Abstract: A new unified modelling framework based on the superposition of additive submodels, functional components, and wavelet decompositions is proposed for nonlinear system identification. A nonlinear model, which is often represented using a multivariate nonlinear function, is initially decomposed into a number of functional components via the well known analysis of variance (ANOVA) expression, which can be viewed as a special form of the NARX(*Nonlinear AutoRegressive with eXogenous* inputs) model for representing dynamic input-output systems. By expanding each functional component using wavelet decompositions including the regular lattice frame decomposition, wavelet series and multiresolution wavelet decompositions, the multivariate nonlinear model can then be converted into a linear-in-the-parameters problem, which can be solved using least-squares type methods. An efficient model structure determination approach based upon a forward orthogonal least squares (OLS) algorithm, which involves a stepwise orthogonalization of the regressors and a forward selection of the relevant model terms based on the error reduction ratio (ERR), is employed to solve the linear-in-the-parameters problem in the present study. The new modelling structure is referred to as a Wavelet-based ANOVA decomposition of the NARX model or simply WANARX model, and can be applied to represent high-order and high dimensional nonlinear systems.

Keywords: Nonlinear system identification; NARX and NARMAX models; wavelets; orthogonal least squares

1. Introduction

The main task in mathematical modelling is to construct a mapping, which connects the inputs and outputs and reflects the relationship between these with an acceptable accuracy. In experimental data based modelling, known as system identification, the key problem is to construct a suitable model, which involves the smallest number of input variables (lagged inputs and lagged outputs for dynamical systems) and the simplest model structure containing the smallest number of adjustable parameters. For high dimensional systems, however, parsimony and accuracy are difficult to achieve simultaneously. Therefore, trade-offs between model parsimony, accuracy, and validity have to be considered.

A key problem in modelling high dimensional nonlinear systems is to develop efficient model construction procedures that overcome the curse-of-dimensionality. One approach for representing continuous functions of several variables is to describe multivariate functions as a superposition of a number of continuous functions with fewer variables. This is the essence of Hilbert's 13th problem, which was resolved by Kolmogorov where it was concluded that every continuous function of several variables can be represented by the superposition of functions with only two variables (see, Gorban 1998 and the references therein). The problem of representing continuous functions of several variables by continuous functions of a single variable has also been solved and

this can be expressed using Kolmogorov's theorem which states that every continuous function of n variables defined in the standard n -dimensional cube can be represented in the following form

$$f(x_1, x_2, \dots, x_n) = \sum_{q=1}^{2n+1} g_q \left(\sum_{p=1}^n h_q^{(p)}(x_p) \right) = \sum_{q=1}^{2n+1} g_q (h_q^{(1)}(x_1) + h_q^{(2)}(x_2) + \dots + h_q^{(n)}(x_n)) \quad (1)$$

where $g_q(\cdot)$ are some continuous functions which depend on the function f and $h_q^{(p)}(\cdot)$ are some continuous functions which are independent the function f . This theorem guarantees that every continuous function can be approximated by the operations of addition, multiplication, and superposition of a number of continuous single variable functions with arbitrary accuracy. This theorem, however, does not provide a solution for how to choose the additive functional components. Therefore it is not easily applicable in real system modelling.

Several applicable approaches have been proposed to realize the idea of representing multivariate functions using a superposition of a number of functions with fewer variables. The projection pursuit regression algorithm (Friedman 1981), radial basis function networks (Chen *et al.* 1990, 1992), and multi-layer perceptron (MPL) architecture (Haykin 1994) are among these representations for multivariate functions. The existing strategies that attempt to approximate general functions in high dimensions are based on additive functional submodels including the polynomial NARMAX (Nonlinear AutoRegressive Moving Average with eXogenous inputs) representation introduced by Billings and Leontaritis (1982, 1985), the multivariate adaptive regression splines (MARS) introduced by Friedman(1991), and the adaptive spline modelling of observational data (ASMOD) introduced by Kavli (1993). The functional components can be arbitrary functions with fewer arguments and with global or local properties. Kernel functions, splines, polynomials and other basis functions can all be chosen as functional components (Hastie and Tibshirani 1990).

A multivariate nonlinear function can often be decomposed into a number of functional components via the well known functional analysis of variance (ANOVA) expansions (Friedman 1991, Chen 1993)

$$\begin{aligned} f(x_1, x_2, \dots, x_n) = & f_0 + \sum_{i=1}^n f_i(x_i) + \sum_{1 \leq i < j \leq n} f_{ij}(x_i, x_j) + \sum_{1 \leq i < j < k \leq n} f_{ijk}(x_i, x_j, x_k) + \dots \\ & + \sum_{1 \leq i_1 < \dots < i_m \leq n} f_{i_1 i_2 \dots i_m}(x_{i_1}, x_{i_2}, \dots, x_{i_m}) + \dots + f_{12 \dots n}(x_1, x_2, \dots, x_n) \end{aligned} \quad (2)$$

where the first functional component f_0 is a constant to indicate the intrinsic varying trend; f_i, f_{ij}, \dots , are univariate, bivariate, etc., functional components. The univariate functional components $f_i(x_i)$ represent the independent contribution to the system output that arises from the action of the i th variable x_i alone; the bivariate functional components $f_{ij}(x_i, x_j)$ represent the interacting contribution to the system output from the input variables x_i and x_j , etc. As that will be seen later, the ANOVA expansion (2) can be viewed as a special form of the NARX (Nonlinear AutoRegressive with eXogenous inputs) model for dynamic input and output systems.

Among almost all the functions used for the purpose of approximation, few have had such an impact and spurred so much interest as *wavelets*. Wavelet decompositions outperform many other approximation schemes and offer a flexible capability for approximating arbitrary functions. Wavelet basis functions have the property of localization in both time and frequency. Due to this inherent property, wavelet approximations provide the

foundation for representing arbitrary functions economically, using just a small number of basis functions. Wavelet algorithms (Coca and Billings 2001) process data at different scales or resolutions, which make wavelet representations more adaptive compared with other basis functions. Therefore, wavelet decompositions can be used to represent each functional component in the model (2).

In this paper, a new model structure which combines wavelets and the additive functional ANOVA decomposition of the NARX model, called the Wavelet-based ANOVA decomposition of the NARX model or simply WANARX, is introduced as a basis for nonlinear system identification. The wavelet decompositions, which have excellent approximation properties, are used to express each functional component. By expanding each functional component into wavelet decompositions, the multivariate nonlinear function can then be converted into a linear-in-the-parameters problem, which can be solved using least-squares type of methods. A stepwise forward least squares (OLS) algorithm, along with an error reduction ratio (ERR) index is used to select the significant model terms from a large number of candidate terms. Emphasis is concentrated on wavelet series and multiresolution decompositions in this study from the point of view of practical data analysis.

The rest of the paper is organised as follows. The paper starts with a description of the well-known NARMAX model in Section 2, and the additive functional ANOVA decomposition of the NARX model is introduced. In Section 3, some introductory material on wavelet decompositions including wavelet frame decompositions, wavelet series and wavelet multiresolution decompositions, which establish the foundation for the WANARX model, are described. Section 4 shows how to expand a WANARX model using the wavelet decompositions. Section 5 addresses system variable selection and model term detection problems. In Section 6, some practical issues associated with the implementation of the WANARX model are discussed. Two examples, one a simulated system and one based on real data relating to the magnetosphere, are given in Section 7 to demonstrate the effectiveness and applicability of the WANARX modelling structure. Conclusions are given in Section 8.

2. Nonlinear input-output representations

In the past few decades, system identification and analysis methods for nonlinear systems have been extensively studied with many applications in approximation, prediction and control. Several nonlinear models have been proposed in the literature including the NARMAX model representation which was initially proposed by Billings and Leontaritis (Billings and Leontaritis 1982, Leontaritis and Billings 1985). The NARMAX model (Pearson 1999) takes the form of the following nonlinear difference equation:

$$y(t) = f(y(t-1), \dots, y(t-n_y), u(t-1), \dots, u(t-n_u), e(t-1), \dots, e(t-n_e)) + e(t) \quad (3)$$

where f is an unknown nonlinear mapping, $u(t)$ and $y(t)$ are the sampled input and output sequences, n_u and n_y are the maximum input and output lags, respectively. The noise variable $e(t)$ with maximum lag n_e , is immeasurable but is assumed to be bounded and uncorrelated with the inputs. The model (3) relates the inputs and outputs and takes into account the combination effects of measurement noise, modelling errors and unmeasured disturbances represented by the noise variable $e(t)$.

The NARX model is a special case of the NARMAX model and is described as

$$y(t) = f(y(t-1), \dots, y(t-n_y), u(t-1), \dots, u(t-n_u)) + e(t) \quad (4)$$

One of the popular representations for the NARMAX model (3) is polynomial models, since any continuous function can be arbitrarily well approximated by a polynomial model (Schumaker 1981). Taking the case of SISO systems as an example and expanding model (3) by defining the function $f(\cdot)$ to be a polynomial of degree ℓ gives the representation

$$\begin{aligned} y(t) = & \theta_0 + \sum_{i_1=1}^n f_{i_1}(x_{i_1}(t)) + \sum_{i_1=1}^n \sum_{i_2=i_1}^n f_{i_1 i_2}(x_{i_1}(t), x_{i_2}(t)) + \dots \\ & + \sum_{i_1=1}^n \dots \sum_{i_\ell=i_{\ell-1}}^n f_{i_1 i_2 \dots i_\ell}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_\ell}(t)) + e(t) \end{aligned} \quad (5)$$

where $\theta_{i_1 i_2 \dots i_m}$ are parameters, $n = n_y + n_u + n_e$ and

$$f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t)) = \theta_{i_1 i_2 \dots i_m} \prod_{k=1}^m x_{i_k}(t), \quad 1 \leq m \leq \ell \quad (6)$$

$$x_k(t) = \begin{cases} y(t-k) & 1 \leq k \leq n_y \\ u(t-(k-n_y)) & n_y + 1 \leq k \leq n_y + n_u \\ e(t-(k-n_y-n_u)) & n_y + n_u + 1 \leq k \leq n_y + n_u + n_e \end{cases} \quad (7)$$

The degree of a multivariate polynomial is defined as the highest order among the terms, for example, the degree of the polynomial $h(x_1, x_2, x_3) = a_1 x_1^4 + a_2 x_2 x_3 + a_3 x_1^2 x_2 x_3^2$ is $\ell = 2+1+2=5$. Similarly, a NARMAX model with polynomial degree ℓ means that the order of each term in the model is not higher than ℓ .

As a general and natural representation for a wide class of linear and nonlinear systems, model (5) includes, as special cases, several model types, including the Volterra and Wiener representations, time-invariant and time-varying AR(X), NARX and ARMA(X) structures, output-affine and rational models, and the bilinear model (Pearson 1995). The ANOVA expansions (2) can also be viewed as a special case of the NARMAX model while representing dynamic input and output systems.

Now, consider the NARX model (4) and assume that the nonlinear mapping f in the model (4) can be decomposed into a number of functional components as the ANOVA expansion (2), then the NARX model (4) can be expressed as

$$\begin{aligned} y(t) &= f(x_1(t), x_2(t), \dots, x_n(t)) + e(t) \\ &= f_0 + F_1(x(t)) + F_2(x(t)) + \dots + F_m(x(t)) + \dots + F_n(x(t)) + e(t) \end{aligned} \quad (8)$$

where $x(t) = [x_1(t), x_2(t), \dots, x_n(t)]^T$ and

$$x_k(t) = \begin{cases} y(t-k), & 1 \leq k \leq n_y \\ u(t-k+n_y), & n_y + 1 \leq k \leq n = n_y + n_u \end{cases} \quad (8a)$$

$$F_1(x(t)) = \sum_{i=1}^n f_i(x_i(t)) \quad (8b)$$

$$F_2(x(t)) = \sum_{i=1}^n \sum_{j=i+1}^n f_{ij}(x_i(t), x_j(t)) \quad (8c)$$

$$F_m(x(t)) = \sum_{1 \leq i_1 < i_2 < \dots < i_m \leq n} f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t)), \quad 2 < m < n, \quad (8d)$$

$$F_n(x(t)) = f_{12 \dots n}(x_1(t), x_2(t), \dots, x_n(t)) \quad (8e)$$

This can be referred to as the ANOVA decomposition of the NARX model. Although the ANOVA expansion (2) or the NARX model (8) involves up to 2^n different functional components, experience shows that a truncated representation containing the components up to the bivariate functional terms is often sufficient

$$y(t) = f_0 + \sum_{p=1}^n f_p(x_p(t)) + \sum_{p=1}^n \sum_{q=p+1}^n f_{pq}(x_p(t), x_q(t)) + e(t) \quad (9)$$

This can often provide a satisfactory description of $y(t)$ for many high dimensional problems providing that the input variables are properly selected. The presence of only low order functional components does not necessarily imply that the high order variable interactions are not significant, nor does it mean the nature of the nonlinearity of the system is less severe. An exhaustive search for all the possible submodel structures of (2) is demanding and can be prohibitive because of the curse-of-dimensionality. A truncated representation is advantageous and practical if the higher order terms can be ignored. In practice, the constant term f_0 can often be omitted since it can be combined into other functional components.

In practice, many types of functions, such as kernel functions, splines, polynomials and other basis functions can be chosen to express the functional components in model (8). In the present study, however, wavelet decompositions, which are discussed in the next section, will be chosen to describe the functional components in the additive models (8) and (9), and this will be referred to as the Wavelet-based the ANOVA decomposition of the NARX model or simply the WANARX model.

3. Wavelet decompositions

Wavelet analysis (Chui 1992, Daubechies 1992) is based on a wavelet prototype function, called the *analysing wavelet*, *mother wavelet*, or simply *wavelet*. Temporal analysis is performed using a contracted, high-frequency version of the same function. Because the signal or function to be studied can be represented in terms of wavelet decompositions, data operations can also be performed using the corresponding wavelet coefficients.

3.1 Wavelet frame decomposition

Let φ be a d -dimensional wavelet function and $f \in L^2(\mathbb{R}^d)$. Assume that there exists a denumerable family derived from φ

$$\Omega = \left\{ \varphi_{(a_j, b_j)} : \varphi_{(a_j, b_j)}(x) = (Q_j)^{1/2} \varphi(A_j(x - b_j)) \right\} \quad (10)$$

where $b_j = [b_{j1}, b_{j2}, \dots, b_{jd}]^T \in \mathbb{R}^d$ is a translation vector, $a_j = [a_{j1}, a_{j2}, \dots, a_{jd}]^T \in \mathbb{R}^{+d}$ is a dilation vector, $Q_j = \det(A_j)$ and $A_j = \text{diag}[a_{j1}^{-1}, a_{j2}^{-1}, \dots, a_{jd}^{-1}]$.

Under the condition that φ generates a frame (Chui 1992), it is assured that any function $f \in L^2(\mathbb{R}^d)$ can be expressed as

$$f(x) = \sum_{j \in \Gamma} c_j (\mathcal{Q}_j)^{1/2} \varphi(A_j(x - b_j)) = \sum_{j \in \Gamma} w_j \varphi(A_j(x - b_j)) \quad (11)$$

where Γ is an index set which might be finite or infinite, c_j and w_j are the decomposition coefficients or weights. Eq. (11) is called the *wavelet frame decomposition*, which can be approximated by a neural network structure and it is therefore often referred to as a *wavelet network* (Zhang 1992).

3.2 Wavelet series

In practical applications the CWT (11) is often discretised in both the scaling and dilation parameters for computational efficiency. Based on this discretization, wavelet decompositions can be obtained to provide an alternative basis function representation. Take the univariate wavelet as an example. The most popular approach to discretise the CWT is to restrict the dilation and translation parameters to a dyadic lattice as $a = 2^{-j}$ and $b = k2^{-j}$ with $j, k \in \mathbb{Z}$. Other non-dyadic ways of discretization are also available.

Under some conditions (Chui 1992, Daubechies 1992), an arbitrary function $f \in L^2(\mathbb{R})$ can be expressed as

$$f(x) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} c_{j,k} \varphi_{j,k}(x) \quad (12)$$

where $\varphi_{j,k}(x) = 2^{j/2} \varphi(2^j x - k)$ and $j, k \in \mathbb{Z}$. Eq. (12) is called a *wavelet series*. In comparison with the CWT (11), the wavelet series is more computationally efficient. But this is obtained at the expense of increased restrictions on the choice of the basic wavelet φ . The wavelet series (12) can be extended to d -dimensional case by taking *tensor product* of one-dimensional wavelets or by choosing the radial types of wavelets.

3.3 Multiresolution wavelet decompositions

It is known that for solving identification problems based on the regression representation it is useful to have a basis of orthogonal (semi-orthogonal or bi-orthogonal) functions whose support can be made as small as required and which provides a universal approximation to any $L^2(\mathbb{R})$ function with arbitrary desired accuracy. One of the original objectives of wavelet theory was to construct orthogonal (semi-orthogonal) basis in $L^2(\mathbb{R})$.

Assume that the wavelet φ and the corresponding scaling function ϕ constitute an orthogonal wavelet system, then any function $f \in L^2(\mathbb{R})$ can be expressed as the following *multiresolution wavelet decomposition*

$$f(x) = \sum_k \alpha_{j_0,k} \phi_{j_0,k}(x) + \sum_{j \geq j_0} \sum_k \beta_{j,k} \varphi_{j,k}(x) \quad (13)$$

where $\alpha_{j_0,k}$ and $\beta_{j,k}$ are the wavelet coefficients, j_0 is an arbitrary integer representing the lowest resolution or scaling level. Notice that from wavelet theory (Chui 1992, Daubechies 1992) if $j_0 \rightarrow -\infty$, the approximation representation (13) becomes the wavelet decomposition (12). In addition, from the property of the

multiresolution decomposition (13), any function $f \in L^2(\mathbb{R})$ can be arbitrarily closely approximated using the basic scaling functions $\phi_{j,k}(x) = 2^{j/2}\phi(2^j x - k)$ by choosing the resolution scale j to be sufficiently large. That is, there exists a sufficiently large integer J , such that

$$f(x) = \sum_{k=-\infty}^{\infty} c_k \phi_{J,k}(x) \quad (14)$$

This means that in wavelet series representation, the wavelet bases can be replaced by scaling functions with a large resolution scale.

Using the concept of *tensor products*, the multiresolution decompositions (13) and (14) can be immediately generalised to the multi-dimensional case, where a multiresolution wavelet decomposition can be defined by taking the *tensor product* of the one-dimensional scaling and wavelet functions (Mallat 1989) and this will be discussed later.

4. Expanding the WANARX model using wavelet decompositions

The wavelet decompositions including the wavelet frame decomposition, wavelet series and wavelet multiresolution decompositions discussed in Section 3 can be adapted to express each functional component in the NARX model (8). Notice that it is impossible in practice to count infinite frame terms or wavelet bases in a wavelet decomposition. Therefore, the infinite decompositions are always truncated at appropriate dilations (resolutions) and translations.

4.1 Expanding the functional components using wavelet frame decomposition

Each functional component in the NARX model (8) can be expressed using the truncated wavelet frame decomposition (11), take the functional component $f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t))$ as an example, this can be expanded as

$$\begin{aligned} & f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t)) \\ &= \sum_{i=1}^{I_{i_1 i_2 \dots i_m}} w_i^{(i_1 i_2 \dots i_m)} \varphi^{(i_1 i_2 \dots i_m)} (A_i^{(i_1 i_2 \dots i_m)} (x^{(i_1 i_2 \dots i_m)}(t) - b_i^{(i_1 i_2 \dots i_m)})) \end{aligned} \quad (15)$$

where

$$\begin{aligned} x^{(i_1 i_2 \dots i_m)}(t) &= [x_{i_1}^{(i_1 i_2 \dots i_m)}(t), x_{i_2}^{(i_1 i_2 \dots i_m)}(t), \dots, x_{i_m}^{(i_1 i_2 \dots i_m)}(t)]^T, \\ b_i^{(i_1 i_2 \dots i_m)} &= [b_{i_1}^{(i_1 i_2 \dots i_m)}, b_{i_2}^{(i_1 i_2 \dots i_m)}, \dots, b_{i_m}^{(i_1 i_2 \dots i_m)}]^T, \\ a_i^{(i_1 i_2 \dots i_m)} &= [a_{i_1}^{(i_1 i_2 \dots i_m)}, a_{i_2}^{(i_1 i_2 \dots i_m)}, \dots, a_{i_m}^{(i_1 i_2 \dots i_m)}]^T, \\ A_i^{(i_1 i_2 \dots i_m)} &= \text{diag}[(a_{i_1}^{(i_1 i_2 \dots i_m)})^{-1}, (a_{i_2}^{(i_1 i_2 \dots i_m)})^{-1}, \dots, (a_{i_m}^{(i_1 i_2 \dots i_m)})^{-1}]. \end{aligned}$$

$I_{i_1 i_2 \dots i_m}$ is the number of wavelets in the wavelet library composed of all the wavelets under consideration and $w_i^{(i_1 i_2 \dots i_m)}$ is the weight for the decomposition. $\varphi^{(i_1 i_2 \dots i_m)}$ indicates that different types of wavelets can be

employed simultaneously for approximating different functional components. This might enable the wavelet decomposition to be more flexible than traditional wavelet networks.

Inserting (15) into (8), yields

$$\begin{aligned} \hat{y}(t) = & \hat{f}_0 + \sum_{i_1=1}^n \sum_{k=1}^{I_{i_1}} w_k^{(i_1)} \varphi^{(i_1)}(A_k^{(i_1)}(x^{(i_1)}(t) - b_k^{(i_1)})) \\ & + \sum_{1 \leq i_1 < i_2 \leq n} \sum_{k=1}^{I_{i_1 i_2}} w_k^{(i_1 i_2)} \varphi^{(i_1 i_2)}(A_k^{(i_1 i_2)}(x^{(i_1 i_2)}(t) - b_k^{(i_1 i_2)})) + \dots \\ & + \sum_{k=1}^{I_{12 \dots n}} w_k^{(12 \dots n)} \varphi^{(12 \dots n)}(A_k^{(12 \dots n)}(x^{(12 \dots n)}(t) - b_k^{(12 \dots n)})) \end{aligned} \quad (16)$$

This will be referred to as a *super wavelet network*. The values of the decomposition parameters $w_k^{(i_1 i_2 \dots i_m)}$, $b_k^{(i_1 i_2 \dots i_m)}$ and $a_k^{(i_1 i_2 \dots i_m)}$ can be obtained by minimizing a criterion function, say

$$\min V = \frac{1}{2} \sum_{t=1}^T e^2(t) = \frac{1}{2} \sum_{t=1}^T [y(t) - \hat{y}(t)]^2 \quad (17)$$

where $y(t)$ is the measurement at time t , and T is the data length. To minimise the function V , gradient descent type methods are required and thus the gradients of unknown parameters should be calculated first. Once the gradients have been obtained, Gauss-Newton type optimisation methods including steepest decent and stochastic gradient methods can be used to obtain the unknown parameters.

Note that the wavelets used in the adaptive wavelet decomposition (wavelet networks) described by (16) should be explicitly expressible and differentiable. This restricts the choice of basic wavelet functions used for wavelet networks to a special class. The Morlet wavelet $\varphi(x) = \exp(j\omega_0^T x - \|x\|^2/2)$, Gaussian wavelet $\varphi(x) = x_1 x_2 \dots x_d \exp(-\|x\|^2/2)$, and Marr (Mexican hat) wavelet $\varphi(x) = (d - x_1 x_2 \dots x_d) \exp(-\|x\|^2/2)$ are among the examples which are often used in wavelet networks. The symbol $\|\cdot\|$ here denotes the Euclidian norm in $L^2(R^d)$.

Notice that a radial wavelet is often considered and the family (10) is often restricted in a regular grid, that is, the translation and dilation parameters a_j and b_j in (10) are designed to form a double indexed regular lattice

$$\{(a_j, b_k) = (\alpha^{-j}, k\beta\alpha^{-j}) : j \in \mathbb{Z}, k \in \mathbb{Z}^d\} \quad (18)$$

where the scalar parameters α and β are the discretization step with typical values $\alpha = 2$ and $\beta = 1$. Expanding each functional component in (8) using a radial wavelet frame

$$\Omega_R = \{\varphi_{j,k} : \varphi_{j,k}(x) = \alpha^{jd/2} \varphi(\alpha^j x - k\beta), j \in \mathbb{Z}, k \in \mathbb{Z}^d\} \quad (19)$$

The NARX structure (8) can then be converted into a linear-in-the-parameters problem, which can be solved using regression analysis techniques, and this will be referred to as a *super wavelet network on fixed grid*, or, *super fixed grid wavelet network*. If only the last functional component $f_{12 \dots n}(x_1(t), x_2(t), \dots, x_n(t))$ in (8) is considered and expanded using a radial wavelet frame with the form of (19), then this decomposition can be

treated as a standard linear regression problem with the dilated and translated wavelets as the regressors. This will be referred to as a *fixed grid wavelet network*, which is a special case of the *super fixed grid wavelet networks* considered here.

4.2 Expanding the functional components using wavelet series

Consider the functional component $f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t))$ in the NARX expansion (8). This functional component can be approximated using the truncated wavelet series (12) or (14)

$$\begin{aligned} & f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t)) \\ &= \sum_{j=j_m}^{J_m} \sum_{k_1 \dots k_m} c_{j; k_1, k_2, \dots, k_m}^{(i_1 i_2 \dots i_m)} B_m(2^j x_{i_1}(t) - k_1, 2^j x_{i_2}(t) - k_2, \dots, 2^j x_{i_m}(t) - k_m) \end{aligned} \quad (20)$$

where $k = [k_1, k_2, \dots, k_m]^T \in Z^m$ is an m -dimensional index, $B_m(x)$ is an m -dimensional wavelet or scaling function and can be decomposed as the direct product of m one-dimensional functions

$$B_m(x) = B_m(x_1, x_2, \dots, x_m) = \prod_{i=1}^m \psi(x_i) \quad (21)$$

where $\psi(\cdot)$ is a scalar wavelet or scaling function. Now (20) can be expressed as

$$f_{i_1 i_2 \dots i_m}(x_{i_1}(t), x_{i_2}(t), \dots, x_{i_m}(t)) = \sum_{j=j_m}^{J_m} \sum_{k_1, k_2, \dots, k_m} c_{j; k_1, k_2, \dots, k_m}^{(i_1 i_2 \dots i_m)} \prod_{p=1}^m \psi(2^j x_{i_p} - k_p) \quad (22)$$

Inserting (22) into (8), yields

$$y(t) = \hat{f}(x_1(t), x_2(t), \dots, x_n(t)) = \hat{f}_0 + \hat{F}_1(x(t)) + \hat{F}_2(x(t)) + \dots + \hat{F}_n(x(t)) + e(t) \quad (23)$$

where \hat{f}_0 is a constant and

$$\hat{F}_1(x(t)) = \sum_{p=1}^n \sum_{j=j_1}^{J_1} \sum_k c_{j;k}^{(p)} \psi(2^j x_p(t) - k_p) \quad (23a)$$

$$\hat{F}_2(x(t)) = \sum_{1 \leq p < q \leq n} \sum_{j=j_2}^{J_2} \sum_{k_1, k_2} c_{j; k_1, k_2}^{(pq)} \psi(2^j x_p(t) - k_1) \psi(2^j x_q(t) - k_2) \quad (23b)$$

$$\hat{F}_m(x(t)) = \sum_{1 \leq i_1 < \dots < i_m \leq n} \sum_{j=j_m}^{J_m} \sum_{k_1, \dots, k_m} c_{j; k_1, \dots, k_m}^{(i_1 i_2 \dots i_m)} \prod_{p=1}^m \psi(2^j x_{i_p}(t) - k_p) \quad (23c)$$

$$\hat{F}_n(x(t)) = \sum_{j=j_n}^{J_n} \sum_{k_1, k_2, \dots, k_n} c_{j; k_1, k_2, \dots, k_n}^{(12 \dots n)} \prod_{p=1}^n \psi(2^j x_p(t) - k_p) \quad (23d)$$

Generally, the initial resolution j_m ($m = 1, 2, \dots, n$) are chosen to be the same, that is, $j_1 = j_2 = \dots = j_n = j_0$.

Similarly, the highest resolution levels are set to be $J_1 = J_2 = \dots = J_n = J$. Note that if the wavelet series (14)

is employed, the initial and highest resolution levels in (22) are usually set to be $j_m = J_m = J$ for $m=1, 2, \dots, n$.

Assume that M wavelet bases (mother wavelet or scaling functions) are required to expand the NARX model (8), and for convenience of representation also assume that the M wavelet bases are ordered according to a single index m , that is, $W = \{\psi_m\}_{m=1}^M$, then (23) can be expressed as a linear-in-the-parameters form as below:

$$y(t) = \sum_{m=1}^M \theta_m \psi_m(t) + e(t) \quad (24)$$

which can be solved using linear regression techniques. Note that, the regressor family $W = \{\psi_m\}_{m=1}^M$ might be redundant, since in practice it is usually true that the sampled data only form a sparse distribution in the input space. Consequently, the regression problem is often ill-posed and therefore some approaches should be employed to resolve this problem. It has been proven that the forward orthogonal least squares (OLS) method is an effective approach to solve this ill-posed problem (Billings *et al.* 1988, 1989, Korenberg *et al.* 1988, Chen *et al.* 1989). The regressor selection problem will be discussed in the next section.

From (12), every wavelet φ , orthogonal or not, generates a wavelet series representation for any $f \in L^2(\mathcal{R})$. From (14), the wavelet bases in the wavelet series representation (12) can be replaced by orthogonal scaling functions with a large resolution. This provides more freedom in the choice of basis functions in the wavelet series decomposition.

4.3 Expanding the functional components using multiresolution wavelets models

Take the two-dimensional additive model (9) as an example. Following Wei *et al.* (2003), each functional component in the model (9) can be expanded into the truncated multiresolution wavelet decompositions as

$$f_p(x_p(t)) = \sum_k \alpha_{j_1,k}^{(p)} \phi_{j_1,k}(x_p(t)) + \sum_{j \geq j_1} \sum_k \beta_{j,k}^{(p)} \varphi_{j,k}(x_p(t)), \quad p = 1, 2, \dots, n, \quad (25)$$

$$\begin{aligned} f_{pq}(x_p(t), x_q(t)) &= \sum_{k_1} \sum_{k_2} \alpha_{j_2;k_1,k_2}^{(pq)(1)} \phi_{j_2,k_1}(x_p(t)) \phi_{j_2,k_2}(x_q(t)) \\ &+ \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(1)} \phi_{j,k_1}(x_p(t)) \varphi_{j,k_2}(x_q(t)) \\ &+ \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(2)} \varphi_{j,k_1}(x_p(t)) \phi_{j,k_2}(x_q(t)) \\ &+ \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(3)} \varphi_{j,k_1}(x_p(t)) \varphi_{j,k_2}(x_q(t)), \quad 1 \leq p < q \leq n. \end{aligned} \quad (26)$$

Inserting Eqs (25) and (26) into (9) yields

$$\begin{aligned} y(t) &= \hat{f}(x_1, x_2, \dots, x_n) + e(t) \\ &= c_0 + \sum_{p=1}^n \sum_k \alpha_{j_1,k}^{(p)} \phi_{j_1,k}(x_p(t)) + \sum_{p=1}^n \sum_{j \geq j_1} \sum_k \beta_{j,k}^{(p)} \varphi_{j,k}(x_p(t)) \\ &+ \sum_{1 \leq p < q \leq n} \sum_{k_1} \sum_{k_2} \alpha_{j_2;k_1,k_2}^{(pq)(1)} \phi_{j_2,k_1}(x_p(t)) \phi_{j_2,k_2}(x_q(t)) \\ &+ \sum_{1 \leq p < q \leq n} \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(1)} \phi_{j,k_1}(x_p(t)) \varphi_{j,k_2}(x_q(t)) \\ &+ \sum_{1 \leq p < q \leq n} \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(2)} \varphi_{j,k_1}(x_p(t)) \phi_{j,k_2}(x_q(t)) \end{aligned}$$

$$+ \sum_{1 \leq p < q \leq n} \sum_{j \geq j_2} \sum_{k_1} \sum_{k_2} \beta_{j;k_1,k_2}^{(pq)(3)} \varphi_{j,k_1}(x_p(t)) \varphi_{j,k_2}(x_q(t)) + e(t) \quad (27)$$

which can be rearranged and converted into a linear-in-the-parameters problem in the form of (24) with respect to the wavelet coefficients $\alpha_{j_1,k}^{(p)}$, $\beta_{j_1,k}^{(p)}$ ($p=1,2,\dots,n$), and $\alpha_{j_2;k_1,k_2}^{(pq)(1)}$, $\beta_{j_2;k_1,k_2}^{(pq)(i)}$ ($1 \leq p < q \leq n$, $i=1,2,3$). This can be solved using least squares type algorithms, which will be discussed in the next section.

Although many functions can be chosen as scaling and wavelet functions, most of these are not suitable in system identification applications, especially in the case of multidimensional and multiresolution expansions because of the *curse-of-dimensionality*. An implementation, which has been tested with very good results, involves B-spline and B-wavelet functions in multiresolution wavelet decompositions (Billings and Coca 1999, Liu *et al.* 2000, Coca and Billings 2001, Wei and Billings 2002). B-spline wavelets were originally introduced by Chui and Wang (1992) to define a class of semi-orthogonal wavelets. The reasons that make this implementation particularly suitable in system identification are summarized below:

- B-spline wavelets are piecewise polynomial functions, efficient algorithms for computing these functions and their derivatives are available.
- B-spline wavelets have local support and provide near-optimal time-frequency localization.
- B-spline wavelets outperform other wavelet decompositions in terms of approximation rate. This means that few resolution levels are required to approximate a function in order to achieve a given accuracy. Since each extra level doubles the amount of computations, the choice of wavelet is clearly important. This supports the key parsimony principle in system identification.
- B-spline wavelets $\varphi^{[m]}(x)$ are symmetric for even order m and anti-symmetric for odd order m , that is,

$$\varphi^{[m]}(x) = (-1)^m \varphi^{[m]}(2m-1-x), \text{ where } [0, 2m-1] \text{ is the support of the B-spline wavelets } \varphi^{[m]}(x). \text{ In}$$

application to signal analysis, it is very important for wavelet functions to possess the property of symmetry and anti-symmetry. This is essential to avoid distortion in the reconstruction of compressed data (Chui 1992).

For the definition of B-spline wavelets and more details about the properties of B-spline wavelets, see the work of Chui and Wang (Chui 1992, Chui and Wang 1992).

4.4 Hybrid decomposition models

It has been shown in subsections 4.1, 4.2 and 4.3 that each functional component in the NARX model (8) can be expressed using wavelet networks, wavelet series or multiresolution wavelet decompositions. Usually, all the functional components in the NARX model (8) are expanded using the same decomposition, for example, the super wavelet network where all the functional components in the NARX model (8) are expressed using the radial wavelet network with the same type of radial mother wavelet, or, the multiresolution wavelet model (27) where all the functional components are expressed using wavelet multiresolution decompositions with the same type of mother wavelet and scaling function. However, it should be pointed out that it is not necessary to require all the functional components be expressed using the same type of decomposition with the same mother wavelet.

In practice, different types of decompositions or different types of mother wavelets can be used simultaneously in a WANARX model, for example,

- Expand all the first-order (univariate) functional components using wavelet multiresolution decompositions based on a certain type of wavelet and scaling function, say the Haar wavelet (first-order B-spline wavelet) and scaling function, and expand all the second-order(bivariate) functional components using wavelet multiresolution decompositions based on another type of wavelet and scaling function, say the 4th-order B-spline wavelet and scaling function.
- Expand all the first-order (univariate) functional components using wavelet multiresolution decompositions and expand all the second-order (bivariate) functional components using wavelet series.

The idea of using hybrid decomposition models is to sufficiently utilize the local properties of different types of basic wavelets or scaling functions simultaneously, and to remedy the weakness of one wavelet and/or scaling function with another. A hybrid decomposition model is often advantageous over a single decomposition model which use only a single type of mother wavelet or scaling function.

4.4.1 *Adaptive wavelet decompositions versus wavelet series and multiresolution wavelet decompositions*

As noted in the section 4.1, the wavelets used in adaptive wavelet decompositions (wavelet networks) should be explicitly expressible and differentiable. The gradients of the criterion function V , and thus the gradients for each of the wavelet functions should be calculated beforehand, and then Gauss-Newton type of optimisation methods such as steepest decent and stochastic gradient methods can be used to optimize the unknown parameters. Gauss-Newton optimisation methods are often in some sense initial-condition dependent. When the number of parameters is large, the convergence rate will be very slow and a great number of iterations are required. In addition, these methods are apt to converge to local minimum. In general, therefore, the adaptive wavelet decomposition may not be suitable for high dimensional problems.

Using wavelet series or multiresolution wavelet decompositions, the WANARX model (8) can be converted into a linear-in-the-parameters problem with respect to the corresponding wavelet coefficients. Notice, however, that the number of potential terms in the model might be very large, but a lot of the candidate terms may be redundant and should be removed from the model. The well known forward orthogonal least squares (OLS) algorithm (Billings *et al.* 1988, 1989, Korenberg *et al.* 1988, Chen *et al.* 1989), combined with the error reduction ratio (ERR) index, which measures the significance of each candidate model term, can be used to solve linear-in-the-parameters problems involving a great number of candidate terms which might possess severe redundancy.

4.4.2 *Radial wavelet networks versus compactly supported wavelet multiresolutoin decompositions*

Both radial wavelet networks (Zhang 1997) and multiresolution wavelet decomposition models (Billings and Coca 1999, Liu *et al* 2000, Coca and Billings 2001, Wei and Billings 2002) provide powerful representations for nonlinear systems. The model based on the radial wavelet frame (19), or the fixed grid wavelet network, resembles in effect the well known radial basis function (RBF) networks in structure with the Gaussian or thin-spline functions replaced by radial wavelets, which can generate single scaling wavelet frames. The main advantage of the decomposition based on the radial wavelet frame (19) is that the radial construction often leads to a smaller number of candidate regressors (model terms) compared with the multiresolution wavelet

decompositions where the compactly supported tensor product wavelets are used. Comparing the multiresolution wavelet models with the radial wavelet networks in detail, the following differences are worth noting:

i) The compactly supported wavelet basis functions, for example, the B-spline wavelet and scaling functions considered in this study, define a hierarchical multiresolution structure with fixed and regular dilation-translation sampling. Thus the location and scale of each basis function is known beforehand (see sections 6.2 and 6.3 for details). In radial wavelet networks, however, the basis functions have to be defined by means of a separate approach, for example, to check the value of each radial wavelet with respect to all the process sampling points.

ii) In the compactly supported wavelet multiresolution model, it is not required that every regressor (model term) include all the process variables as in a radial wavelet network. This allows more flexibility in selecting the correct model structure and avoids model over-fitting.

iii) B-spline wavelets are compactly supported. Thus, at a given resolution scale, the number of B-spline wavelets is deterministic. In fact, at each resolution level only the B-spline wavelets which cover the data domain need to be considered. This means that a limited number of B-spline wavelets need to be considered in the truncated multiresolution wavelet model and these are determined by the lowest and the highest resolution scales. Although almost all radial wavelet functions are nearly compactly supported, they only vanish rapidly as the independent variables of these functions are far from the centre. In practice, radial wavelets are usually truncated so that the wavelet support overlaps with the data domain. However, the truncation of the wavelet support might deteriorate the natural approximation property of wavelets.

5. System variable selection and model term (wavelet regressor) determination

Variable and term selection are generic problems in nonlinear system identification. Once the significant variables have been selected, the model terms can be determined using a term selection algorithm operating over the selected variables, a parsimonious model structure can then be identified from the candidate model set, and finally the parameters can be estimated based on this model structure.

5.1 System variable selection

The first problem encountered in WANARX modelling is how to determine which variables should be included in the model. It is often the case in practice that some of the variables x_1, x_2, \dots, x_n are redundant and only a subset of these variables is significant. Inclusion of redundant variables might result in a much more complex model since the number of model terms increases dramatically with the number of variables. Furthermore, including redundant variables might lead to a large number of free parameters in the model, and as a consequence the model may become oversensitive to training data and is likely to exhibit poor generalisation properties. Therefore, it is important to determine which variables should be included in the model.

The purpose of variable selection is to pre-select a subset consisting of the significant variables or to eliminate redundant variables from all the candidate variables of a system under study prior to model term detection. It is required that the selected significant variables alone should sufficiently represent the system. Based on these observations, a new effective variable selection algorithm (Wei *et al.* 2004), has been proposed and can be used to select significant variables prior to fitting a WANARX model.

5.2 Model term determination

As explained in Section 4, the truncated regular wavelet frame, wavelet series and multiresolution wavelet decompositions can be converted into a linear-in-the-parameters form

$$y(t) = \sum_{m=1}^M \theta_m p_m(t) + e(t) \quad (28)$$

where $p_m(t)$ ($m=1,2,\dots,M$) are regressors (model terms) produced by the dilated and translated versions of mother wavelets or scaling functions, which are in the dictionary considered. Generally, not all the model terms make an equal contribution to the system output and terms, which make little contribution can be omitted. A parsimonious representation, which contains only the significant terms, can often be obtained without the loss of representational accuracy by eliminating the redundant terms. Define

$$P^{(m)} = \{p_{i_k} : 1 \leq i_k \leq M; k = 1, 2, \dots, m\}, \quad m=1, 2, \dots, M, \quad (29)$$

The model term selection procedure is in fact an iterative process which searches through a nested term set in the sense that

$$P^{(1)} \subset P^{(2)} \subset \dots \subset P^{(m)} \subset \dots \quad (30)$$

This makes both the complexity and the accuracy of the representation based on these term sets to increase until a suitable term set is found, i.e., there exists an integer M_0 (generally $M_0 \ll M$), such that the model

$$y(t) = \sum_{k=1}^{M_0} \theta_{i_k} p_{i_k}(t) + e(t) \quad (31)$$

provides a satisfactory representation over the range considered for the measured input-output data.

A fast and efficient model structure determination approach has been implemented using the forward orthogonal least squares (OLS) algorithm and the error reduction ratio (ERR) criterion, which was originally introduced to determine which terms should be included in a model (Billings *et al.* 1988, 1989, Korenberg *et al.* 1988, Chen *et al.* 1989). This approach has been extensively studied and widely applied in nonlinear system identification (see, for example, Chen *et al.* 1991, Wang and Mendel 1992, Zhu and Billings 1996, Zhang 1997, Hong and Harris 2001). The forward OLS algorithm involves a stepwise orthogonalization of the regressors and a forward selection of the relevant terms in (28) based on the error reduction ratio (ERR) (Billings *et al.* 1988, 1989).

6. Some practical issues associated with implementation

Emphasis is concentrated on wavelet series and multiresolution decompositions, and it is assumed that some compactly supported wavelets or/and scaling functions are considered in these decompositions. Some practical issues including data normalization, highest resolution level determination, translation parameter selection and wavelet dictionary determination are considered.

6.1 Data pre-processing

The original observational data $\tilde{x}(t) = [\tilde{x}_1(t), \tilde{x}_2(t), \dots, \tilde{x}_n(t)]^T$ are often normalized into a standard domain, for example the unit hypercube $[0, 1]^n$, for the convenience of problem description. This is especially true when

a compactly supported wavelet and/or a scaling function are chosen in the wavelet series (12) or (14), and the multiresolution decomposition (13). Taking the univariate Haar wavelet (the first-order B-spline wavelet) as an example, it is much easier to select the starting resolution level and the range of the shift parameters if the sample data has been normalized to $[0, 1]$.

Assume that the initial observations $\tilde{x} \in R^n$ fall into the finite hypercube $[a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n]$, $\tilde{x}(t)$ can be normalized into the unit hypercube $[0, 1]^n$ by means of the following simple linear transform $x_i(t) = (\tilde{x}_i(t) - a_i)/(b_i - a_i)$, $i = 1, 2, \dots, n$.

By another transform, $x_i(t) = [2\tilde{x}_i(t) - (b_i + a_i)]/(b_i - a_i)$, $i = 1, 2, \dots, n$, the original data \tilde{x} can be normalized into the standard hypercube $[-1, 1]^n$.

The modelling can then be performed in the standard hypercube $[0, 1]^n$ or $[-1, 1]^n$, and the model output can then be recovered to the original system operating domain by taking the inverse transform which converts x back into \tilde{x} .

6.2 Determination of the highest resolution level

In theory, the wavelet series (12) and the multiresolution wavelet decomposition (13) are infinite expansions. In practice, however, it is impossible to include infinite terms in these wavelet decompositions. Therefore, the infinite decompositions are always truncated at appropriate dilations (resolutions) and translations.

Consider the one-dimensional multiresolution wavelet decomposition (13) and assume that the function $f(x)$ is defined in $[0, 1]$ and x is an independent variable which is uniformly distributed in $[0, 1]$, that is, x itself can be considered as ‘‘time’’, then the basis functions (dilated and translated versions of the wavelet and scaling function) in the multiresolution wavelet decomposition (13) are mutually orthogonal and the decomposition is unique. Assume also that the Haar wavelet (the first-order B-spline wavelet) and scaling function are used in the decomposition, then a truncated decomposition with the initial resolution scale j_0 and the highest resolution scale $j_{\max} = J$ can be expressed as

$$f(x) = \sum_{k=0}^{2^{j_0}-1} \alpha_{j_0,k} \phi_{j_0,k}(x) + \sum_{j=j_0}^J \sum_{k=0}^{2^j-1} \beta_{j,k} \varphi_{j,k}(x) \quad (32)$$

Clearly, the higher the upper resolution scale level J , the more accurate the approximation is. A recommended approach for selecting the highest scale J is to utilize the features of the sampled signal, for example, the natural frequency of the signal to be approximated. Assume that the maximum natural frequency of the sampled signals is f_{\max} , the highest scale can be empirically chosen as $j_{\max} = [\log_2(Mf_{\max})]$, where M is a positive number, say between 2^4 and 2^6 , and $[\cdot]$ denotes taking the integer value of the corresponding number (Wei and Billings 2002).

In practical identification problems, however, the orthogonality of the multiresolution wavelet decomposition might be lost, since most observational data fail to satisfy the uniform distribution assumption. Also in dynamical system modelling, the variable x in (32) is usually dependent on time t , and $x(t)$ often represents lagged outputs $y(t-p)$ ($p = 1, 2, \dots, n_y$) or lagged inputs $u(t-q)$ ($q = 1, 2, \dots, n_u$), which are usually sparse in the

normalized interval $[0, 1]$. The empirical rule $j_{\max} = \lceil \log_2(Mf_{\max}) \rceil$ for selecting the highest resolution scale can however still be used.

6.3 Shift parameter selection

For a compactly supported wavelet, the shift parameter k is determined by the corresponding resolution scale j . For example, at a given scale j , the shift parameter k in the Haar wavelet multiresolution decomposition (32) is chosen as $k = 0, 1, \dots, 2^j - 1$ ($j=0, 1, \dots$). Generally, for a compactly supported wavelet $\varphi(x)$ with an integer support $S_\varphi = [0, K_s]$, where K_s is integer, the support for the dilated and translated wavelet $\varphi_{j,k}(x) = 2^{j/2}(2^j x - k)$ is $[2^{-j}k, 2^{-j}(K_s + k)]$, therefore, the shift parameter k at a resolution scale j should be taken as $-(K_s - 1) \leq k \leq 2^j - 1$. This is also true for a compactly supported scaling function $\phi(x)$.

6.4 Wavelet dictionary determination

Taking the truncated wavelet series (23) and the truncated multiresolution wavelet decomposition (27) as an example. The elements of the wavelet dictionary are defined as the wavelet bases (dilated and translated versions of wavelets and scaling functions) involved in the decompositions. The number of all the dilated and translated versions of wavelets and/or scaling functions is defined as the length of the wavelet dictionary. The model terms in the approximation expressions are produced by some of the elements of the wavelet dictionary. Clearly, once the mother wavelets and/or scaling functions have been chosen, the wavelet dictionary is determined by the resolution scale parameter j and the shift parameter k . For compactly supported wavelets and scaling functions, the wavelet dictionary depends upon the initial resolution scale j_{\min} and the highest resolution scale j_{\max} . Therefore, it is important to choose appropriate values for the initial resolution scale j_{\min} and the highest resolution scale j_{\max} , since these values determine the degree of the complexity of the wavelet dictionary whatever types of wavelets are used. Theoretically, for a given initial resolution scale j_{\min} , the higher the upper resolution scale level j_{\max} , the more accurate the approximation is, however this may result in a more complex wavelet dictionary and thus a more complex decomposition, since too much resolution might result in a severely redundant wavelet dictionary or an over-fitted model.

In practice, for dynamical systems identification, the variable x in the wavelet function $\varphi_{j,k}(x)$ and the scaling function $\phi(x)$ is usually the lagged system inputs or/and outputs, and the observations of $x(t)$ are often sparsely distributed and therefore the problem can be ill-posed. This can produce a wavelet dictionary and the candidate model terms (regressors) that are redundant. However, the redundancy problem can be solved and the significant terms can be detected using a term detection algorithm.

7. Examples

In this section, two examples are provided to illustrate the application of the WANARX modelling structure. The input-output data used for identification in the first example are simulated from a nonlinear system with a known model; it is assumed, however, that no a priori information is available. The second example involves a real system and the measurements taken from satellite data, correspond to the solar wind parameter VBs (input) and the Dst index (output) for this terrestrial magnetospheric dynamic system.

7.1 Example 1—a nonlinear system disturbed by noise

Consider the following model

$$y(t) = \frac{0.5 + y(t-1)}{1 + y^2(t-1)} - \frac{2y(t-2)u(t-1)}{1 + u^2(t-1)} + u(t-1) + \xi(t) \quad (33)$$

where $u(t)$ is an impulse sequence with random amplitude $A(t)$ and random duration $\Delta(t)$, $5 \leq A(t) \leq 19$, $1 \leq \Delta(t) \leq 40$; $\xi(t)$ is a noise sequence obeying a normal distribution with a standard derivation $\sigma_{\xi}^2 = 0.0025$.

A data set consisted of 1000 input-output samples, which are illustrated in Figure 1, was generated by simulating the system. The data set was divided into two parts: the first 500 samples (from 1 to 500) were used for identification and the second part (from 501 to 1000) was used for testing.

The aim of the identification was to fit a WANARX model to describe the relationship between the input and output. The first step is to determine the significant variables which can sufficiently describe the relationship between the input and output. The variable selection algorithm of Wei *et al.* (2004) was applied and the three significant variables: $\{y(t-1), y(t-2), u(t-1)\}$ were selected. A one-dimensional WANARX model was therefore selected for this system

$$\begin{aligned} y(t) &= f(y(t-1), y(t-2), u(t-1)) + e(t) \\ &= f_1(y(t-1)) + f_2(y(t-2)) + f_3(u(t-1)) + e(t) \end{aligned} \quad (34)$$

Expanding each $f_i(\cdot)$ using the multiresolution wavelet decomposition (13), gives

$$f_i(x_i(t)) = \sum_{k \in K^0} \alpha_{0,k}^{(i)} \phi_{0,k}(x_i(t)) + \sum_{j=0}^4 \sum_{k \in K_j} \beta_{j,k}^{(i)} \varphi_{j,k}(x_i(t)), \quad i = 1, 2, 3, \quad (35)$$

where $x_1(t) = y(t-1)$, $x_2(t) = y(t-2)$, $x_3(t) = u(t-1)$; the 4th-order B-spline wavelet and scaling function were used in this decomposition, thus $K^0 = \{-3, -2, -1, 0\}$ and $K_j = \{-6, -5, \dots, -1, 0, 1, \dots, 2^j - 1\}$ for $j=0, 1, 2, 3, 4$.

Although 195 basis functions (model terms) are involved in the one-dimensional WANARX model, only 13 of these were selected to be significant using the forward OLS algorithm. The final model contained only 13 terms (basis functions), which are listed in Table 1. A comparison of the model predicted outputs and the measurements, along with the model prediction errors over the test set, are shown in Figure 2. The model predicted output (MPO) of an identified NARX model is defined as

$$\hat{y}_{mpo}(t) = f(\hat{y}_{mpo}(t-1), \dots, \hat{y}_{mpo}(t-n_y), u(t-1), \dots, u(t-n_u)) \quad (36)$$

The model predicted outputs are recursively estimated and are used to calculate the model prediction errors

$$\hat{e}(t) = y(t) - \hat{y}_{mpo}(t) \quad (37)$$

where $y(t)$ ($t=1,2,\dots,N$) are the system measurements.

7.2 Example 2—a terrestrial magnetosphere dynamic system

The sun is a source of a continuous flow of charged particles, ions and electrons called the solar wind. The terrestrial magnetic field shields the Earth from the solar wind, and forms a cavity in the solar wind flow that is called the terrestrial magnetosphere. The magnetopause is a boundary of the cavity, and its position on the day side (sunward side) of the magnetosphere can be determined as the surface where there is a balance between the dynamic pressure of the solar wind outside the magnetosphere and the pressure of the terrestrial magnetic field inside. A complex current system exists in the magnetosphere to support the complex structure of the magnetosphere and the magnetopause. Changes in the solar wind velocity, density or magnetic field lead to changes in the shape of the magnetopause and variations in the magnetospheric current system. In addition if the solar wind magnetic field has a component directed towards the south a reconnection between the terrestrial magnetic field and the solar wind magnetic field is initiated. Such a reconnection results in a very drastic modification to the magnetospheric current system and this phenomenon is referred to as magnetic storms. During a magnetic storm, which can last for hours, the magnetic field on the Earth's surface will change as a result of the variations of the magnetospheric current system. Changes in the magnetic field induce considerable currents in long conductors on the terrestrial surface such as power lines and pipe-lines. Unpredicted currents in power lines can lead to blackouts of huge areas, the Ontario Blackout is just one recent example. Other undesirable effects include increased radiation to crew and passengers on long flights, and effects on

communications and radio-wave propagation. Forecasting geomagnetic storms is therefore highly desirable and can aid the prevention of such effects. The *Dst* index is used to measure the disturbance of the geomagnetic field in the magnetic storm. Numerous studies of correlations between the solar wind parameters and magnetospheric disturbances show that the product of the solar wind velocity V and the southward component of the magnetic field, quantified by B_s , represents the input that can be considered as the input to the magnetosphere. Denote the multiplied input by VB_s .

Figure 3 shows 1000 data points of measurements recorded from satellites, of the solar wind parameter VB_s (input) and the *Dst* index (output) with a sample period $T=1$ hour. The purpose here is to identify a nonlinear model to represent the input-output relationship between VB_s (input) and *Dst*. The effects of other inputs on the system will be neglected in the present study. A variable selection algorithm of Wei *et al.* (2004) was applied and nine significant variables, $\{y(t-1), y(t-2), y(t-3), y(t-4), y(t-5), y(t-6), y(t-7), u(t-1), u(t-2)\}$ were selected. These nine variables are used to form a hybrid WANARX model for the data set

$$\begin{aligned}
y(t) &= f(y(t-1), y(t-2), \dots, y(t-7), u(t-1), u(t-2)) + e(t) \\
&= a_0 + \sum_{i=1}^9 a_i x_i(t) + \sum_{i=1}^9 \sum_{j=i}^9 b_{ij} x_i(t) x_j(t) \\
&\quad + \sum_{i=1}^9 f_i(x_i(t)) + \sum_{i=1}^8 \sum_{j=i+1}^9 f_{ij}(x_i(t), x_j(t)) + e(t)
\end{aligned} \tag{38}$$

where $x_i(t) = y(t-i)$ for $i=1,2,\dots,7$ and $x_i(t) = u(t-i+7)$ for $i=8,9$, f_i and f_{ij} are unknown univariate and bivariate functions which can be approximated by one- and two-dimensional wavelet decompositions. In this example, both the input and output data points were initially normalized and the modelling procedure was performed on the standard hypercube $[0, 1]^n$, where $n=9$. The first 500 input-output data points were used for model identification and the remaining 500 data points were used for testing. By expanding each f_i and f_{ij} using the wavelet series decomposition (14), where the 4th-order B-spline scaling functions were used in each decomposition, the model (38) was then converted into a linear-in-the-parameters problem and this was then estimated using the forward OLS-ERR algorithm (Billings *et al.* 1988, 1989, Korenberg *et al.* 1988, Chen *et al.* 1989). The final identified model, which involved 16 regressors selected from 891 candidate terms, was of the form

$$y(t) = \theta_1 y(t-1) + \sum_{i=2}^{16} \theta_i B_i(t) \tag{39}$$

where $B_i(t)$ ($i=2,3, \dots,16$) are wavelet regressors formed by the 4th-order B-spline scaling functions, and θ_i ($i=1,2,\dots,16$) are the parameters. The terms, parameters and corresponding ERR values are listed in Table 2. Notice again that each variable in the model (38) and (39) was initially normalized to $[0, 1]$, and the model outputs were recovered to the original system operating domain by taking inverse transforms.

In practice the one-step-ahead (one-hour-ahead) predictions for the *Dst* index are not useful, since it is difficult during a few minutes to collect all data from both satellite measurements and ground based magnetometers and to feed them into the model (39) to obtain predictions. On the other hand, forecasting the *Dst* index several months ahead of the real measurements is not required. To be practically useful, the predictions should be made

on some time scale which is intermediate between the two extreme cases. A 12-hour-ahead prediction based on (39) is considered here. The comparisons between the 12-step-ahead predictions, the model predicted outputs and the measurements are shown in Figure 4. As expected the model predicted outputs are not as good as the 12-step-ahead predictions, but the model predicted outputs provide good long term predictions and give confidence in the identified model. The discrepancy between the model predicted outputs and the measured values of the *Dst* index are believed to be the result of other inputs which affect the system output but were not included in the current model.

8. Conclusions

A unified wavelet-based NARX model structure, which incorporates wavelet networks, wavelet series and wavelet multiresolution decompositions, has been introduced for nonlinear input-output system identification. The new WANARX model structure allows high-order nonlinear systems to be expressed as a sum of additive low-dimensional submodels. This in some sense partially alleviates the difficulty of the *curse-of-dimensionality* for high-order nonlinear system modelling. The new identification algorithm is more constructive and transparent compared with most of the existing modelling approaches such as traditional neural networks and radial basis function networks in the sense that the new algorithm automatically detects the model terms and estimates the parameters simultaneously, and finally provides a transparent parsimonious model. The new algorithm is also more flexible in the sense that it can be used to identify arbitrary severely nonlinear systems, even systems with discontinuities and jumps, owing to the inherent time-frequency property of wavelets.

In the literature two classes of wavelet-based modelling algorithms have been proposed for nonlinear system identification, these include wavelet networks and additive models of univariate functions with respect to multiresolution decompositions. In wavelet networks, the basis functions are often chosen to be radial wavelet functions, which can generate single scaling wavelet frames but which generally require that every regressor (model terms) are included in all the process variables. Most radial wavelets are infinitely supported and should be truncated so that the wavelet support overlaps within the data domain. Although these features of wavelet

networks may involve a relatively small number of candidate regressors, it follows that these features might also lead to a deterioration of the natural approximation properties of wavelets and this suggests that wavelet networks will be more liable to over-fitting. The new identification algorithm proposed in this study, however, overcomes the drawbacks associated with radial wavelets by introducing a semi-orthogonal multiresolution wavelet decomposition structure based on B-spline wavelets as discussed in Section 4.

Additive submodels of univariate functions with respect to multiresolution decompositions are simple and generally involve a small number of candidate regressors. However, these models may sometimes not be able to effectively describe severe nonlinearities of complex systems. This motivates the introduction of the expressions of additive submodels of multivariate functions with respect to multiresolution decompositions as proposed in this study. Every functional component in each of the additive submodels can be decomposed using wavelet frame decompositions, wavelet series or wavelet multiresolution decompositions. An emphasis in the present study has been to focus on wavelet series and multiresolution wavelet decompositions, and the semi-orthogonal multiresolution wavelet decomposition structure based on B-spline wavelets which was recommended as a powerful approximation approach for a wide range of nonlinear systems. By expanding each functional component in the WANARX model using multiresolution wavelet decompositions, the model identification and parameter estimation problem can be converted into a linear-in-the-parameters problem.

The main disadvantage of the new wavelet based modelling approach is that a large number of candidate wavelet basis functions might be involved in the initial wavelet models for a high-dimensional system with several variables (large time lags for the system input and/or system output). Fortunately, this problem can be successfully resolved by employing an iterative model structure detection procedure coupled with the forward OLS-ERR algorithm which can efficiently select the significant model terms and estimate the parameters simultaneously.

Problems which need to be considered further include how to determine the highest order of the submodels (multivariate functional components), and how to choose the highest resolution scale for wavelet decompositions. For a high-dimensional system with several variables (or with many lagged inputs and/or outputs of the system), these two factors will dramatically affect the number of candidate model terms in the initial wavelet models. An effective and/or possible automatic way of determining these two factors is an important topic for future study and applications.

Acknowledgment

The authors gratefully acknowledge that part of this work was supported by EPSRC. We are grateful to Dr M. Balikhin for providing the magnetosphere data.
