GGT [22,25,26] and iron are present at adequate concentrations [38]. In fact, in a previous study, we showed that in carotid

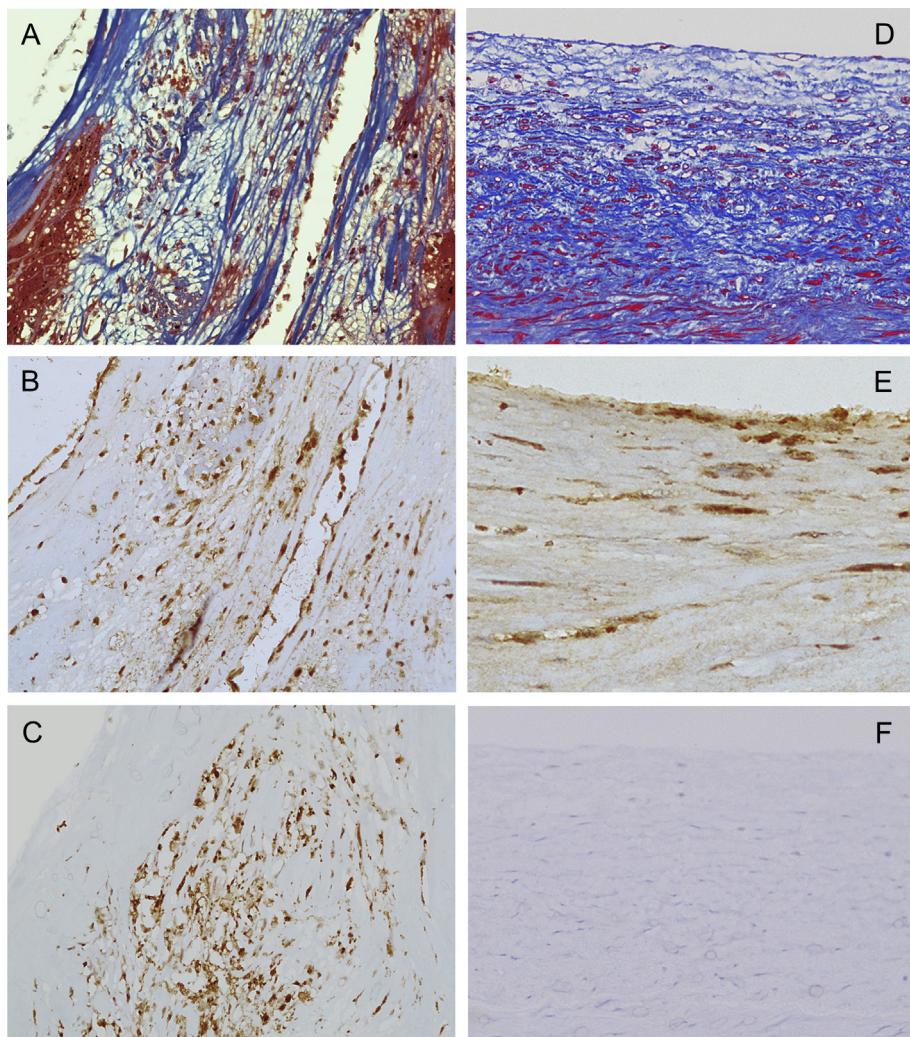

Fig. 2. A thin cap fibroatheroma without ulceration (A) shows higher immunoreactivity for GGT (B) and for CD68 macrophage antigen (C) than a plaque with a thick fibrous cap (D) with GGT (E) immunoreactivity limited to few cells and no detectable CD68 immunostaining (F). In the thin cap fibroatheroma, either endothelial layer and macrophage-rich areas shows GGT immunostaining that in the thick fibrous cap is localized to the endothelial layer and to few interstitial cells (A, D: Masson's trichrome staining; B, C, E, F: Immunoperoxidase with Haematoxylin counterstaining. Original magnification: 20×).

plaques GGT activity coexists with products deriving from the pro-oxidant reactions catalysed by GGT, including protein-linked CysGly [26], the biochemical marker which documents that GGT-mediated redox reactions have taken place [26,39].

Redox events can play a relevant role in several processes favouring atherosclerotic plaque destabilization and rupture, i.e., LDL oxidation [23], activation of matrix metalloproteinase expression/activity and TIMP inhibition [25,40,41], matrix remodelling and fibrous cap thinning. Our study shows that intra-plaque b-GGT activity correlates with circulating b- and f-GGT level. This observation adds to findings from population studies showing the highest predictive value of serum total GGT activity for cardiovascular events at medium–high levels within normal 25–50 U/L reference range [17,20,21]. Metabolic and cardiovascular risk markers are important correlates of GGT fractions, in particular of b-GGT in healthy subjects [42] and in Framingham population [43]. It is noteworthy that non-alcoholic fatty liver disease, a component of the metabolic syndrome which is associated to increased cardiovascular risk [44], seems to be a rather specific cause of plasma b-GGT increase in blood [45], while alcohol abuse and liver diseases are more specifically associated with s-GGT elevation [46].

Interestingly we observed that fractional GGT analysis identified a unique distinct peak of b-GGT activity within plaque homogenates, thus raising the issue of the intra-plaque GGT-activity origin. The 2000 kDa molecular weight of b-GGT corresponds to that of microparticles or exosomes and could allow its deposition within the plaque from the bloodstream through damaged endothelium in subjects with elevated plasma b-GGT level, while its ability to oxidize LDL [23] and its chemokine properties [47] could explain its co-localization with CD68⁺ macrophages. The association between intra-plaque b-GGT and CD68⁺ macrophage infiltration might even in part depend upon the ability of activated macrophages to release b-GGT, as already shown for neutrophils [48]. Furthermore, we observed a significant correlation between intra-plaque b-GGT and cholesterol plaque content. Either cholesterol increase and macrophage infiltration may lead to endothelial damage from oxidized-LDL, which might in turn facilitate plasma b-GGT passage into the plaque. Thus plaque GGT may derive both from insudation of plasma b-GGT as well as from endogenous synthesis by cellular elements of likely inflammatory nature. The major candidate are the macrophages that are known to express GGT activity [49] and that might be the source of the mRNA transcribed from GGT-I gene

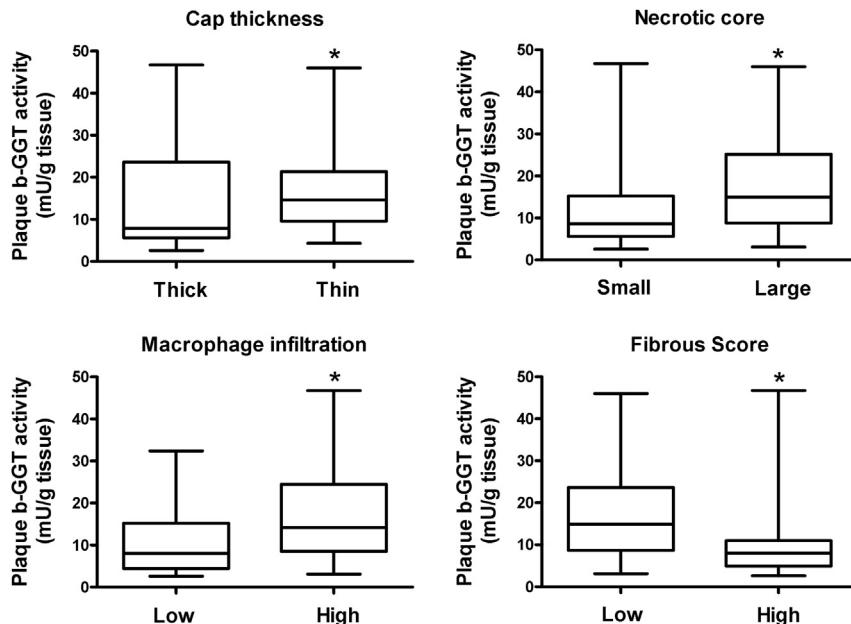

Fig. 3. Intra-plaque b-GGT activity distribution according to the histopathological features. Cap thickness: thick ($n = 24$), thin and ulcerated ($n = 41$). Necrotic core: score 0–2 (absent up to medium, $n = 24$), large (3; $n = 41$). CD68⁺ macrophage infiltration: score 0–1 (absent-low, $n = 16$), 2–3 (medium-high, $n = 49$). Fibrous tissue: score 0–1 (absent-low, $n = 47$), 2–3 (medium-high, $n = 18$). Student's *t* test has been performed on ln-transformed data. * $P < 0.05$.

detectable in plaque homogenate [26]. Further studies will be aimed to elucidate how differentiation from monocytes, to macrophages and to foam cells influence GGT expression. The study of the properties of GGT expressed by macrophages will allow the quantification of the cellular and plasma contribution to intra-plaque GGT activity.

Finally, the correlation between intra-plaque GGT activity and plasma f-GGT suggests that also this fraction might infiltrate into plaque through the damaged endothelium.

It is noteworthy that the intra-plaque residual GGT activity, even if greater than intra-plaque b-GGT activity, showed lesser association with histological features of plaque vulnerability, thus strengthening the role of b-GGT activity in plaque vulnerability.

In the present series including patients undergoing elective carotid endarterectomy, independently from presence of symptoms (observed only in a minority of patients, i.e., 15/65 subjects, 23%) we did not observe any correlation between serum CRP levels and intra-plaque or circulating GGT levels; CRP is considered a non-specific predictive marker of cardiovascular events and previous studies have shown that serum CRP and serum GGT are independent and additive predictors of cardiovascular events [17]. CRP and GGT might be related to different aspects of the atherosclerotic disease; elevated serum CRP levels appear more likely to indicate the systemic nature of progressive atherosclerotic disease rather than uncovering the presence of a single vulnerable lesion [50], whereas GGT could represent an index of on-going oxidative stress.

Limits of the study. This study did not investigate the possible relationships between b-GGT and symptomatic carotid artery disease; the selection criteria of this series (i.e., patients undergoing elective carotid endarterectomy on the basis of imaging results and of clinical evaluation) and the small number of patients with symptomatic disease ($N = 15/65$, 23%) did not allow us to look for possible correlations between intra-plaque b-GGT activity, plaque histological features and cerebrovascular symptoms.

In conclusion, intra-plaque b-GGT was associated to histological features of vulnerable plaques in carotid endarterectomies, and to circulating b-GGT in the same patients. b-GGT fraction might play a

role in atherosclerosis progression, and, rather than total GGT itself, might be related to the previously observed risk of acute cardiovascular events. On the basis of these results, future studies will be aimed to recruit a larger cohort for a prospective study in order to deepen the clinical meaning of circulating b-GGT in atherosclerotic disease; future applications for novel imaging monitoring of plaque instability might as well be evaluated.
