### ABSTRACT

Tuberculosis (TB), a disease caused by the human pathogen *Mycobacterium tuberculosis*, recently joined HIV/AIDS on the top rank of deadliest infectious diseases. Low patient compliance due to the expensive, long-lasting and multi-drug standard therapies often results in treatment failure and emergence of multi-drug resistant strains. In this scope, antimicrobial peptides (AMPs) arise as promising candidates for TB treatment.

Here we describe the ability of the exogenous AMP LLKKK18 to efficiently kill mycobacteria. The peptide's potential was boosted by loading into self-assembling Hyaluronic Acid (HA) nanogels. These provide increased stability, reduced cytotoxicity and degradability, while potentiating peptide targeting to main sites of infection. The nanogels were effectively internalized by macrophages and the peptide presence and co-localization with mycobacteria within host cells was confirmed. This resulted in a significant reduction of the mycobacterial load in macrophages infected *in vitro* with the opportunistic *M. avium* or the pathogenic *M. tuberculosis*, an effect accompanied by lowered pro-inflammatory cytokine levels (IL-6 and TNF- $\alpha$ ). Remarkably, intra-tracheal administration of peptide-loaded nanogels significantly reduced infection levels in mice infected with *M. avium* or *M. tuberculosis*, after just 5 or 10 every other day administrations. Considering the reported low probability of resistance acquisition, these findings suggest a great potential of LLKKK18-loaded nanogels for TB therapeutics.

### 1. Introduction

Tuberculosis (TB) is a life-threatening disease caused by *Mycobacterium tuberculosis*. The World Health Organization recently reported about 9.6 million TB cases in 2014, having its death toll increased to around 1.5 million people, which places TB alongside HIV/AIDS as the deadliest infectious diseases [1].

The emergence of multidrug-resistant TB (MDR-TB) strains at an estimated rate of 3.3% is a further concern. MDR-TB may be mostly attributed to the selection of drug resistance mutations resulting from overuse and/or misuse of antibiotics. In addition, it has been demonstrated that primary transmission of MDR strains plays an important role in MDR-TB epidemics [2].

Tuberculosis transmission occurs mostly *via* the respiratory tract [3]. Mycobacteria are then phagocytized by alveolar macrophages and quickly spread across the lungs by lymphatic circulation. Weeks later,

bacilli may disseminate from the lungs to highly irrigated organs such as liver and kidneys [4,5]. Inside macrophages, mycobacteria are able to multiply within phagosomes, provided they arrest the phagosome maturation and its fusion with lysosomes, thereby avoiding contact with potent hydrolytic enzymes and antigen-presenting organelles present in the host macrophage [6,7].

TB control represents a major challenge. The only vaccine available, Bacille Calmette-Guérin (BCG), successfully prevents childhood TB but fails in protecting adults already infected or sensitized to mycobacteria [8]. Standard chemotherapy for drug-susceptible TB consists in the administration of a four antibiotic cocktail comprising isoniazid, rifampicin, pyrazinamide and ethambutol over a 6-month period. The presence of mycobacteria in stationary or low proliferating phases, as well as of multidrug-resistant strains, requires a more prolonged treatment regimen, involving the administration of pyrazinamide in combination with second-line drugs (e.g. fluoroquinolones, ethionamide, cycloserine, capreomycin or prothionamide) that can last up to 24 months [9,10].

However, toxicity issues and elevated costs associated with these drugs, as well as low patient compliance to the long-lasting regimens, represent crucial drawbacks to the pharmacotherapy [11,12].

Additional major problems include: 1) the rapid degradation or excretion of most drugs (usually within hours); 2) the systemic distribution of drugs, in opposition to a more limited action upon their target cells and tissues; 3) the limited bioavailability and poor absorption via specific routes (e.g. oral) [13,14]. As such, finding new treatments to improve and shorten TB therapy, while comprising different action mechanisms (less prone to resistance acquisition) has become imperative [15,16].

In this scope, antimicrobial peptides (AMPs) have gained interest as promising candidates for the treatment of mycobacterial infections [17]. AMPs are typically cationic and amphipathic members of the innate immune system, present in many living organisms. They usually comprise a short amino acid chain (10–50 residues) and show a broader spectrum of antimicrobial activity compared to standard antibiotics, often attributed to their non-specific killing mechanism [18,19]. Moreover, this non-specificity, along with the high metabolic costs associated with resistance-related mutations, is believed to have major implications in the reduced acquisition of AMP-resistance by mycobacteria [20,21].

The involvement of LL37, the only known human cathelicidin (a family of AMPs), in the killing of mycobacteria within macrophages has already been reported [22]. An ongoing clinical trial (NCT01580007) has evaluated the potential of the administration of 1,25-dihydroxyvitamin D3 (vitamin D) and phenylbutyrate, as synergistic inducers of LL37 expression, to enhance intracellular mycobacteria killing in *M. tuberculosis*-infected patients [23]. Several analogues of LL37 have also been engineered to enhance its activity. In the 18-mer LLKKK18, the polar uncharged residues glutamine and asparagine, and the negatively charged aspartic acid, are substituted by positively charged lysines. This results in a higher cationicity, hydrophobicity and ultimately higher antimicrobial activity, when compared to LL37 [24,25]. Indeed, we recently demonstrated LLKKK18 anti-mycobacterial activity against the opportunistic *Mycobacterium avium* (*M. avium*) growing in axenic conditions [26]. However, it remains unknown whether this peptide is able to reduce the mycobacterial load within infected macrophages or if it is active against more virulent mycobacteria.

The use of drug delivery systems may help circumvent some issues regarding the exogenous administration of AMPs, particularly by: 1) specifically targeting the peptide to a particular organ, allowing co-localization with bacteria; 2) preventing degradation by proteases; 3) improving stability and 4) increasing patient compliance through the possible reduction of the administration period [27,28].

Recently, we developed self-assembling Hyaluronic acid (HA) nanogels by grafting a hydrophobic molecule to HA [29]. The obtained amphiphilic conjugates self-assemble in aqueous environments and allow the entrapment of bioactive molecules in their hydrophobic core. In normal physiological conditions, macrophages do not internalize HA. However, Sladek and collaborators [30] showed that macrophages express the CD44 receptor in the beginning of an inflammatory response. Since activated macrophages express CD44 and can internalize HA [31], these nanogels seem to be a promising option to deliver drugs to infected macrophages.

In this work we evaluated the potential of LLKKK18 to efficiently kill the opportunistic *M. avium* and, most important, the human pathogen *M. tuberculosis*, using both *in vitro* and *in vivo* models of infection. We also hypothesized that the encapsulation of LLKKK18 into self-assembling HA nanogels could boost the potential of LLKKK18 to treat pulmonary mycobacterial infections, by enhancing the peptide's stability and targeting to infected macrophages, while reducing systemic toxicity and proteolytic degradability.

## 2. Materials and methods

### 2.1. Materials

Custom synthesis of LLKKK18 (KEFKRIVKRIKKFLRKLIV) was obtained from Schafer-N (Copenhagen, Denmark). Sodium hyaluronate (7.46 kDa, 401 g/mol per disaccharide unit) was purchased from

Lifecore Biomedical. AG 50W-X8 resin was acquired from Bio-Rad (USA).

All other reagents, including tetrabutylammonium fluoride hydrate (TBA-F), 11-amino-1-undecanethiol hydrochloride (AT), *N*-hydroxysulfosuccinimide (NHS) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) were purchased from Sigma Aldrich (Barcelona, Spain), unless stated otherwise.

### 2.2. Production of self-assembling hyaluronic acid-based nanogels

Production and characterization of self-assembling HA-based nanogels were performed according to a previously described method [29]. Firstly, a cationic exchange resin (AG 50 W) was used to exchange the cations of sodium hyaluronate with the lipophilic tetrabutylammonium (TBA) ion, to enable HA solubilization in dimethyl sulfoxide (DMSO). For this, 1 g AG 50 W resin was mixed with 3.5 g TBA in ultrapure water, for 1 h at room temperature, under mild stirring. After washing and purification, the resin was moved to a 1% (w/v) HA solution in ultra-pure water and the ion exchange of TBA ions with HA occurred for 2 h at room temperature, under mild stirring. The resin was then removed by centrifugation (2 min, 5000 rpm) in a Sigma 113 centrifuge and the resulting supernatant (HA-TBA) freeze-dried. Ion exchange was confirmed by <sup>1</sup>NMR spectroscopy. Crosslinking of the hydrophobic 11-amino-1-undecanethiol (AT) was performed through EDC/NHS chemistry [32]. The resulting solution was dialyzed (MWCO 1000 Da) against 150 mM NaCl for 3 days to remove any remaining TBA ions and 2 days in distilled water to further remove NaCl. Finally, the solution was freeze-dried and the resulting material (HA-AT) stored at room temperature until further use.

### 2.3. Antimicrobial peptide encapsulation into HA-based nanogels

Peptide encapsulation efficiency was quantified after mixing 100 μM LLKKK18 (Schafer-N, Denmark) with 0.5 mg/ml HA nanogels in Phosphate Buffered Saline (PBS) under mild rotation in a wheel, for 24 h at room temperature. Unloaded peptide was removed by transferring the solution into Amicon® Ultra-centrifugal filter units (Millipore) with a molecular weight cut-off of 100 kDa and centrifugation for 2 min at 2000 rpm. The original volume in the concentrated solution containing the peptide-loaded nanogels was then restored. The amount of free and loaded LLKKK18 was quantified by the Waddell method [33] and the encapsulation efficiency was expressed as the percentage of loaded peptide. Waddell's is a sensitive and accurate method for determining protein concentration in a sample, based on the quantification of peptide linkages, thus not being affected by variations in protein composition and structure. Peptide concentration is calculated by subtracting the absorbance reading at 225 nm from the 215 nm reading and multiplying that difference by 0.144.

The peptide-nanogel solution was sterilized through filtration using a 0.22 μm polyethersulphone (PES) syringe filter.

For subsequent tests the amount of peptide mixed with the nanogels was set considering the observed encapsulation efficiency (around 70%). Formulations were stored at 4 °C for up to 1 month until they were needed for further assays.

### 2.4. Characterization of the nanogels

Size distribution (diameter) and zeta potential of blank and peptide-loaded nanogels were analyzed by Dynamic Light Scattering (DLS), as previously described [29]. Briefly, 1 ml of the blank or peptide-loaded HA nanogels was dispersed in distilled water at 1 mg/ml and filtered with a 0.22 μm polyethersulfone (PES) syringe filter. LLKKK18 was encapsulated at the concentration used for the subsequent tests (100 μM). The samples were then analyzed in a polystyrene cell or in a folded capillary cell, for size distribution or zeta potential measurements,

respectively, in a Zetasizer NANO ZS (Malvern Instruments Limited, UK) using a He-Ne gas laser (wavelength of 633 nm) and a detector angle of 173°. For each sample, the polydispersity index (PDI), z-average diameter (corresponding to the mean hydrodynamic diameter) and zeta potential were evaluated after 6 repeated measurements. Zeta potential values were determined using Henry's equation.

## 2.5. Bacterial strains

The mycobacteria used in this study were selected based on their virulence. Two strains of the opportunistic *Mycobacterium avium*, 2447 and 25291, which form smooth transparent (SmT) colonies were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). These strains were grown in Middlebrook 7H9 medium (Difco, Sparks, MD) supplemented with Middlebrook Albumin, Dextrose, Catalase (ADC) Supplement (Sigma-Aldrich, Barcelona, Spain) and 0.04% Tween 80, at 37 °C, according to the supplier's instructions. For CFU counting, these strains were plated in solid Middlebrook 7H10 medium supplemented with Middlebrook Oleic acid, Albumin, Dextrose, Catalase (OADC) Supplement (Sigma-Aldrich, Barcelona, Spain) and 0.5% glycerol. *M. tuberculosis* H37Rv was obtained from the Trudeau Institute Mycobacterial Collection and grown in conditions similar to *M. avium* (Middlebrook 7H9 medium supplemented with ADC and 0.04% Tween 80, at 37 °C), according to the supplier's instructions. Colony forming units (CFUs) were grown in Middlebrook 7H11 medium supplemented with 10% OADC (Sigma-Aldrich, Barcelona, Spain) and 0.5% glycerol, at 37 °C.

## 2.6. Anti-mycobacterial activity in axenic culture

Determination of the anti-mycobacterial activity of free and loaded peptide was performed as previously described [26]. Frozen aliquots of *M. avium* 2447 or *M. tuberculosis* H37Rv were thawed and diluted in 7H9 broth medium supplemented with 10% ADC and 0.05% Tween 80 to attain a final concentration of  $2 \times 10^4$  CFU/ml and 50 µl of this culture was added to a 96-well plate, in triplicate. Serial dilutions of the peptide in distilled water, loaded or not into nanogels, were added to the mycobacteria to a final volume of 100 µl/well. Distilled water was added to the control. The plate was then incubated in a humidified chamber at 37 °C during 4 or 7 days (for *M. tuberculosis* or *M. avium*, respectively) after which the antimicrobial effect was evaluated by plating serial dilutions of the suspensions on solid Middlebrook 7H10 (*M. avium*) or 7H11 (*M. tuberculosis*) agar medium supplemented with 10% OADC and 0.5% glycerol. CFUs in each plate were counted 1 or 3 weeks after plating, depending on the species. Mycobacterial survival after 4 (*M. tuberculosis*) or 7 days (*M. avium*) of incubation was expressed as a percentage relatively to a control group of mycobacteria grown without LLKKK18. The concentration needed to reduce *M. tuberculosis* growth by 50% (IC<sub>50</sub>) was calculated from a dose-effect plot.

## 2.7. Culture of murine bone marrow-derived macrophages

Bone marrow-derived cells (BMMΦ) from C57BL/6 mice were isolated from femurs and tibia, removed under aseptic conditions, according to a previously reported method [34]. Bones were flushed with 5 ml of Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% Fetal Bovine Serum (FBS), passed through a cell strainer and centrifuged at 1200 rpm, 6 min, at 4 °C. The pellet was resuspended in 10 ml DMEM supplemented with 20% L929-cell conditioned medium (LCCM) and cells were allowed to differentiate into macrophages for 7 days in 100 mm diameter Petri dishes. Another 10 ml of DMEM containing 20% LCCM was added to the cells at day 4. At day 7, differentiated cells were scraped from the Petri dishes and seeded at the desired concentration in 24 or 96 well plates.

## 2.8. Viability and metabolic activity assays

### 2.8.1. MTS reduction test

The cells' metabolic activity in the presence of the LLKKK18-loaded NPs was assessed by measuring the reduction of the tetrazolium salt MTS (3-(4,5-dimethyl-2-yl)-5-(3-carboxy-methoxyphenyl)-2-(4-sulfophenyl)-2H tetrazolium). BMMΦ were seeded in 96-well plates at  $5 \times 10^4$  cells/well and allowed to adhere overnight. The cell culture medium was then replaced by empty HA nanogels at different concentrations, prepared in DMEM to a final volume of 200 µl. After 24 h, at 37 °C, 5% CO<sub>2</sub>, 20 µl of MTS (CellTiter 96® Aqueous One Solution Cell Proliferation Assay, Promega, WI, USA) was added per well and the plate was further incubated for 2 h at 37 °C, protected from light, to allow the formazan reduction to occur. Metabolic activity was then measured spectrophotometrically at 490 nm in a Bio-Rad Model 680 (Bio-Rad laboratories, UK) microplate reader.

### 2.8.2. Trypan blue dye exclusion assay

BMMΦ were seeded in 96-well plates at the concentration of  $5 \times 10^4$  cells/well. The cells were incubated for 24 h in the presence of the blank and peptide-loaded NPs, in a final volume of 100 µl/well. On the following day, the plate was placed on ice for 1 h to detach BMMΦ, which were then scraped and mixed with Trypan blue (1:1) for cell counting using a Neubauer Chamber. Trypan blue is only uptaken by cells with a disrupted cell membrane (non-viable), thus allowing the distinction between viable and non-viable cells.

### 2.8.3. Live/Dead assay

Cell viability was also assessed using the Live/Dead® Viability/Cytotoxicity Kit (Invitrogen, CA, USA), according to the manufacturer's instructions. BMMΦ were seeded in 96-well plates at  $5 \times 10^4$  cells/well and allowed to adhere overnight. The cell culture medium was then replaced by fresh culture medium, non-loaded (blank) or peptide-loaded nanogels at the desired concentrations, and cells were incubated for 24 h at 37 °C, 5% CO<sub>2</sub>. Cell culture medium was then replaced by 100 µl of PBS containing 1 µM calcein AM and 2 µM ethidium homodimer-1 (EthD-1) and incubated for 30 min at 37 °C, 5% CO<sub>2</sub>. Calcein-AM and EthD-1 are indicators of intracellular esterase activity and plasma membrane integrity, respectively. Cells were observed under a fluorescence microscope (Leica DMIRE2, with a DCF350FX camera) and pictures taken from five random fields for each condition. The amount of viable cells was expressed as a percentage relatively to a control with no nanogels or peptide.

### 2.8.4. Apoptotic cell death detection

Evaluation of apoptotic cell death was performed using an *in situ* cell death detection kit (Roche, UK), based on the Terminal deoxynucleotidyl transferase dUTP nick end-labeling (TUNEL) assay. BMMΦ were seeded on top of coverslips, in a 24-well plate, at  $5 \times 10^5$  cells/well. Infection with *M. avium* was performed at a multiplicity of infection (M.O.I.) = 2 and both infected and non-infected cells were treated as described in the sections above. After 24 h, the cells were fixed using 2% paraformaldehyde (PFA) and TUNEL was applied according to the manufacturer's instructions. The coverslips were observed under a fluorescence microscope (Leica DMIRE2, with a DCF350FX camera) and at least 300 cells were counted per condition.

### 2.8.5. Free nitric oxide estimation

The accumulation of extracellular nitrites (NO<sub>2</sub>), an indicator of nitric oxide synthase activity, was quantified by the Griess reaction, according to a previously described protocol [35]. Nitrites react with Griess reagent (1% sulfanilamide–0.1% naphthylethylenediamine dihydrochloride in 5% concentrated H<sub>3</sub>PO<sub>4</sub>), forming a pink azo product [36]. BMMΦ were seeded in 24-well plates at the concentration of  $5 \times 10^5$  cells/well and further incubated for 24 h with blank and loaded nanogels. NO<sub>2</sub> accumulation was measured by mixing 50 µl of cell

culture medium from each well with an equal volume of Griess reagent, followed by an incubation period of 10 min at room temperature, protected from light. Absorbance was measured at 550 nm in a microplate reader and the nitrite concentration determined from a calibration curve using sodium nitrite as a standard.

### 2.9. Intracellular effect of the nanogels on mycobacteria killing

The intracellular reduction of the mycobacterial burden was assessed in BMM $\Phi$  infected with either *M. avium* 2447 or *M. tuberculosis* H37Rv, as previously described [26]. BMM $\Phi$  were seeded at  $5 \times 10^5$  cells/ml in 24-well plates, allowed to adhere overnight and infected with either mycobacteria strain at a multiplicity of infection of 2 for 4 h to allow mycobacteria internalization. After that period, non-internalized mycobacteria were removed by 4 washes in pre-warmed DMEM and cells incubated with the blank or LLKKK18-loaded NPs. A PBS solution was used as a control. After a 7- or 4-day incubation period, for *M. avium* and *M. tuberculosis*, respectively, BMM $\Phi$  were permeabilized with saponin and mycobacteria survival was evaluated by plating serial dilutions on 7H11 agar plates. CFUs were then counted after 2 weeks of incubation at 37 °C, 5% CO<sub>2</sub>. The initial intracellular bacterial burden was assessed identically at day 0. Of note, an independent researcher additionally performed a blind experiment of the *M. avium* assay.

### 2.10. Internalization studies

#### 2.10.1. Confocal microscopy

*M. avium* strain 104 expressing recombinant GFP [37] was used to visualize intracellular mycobacteria, similarly to a previously described method [38]. BMM $\Phi$  were seeded at  $5 \times 10^5$  cells/well in 24-well plates with 12 mm diameter coverslips. Mycobacteria were added at a multiplicity of infection of 10 and, after 4 h, each well was extensively washed 4 times with pre-warmed DMEM. The macrophages were then incubated for different time points with LLKKK18 and HA nanogels fluorescently labeled with TAMRA (Schafer-N, Denmark) or Alexa Fluor 488, respectively. Free LLKKK18 was added at a concentration below the toxicity threshold (10  $\mu$ M), whereas encapsulated LLKKK18 was added at 30  $\mu$ M per well in 0.5 mg/ml HA nanogels. At the defined endpoints, cells were fixed with 2% paraformaldehyde (in PBS) for 20 min and the coverslip placed on top of a microscopy slide for observation under a Confocal Scanning Laser Microscope (CLSM, Olympus BX61, Model FluoView 1000), comprising a Laser DM 405/488/515/559/635 and the following emission filters: BA 505–540 (green channel), BA 575–620 (orange channel) and BA 655–755 (red channel). Images were analyzed on the software FV10-ASW 4.2.

#### 2.10.2. MALDI-ToF mass spectrometry

Internalization and intracellular degradation of LLKKK18 were also assessed by Matrix-assisted laser desorption/ionization–time of flight (MALDI-ToF) mass spectrometry, according to a previously reported protocol [39]. This method allows the measurement of the total amount of intact internalized peptide and the identification of possible degraded products. Briefly, BMM $\Phi$  seeded at  $5 \times 10^5$  cells/well in 12-well plates were incubated (37 °C, 5% CO<sub>2</sub>) for different time points in the presence of 5  $\mu$ M (corresponding to 5 pmol/ $\mu$ l) of free or loaded peptide, containing an isotope tag of four non-deuterated glycines ([<sup>1</sup>H]LLKKK18, Schafer-N, Denmark). Peptides were also biotinylated to facilitate extraction, purification, concentration and desalting, which was performed with streptavidin-coated magnetic beads.

After the incubation period, cells were scraped and centrifuged for 2 min at 640 g in an Eppendorf® 5430R centrifuge (Eppendorf, NY, USA) to recover intact cells. The pellet was further washed with 1 ml Buffer A (50 mM Tris-HCl, (pH 7.4), 0.1 mg/ml Bovine Serum Albumin (BSA)) and again centrifuged for 2 min at 640 g. 1 pmol of peptide with four bi-deuterated glycines ([<sup>2</sup>H]LLKKK18) was then added to

the pellet and the cells were lysed for 15 min at 100 °C in the presence of 150  $\mu$ l lysis solution (0.3% Triton X-100, 1 M NaCl). The lysate was centrifuged for 5 min at 12,000 g and 4 °C, and the supernatant transferred to a clean tube. The pellet was further washed with 850  $\mu$ l of Buffer A, again centrifuged for 5 min at 12,000 g and 4 °C, and the supernatant was combined with the previous one. A 10  $\mu$ l solution of washed streptavidin-coated magnetic beads (Dynabeads MyOne Streptavidin C1, Invitrogen, UK) was added to the lysate and stirred gently for 1 h at room temperature, to allow the binding of the beads to the biotinylated peptides. The beads were then immobilized with a Dynabeads® MPC®-S magnetic particle concentrator (Invitrogen, UK), the supernatant was removed and the beads washed twice with 200  $\mu$ l of Buffer A, twice with 200  $\mu$ l of Buffer B (50 mM Tris-HCl, (pH 7.4), 0.1 mg/ml BSA, 0.1% SDS), twice with 200  $\mu$ l of Buffer C (50 mM Tris-HCl, (pH 7.4), 0.1 mg/ml BSA, 1 M NaCl) and twice with 200  $\mu$ l of distilled water. Saturation of the beads ensued, by incubating them for 2 min with 400 pmol of biotin. The beads were then washed with 50  $\mu$ l of a 1:1 acetonitrile/water solution, and after removing that solution, mixed with 5  $\mu$ l of matrix ( $\alpha$ -cyano-4-hydroxycinnamic acid (CHCA) saturated solution in acetonitrile:0.1% TFA (1:1)). After mixing the beads with CHCA matrix, 1  $\mu$ l of each sample was spotted on the MALDI sample holder. Mass spectra were acquired in a 4800 Plus MALDI TOF/TOF Analyzer (Sciex, MA, USA) reflector positive mode for the ranges  $m/z = 2750$ – $2850$  and  $m/z = 1000$ – $3000$ . The obtained mass spectra were internally calibrated for [<sup>1</sup>H]LLKKK18 at  $m/z = 2783.5$  and [<sup>2</sup>H]LLKKK18 at  $m/z = 2791.5$ .

The area of the peaks of the [M + H]<sup>+</sup> signals (including all isotopes) of intact [<sup>1</sup>H]LLKKK18 and [<sup>2</sup>H]LLKKK18 was determined and the amount of intact [<sup>1</sup>H]LLKKK18 was calculated from the area ratio.

### 2.11. Cytokines expression

Levels of Interleukin-6 (IL-6) and Tumor Necrosis Factor- $\alpha$  (TNF- $\alpha$ ) were determined by ELISpot (eBiosciences, Carlsbad, CA, USA) [40] in infected and non-infected macrophages after incubation with the formulations. Briefly, BMM $\Phi$  seeded in 96-well plates at  $5 \times 10^4$  cells/well and allowed to adhere overnight. A part of the macrophages was then infected with *M. tuberculosis* at a M.O.I. = 2 and both infected and non-infected cells were incubated with either blank or peptide-loaded nanogels. Peptide was loaded at a concentration of 100  $\mu$ M. PBS was added to the control group. At defined time points, cell culture medium was collected from each well and 50  $\mu$ l of each condition placed on 96-well plates previously coated with IL-6 or TNF- $\alpha$  antibodies (eBiosciences, Carlsbad, CA, USA). Prior to the addition of the samples, the antibody-coated plate was washed and blocked for 1 h at room temperature with 200  $\mu$ l Assay Diluent. The antibodies were then allowed to bind the samples' proteins for 2 h at room temperature. The wells were washed four times with PBS containing 0.05% Tween 80 and further incubated with the secondary antibodies (1:100 dilution) for 1 h at room temperature. Fifty  $\mu$ l of horseradish peroxidase-labeled avidin was then added to the wells and the plate was incubated for 30 min at room temperature, protected from light. After thorough washing of the wells, color development was achieved by adding 50  $\mu$ l of 3,3',5,5'-Tetramethylbenzidine (TMB) to the wells and incubating the plate for 20 min, protected from light, after which the reaction was stopped by addition of 25  $\mu$ l of stop solution. Absorbance was measured at 450 nm in a Bio-Rad Model 680 (Bio-Rad laboratories, UK) microplate reader and total protein expression levels determined from calibration curves using standard concentrations of each protein.

### 2.12. In vivo assays

Female C57BL/6 mice aged 6–8 weeks were purchased from Charles River Laboratories, Inc. (Barcelona, Spain) and housed at the ICVS animal facility under a 12 h dark/light cycle in a room with controlled temperature and humidity. Standard chow and water were supplied *ad*

*libitum*. All animal experiments were performed according to the European Union Directive 86/609/EEC and were approved by the Portuguese Veterinary authorities (Direção Geral de Veterinária).

Mice were infected aerogenically through exposure to an aerosolized suspension of each mycobacteria strain mentioned in Section 2.5 for 40 min using a Glas-Col Inhalation Exposure System: a  $2 \times 10^6$  CFU/ml suspension resulted in the implantation of ~20 CFU of mycobacteria in the lungs of each mouse [41]. After 3 months to allow the infection to reach a chronic stage, mice were anesthetized with an intraperitoneal injection of ketamine (Imalgene®) and medetomidine (Dorbene®).

HA nanogels were prepared at a concentration of 0.5 mg/ml and administered either empty or loaded with 100  $\mu$ M LLKKK18. PBS solution was used as a control. Either 5 or 10 doses of the treatments (50  $\mu$ l each) were administered intra-tracheally every other day, using a MicroSprayer® aerosolizer (IA-1C; Penn-Century, Philadelphia, PA, USA) attached to a high-pressure syringe (FMJ-250; Penn-Century) [42]. The aerosol is generated through a sub-miniaturized atomizer situated in the tip of a stainless steel tube, which is attached to a hand-operated, high-pressure syringe. For administration, mice were placed with their dorsa against an acrylic platform lifted at an angle of about 45°. Mice were suspended with a rubber band by their upper teeth and another rubber band was used to prevent lateral movements during endotracheal administration. A lamp was also used to provide proper illumination of the trachea. Blunted forceps were used to help displace the tongue to allow proper oropharyngeal exposure.

Mice were sacrificed by CO<sub>2</sub> asphyxiation one week after the last treatment and lungs were aseptically removed. The right superior lobe was collected in 2% paraformaldehyde for histological analysis and the remainder was homogenized in DMEM. A pre-treatment with collagenase (37 °C, 30 min) was applied to degrade the extracellular matrix and saponin was finally added to the lung homogenate to release intracellular mycobacteria. Serial dilutions were plated on Middlebrook 7H11 agar and CFUs were counted after about 1 or 3 weeks of incubation at 37 °C, depending on the species.

### 2.13. Statistical analysis

Statistical analysis was performed using GraphPad Prism 5 (GraphPad Software, La Jolla, CA). Normality of the distributions was examined prior to each analysis using Kolmogorov-Smirnov and Shapiro-Wilk normality tests, and taking into account the acceptability of skewness and kurtosis values. According to the results from the normality tests, one-way ANOVA, followed by a Newman-Keuls comparison post-test was conducted wherever appropriate. A 95% confidence interval was considered as statistical significant.

## 3. Results

### 3.1. Characterization of the nanogels

In this work we used hydrophobized HA nanogels capable of self-assembling in aqueous environments, which had been previously developed at our lab [29]. These nanogels allowed an encapsulation efficiency of LLKKK18 of about 70%. We showed that at a concentration of 0.5 mg/ml, the thylated HA forms nanogels with a diameter of  $133 \pm 4$  nm (Fig. 1A), with a polydispersity index (PDI) of  $0.27 \pm 0.02$ . An average zeta potential of  $-23.5 \pm 0.5$  mV was obtained (Fig. 1B), a value similar to the one presented by Pedrosa and co-workers [29]. However, both size and zeta potential were significantly altered after loading of the nanogels with the positively charged LLKKK18 (Fig. 1A–B). Indeed, in the presence of the peptide, the average diameter increases to  $533 \pm 13$  nm, with a PDI of  $0.1 \pm 0.1$ . This small PDI indicates that peptide loading resulted, remarkably, in a monomodal size distribution, compared to the bimodal distribution of the empty

nanogels. The presence of the peptide also resulted in a change in zeta potential to  $2.4 \pm 0.1$  mV, which may be attributed to the high cationicity of the peptide (+8) and neutralization of the hyaluronic acid negative charge [43].

Evaluation of the empty (non-loaded) nanogels effect on the macrophages metabolic activity was assessed using the MTS reduction test. As observed in Fig. 1C, HA nanogels induce a dose-dependent decrease in metabolic activity, showing a significant reduction at 1.5 mg/ml. As such, a concentration of 0.5 mg/ml HA nanogels was selected for subsequent assays.

### 3.2. Toxicity of LLKKK18-loaded nanogels towards BMM $\Phi$

Two different methods were used to evaluate cell death caused by the loaded nanogels: Live/Dead (Fig. 2A) and Trypan Blue Exclusion assays (Fig. 2B). Results from both assays revealed that loaded LLKKK18 did not cause BMM $\Phi$  death up to a 100  $\mu$ M concentration, after 24 h (Fig. 2A–B). These results are even more relevant considering that at 5  $\mu$ M the free peptide reduced cell viability in about 21–26% and at 100  $\mu$ M more than 90% of the cells were non-viable.

Nevertheless, at 200  $\mu$ M, loaded LLKKK18 induces a significant decrease in cell viability, causing approximately 44% and 34% of cell death, after the Live/Dead and Trypan blue assays, respectively.

Additionally, we observed no significant effect in terms of the number of apoptotic cells, regardless of the treatment or whether the BMM $\Phi$  were or not infected with *M. avium* 2447 (Fig. 2C). We also quantified the concentration of nitrites released to the cell culture medium by BMM $\Phi$ , as an indicator of reactive nitrogen species (RNS) levels, in particular nitric oxide. These are commonly produced by macrophages as a way of coping with foreign particles or microorganisms and may be deleterious to the cells themselves [44]. Although the HA nanogels did not induce the overproduction of NO<sub>2</sub>, a significant increase in extracellular nitrites was found in the presence of the peptide (Fig. 2D). Nevertheless, the nitrite concentration remained very low (less than 5  $\mu$ M) as compared to other reports of nitrite production by macrophages [45].

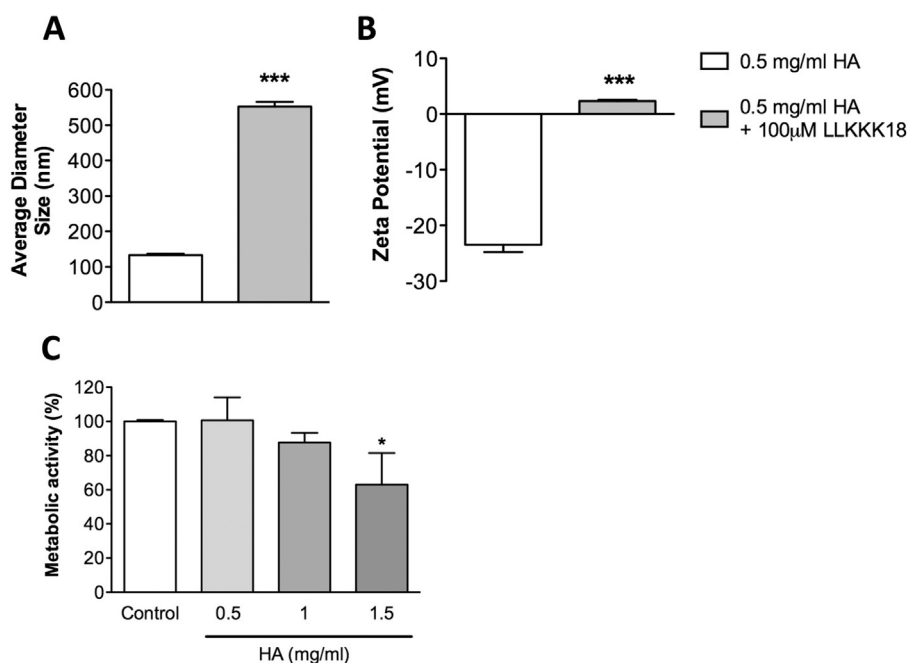

### 3.3. Mycobactericidal effect of LLKKK18

Previously, we reported that a LLKKK18 concentration of  $58.81 \pm 0.07$   $\mu$ M reduced the axenic growth of *M. avium* to 50% [26]. Compared with the MICs of standard antibiotics against *M. avium*, this value (corresponding to about 135  $\mu$ g/ml) may be considered high. Indeed, Heifets and co-workers [46] reported MICs ranging between 0.6 and above 10  $\mu$ g/ml for isoniazid, 0.12–16.0  $\mu$ g/ml for rifampicin and 0.94–15  $\mu$ g/ml for ethambutol. Recently, Andrejak et al. [47] reported MICs of 8–>16  $\mu$ g/ml for rifampicin, 2–>4  $\mu$ g/ml for clarithromycin and 16–32  $\mu$ g/ml for ethambutol. These authors also determined the MIC of combined antibiotics, observing that, for example, the MIC of rifampicin lowered from 16  $\mu$ g/ml (alone) to 4  $\mu$ g/ml when combined with ethambutol.

To evaluate if LLKKK18's effect remained after encapsulation in the HA nanogels, axenic cultures of *M. avium* were incubated with different concentrations of peptide loaded in 0.5 mg/ml HA. It is worth noticing that as the peptide is loaded into the HA nanogels, its readily available concentration will not be as high as it would be expected from its free (non-loaded) form. In this sense, it is reasonable to believe that a higher concentration would be required to achieve similar results, hence the increase in the concentration of loaded peptide. As observed in Fig. 3A, the encapsulated AMP requires a higher dose (200  $\mu$ M) to induce a significant reduction of *M. avium* growth.

The effect of LLKKK18 on mycobacteria residing within macrophages was further evaluated after incubating *M. avium*-infected BMM $\Phi$  for 7 days in the presence of the peptide-loaded nanogels.

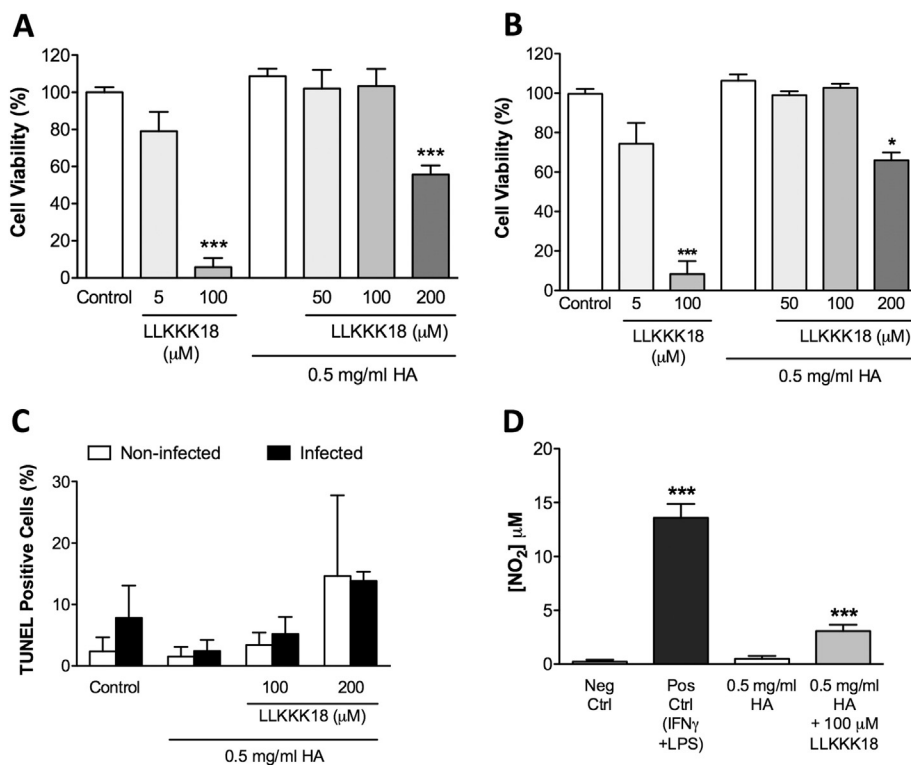

Fig. 3B indicates that peptide-loaded nanogels resulted in the significant reduction of mycobacterial load within BMM $\Phi$ , being this effect stronger for higher peptide concentrations. Indeed, approximately 1.9

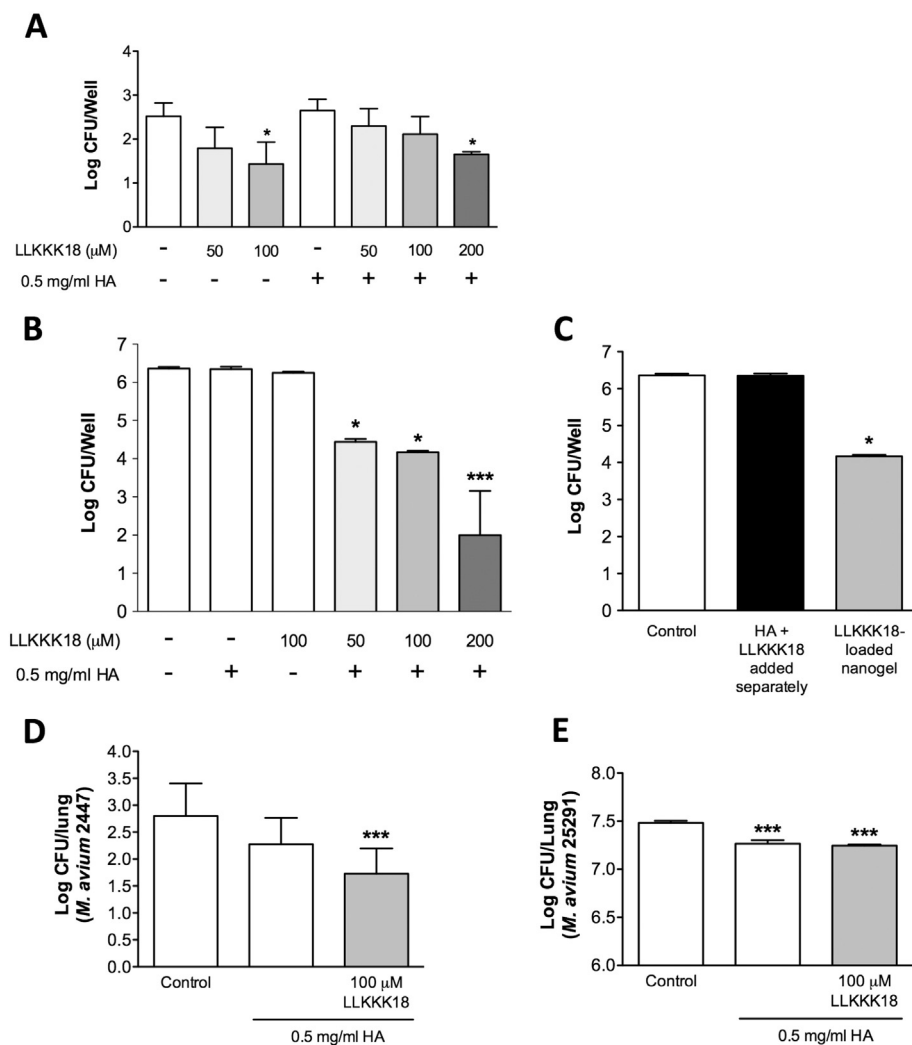

**Fig. 1.** Characterization of the blank and LLK18-loaded HA nanogels. The effect of LLK18 encapsulation on average diameter size (A) and zeta potential (B). Assays were carried out after overnight encapsulation of 100 μM LLK18 in a 0.5 mg/ml HA nanogel solution. Formulations were filtered through a pore size of 0.22 μm prior to analysis. Both parameters were measured in a Malvern Zetasizer. Values represent the mean ± SD (n = 6). \*\*\*  $p < 0.001$ , compared to blank nanogels. (C) Metabolic activity of BMMΦ in the presence of increasing concentrations of empty HA nanogels, determined using the MTS reduction assay. Values represent the mean ± SEM, for at least 3 independent experiments performed in triplicates. \*  $p < 0.05$ , compared to control (cells alone).

log-, 2.2 log- and 4.4 log-reductions were attained for 50, 100 and 200 μM, respectively. Neither the free peptide nor empty nanogels had any antimycobacterial effect on infected macrophages. Interestingly,

when added separately, LLK18 and nanogels yielded no mycobacteria killing (Fig. 3C), leading to the conclusion that the nanogel supports the targeted intracellular delivery of the peptide.

**Fig. 2.** Cytotoxicity evaluation of the LLK18-containing formulations. BMMΦ were incubated in the presence of free peptide, as well as blank or peptide-loaded nanogels for 24 h and cytotoxicity of these nanogels was determined through different methods: plasma membrane integrity evaluated by (A) Live/Dead assay and (B) Trypan blue dye exclusion; (C) quantification of total number of apoptotic cells using the TUNEL-assay. Cells were either infected (m.o.i. = 2) or non-infected with *M. avium* 2447; (D) Estimation of nitrite production using Griess reaction. A combination of lipopolysaccharide (LPS) and interferon-γ (IFN-γ) was used as positive control. Columns represent the mean ± SEM, for at least 3 independent experiments performed in triplicates. \*  $p < 0.05$ . \*\*\*  $p < 0.001$ , compared to respective controls. No statistically significant differences were observed in the TUNEL assay.

**Fig. 3.** Activity of LLKKK18 against *M. avium*. The efficacy of LLKKK18 in suppressing the growth of *M. avium* strain 2447 was firstly determined in axenic conditions, by adding it to the culture either free or loaded into HA nanogels (A). Blank and peptide-loaded nanogels were also added to *M. avium* 2447-infected BMM $\Phi$ . After 7 days, macrophages were lysed and the number of *M. avium* CFUs counted (B). BMM $\Phi$  were also incubated with 100  $\mu$ M LLKKK18 and 0.5 mg/ml HA nanogels added separately, to ascertain a possible adjuvant effect of the nanogels on LLKKK18 action (C). Data represents the mean  $\pm$  SEM, for at least 3 independent experiments performed in triplicates. \*  $p < 0.05$ . \*\*\*  $p < 0.001$ , compared to control. Finally, the *in vivo* activity of LLKKK18-loaded nanogels was tested by administering them intra-tracheally (using a Microsprayer aerosolizer) to C57BL/6 animals infected with *M. avium* strains 2447 (D) or the highly virulent 25291 (E). Therapy regimen consisted of 5 administrations (100  $\mu$ M LLKKK18 in 0.5 mg/ml HA) every other day. A PBS solution was administered to the control group. Data represents the mean  $\pm$  SD, for at least 9 mice per group. \*\*\*  $p < 0.001$ , compared to control.

The *in vivo* efficacy of the LLKKK18-loaded nanogels against opportunistic *M. avium* strains 2447 and 25291 (highly virulent) was evaluated by treating infected mice after a 3-month infection settlement period. Loaded nanogels were administered intra-tracheally 5 times every other day and lungs were removed for CFU counting one week after the last treatment.

Fig. 3D shows a significant reduction ( $\sim 1$  log) of the *M. avium* 2447 load in the lungs of infected mice, a relevant decrease considering the low concentration (100  $\mu$ M, which corresponds to about 8 mg/kg) and short therapy regimen applied. It should be noted that Bermudez et al. [48] reported a significant reduction of *M. avium* in the lungs of infected mice after the daily administration of 100 mg/kg clarithromycin (a concentration 12.5 times higher than the one herein reported), during a 4-week therapy. Similarly, Roque et al. [49] attained about 1-log reduction in liver and spleen of infected mice after 4 weeks of therapy consisting on the daily administration of three combined drugs at high concentrations (4.67 mg/ml rifampicin, 22.5 mg/ml clarithromycin, and 2.92 mg/ml).

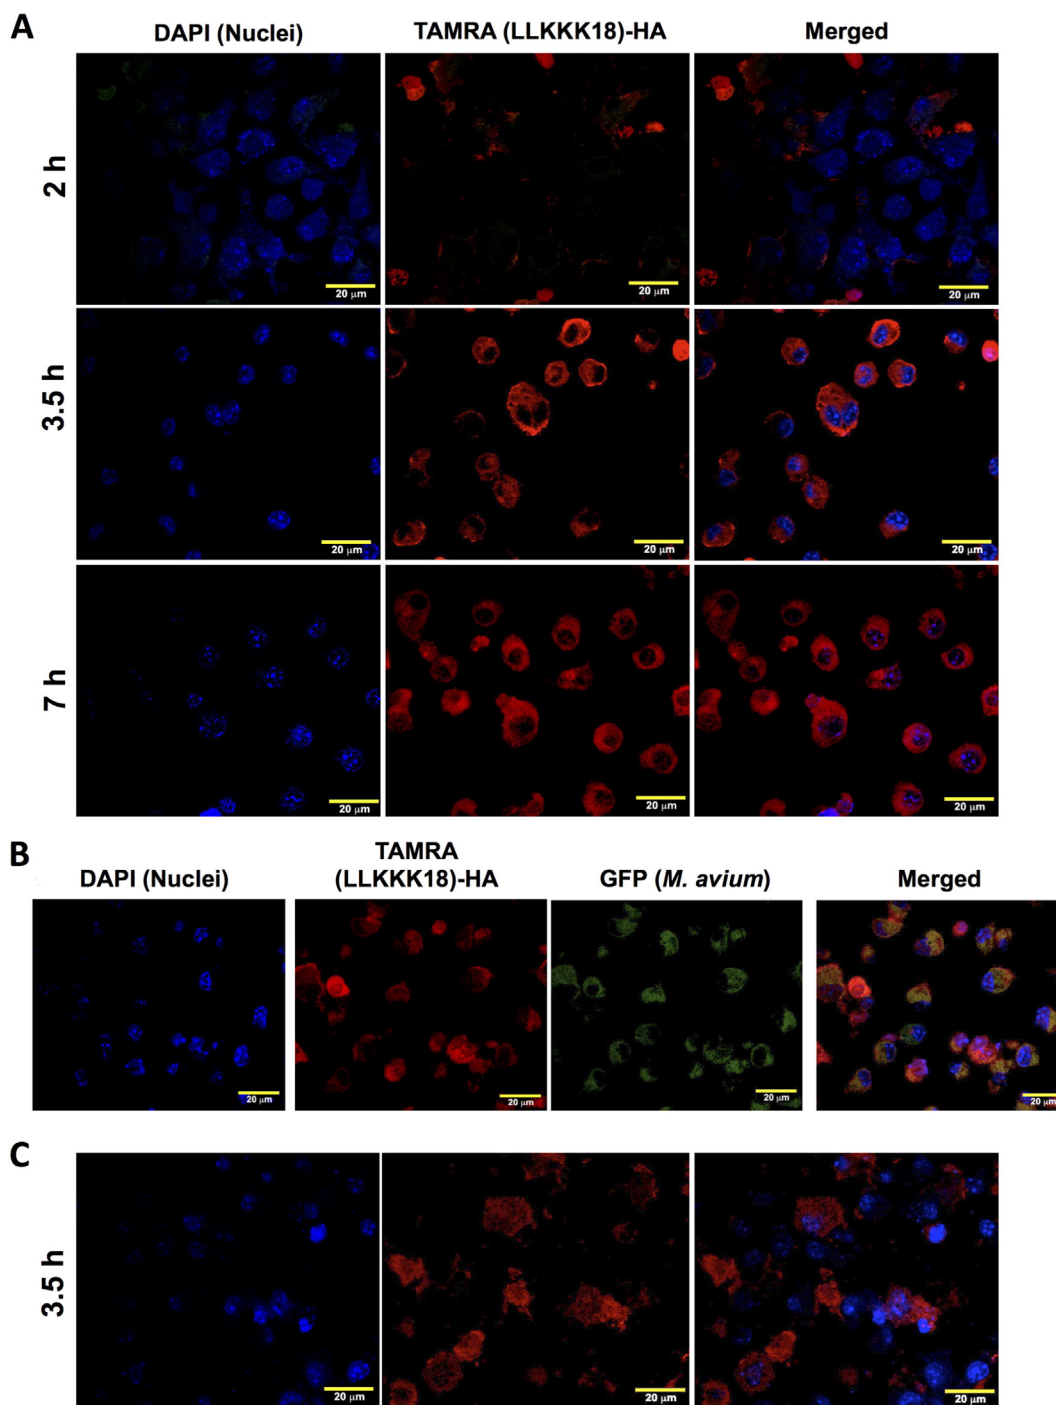

Since mycobacteria growth in untreated mice was not very high, we also tested the effect of the peptide on the highly virulent *M. avium* strain 25291. We expected that a larger mycobacterial growth would allow the detection of a more pronounced effect of the peptide.

However, as shown in Fig. 3E, both loaded and empty nanogels significantly reduced *M. avium* 25291 growth by about 0.3 log.

#### 3.4. Internalization and intracellular distribution of LLKKK18

BMM $\Phi$  were infected with an *M. avium* strain expressing recombinant GFP [37] and further incubated with LLKKK18 tagged with a fluorescent red label (TAMRA) loaded into HA nanogels. Fig. 4A shows that the loaded peptide uptake increases over time (up to 7 h), as indicated by an increasing larger red area (peptide) in the cytoplasm. Most important, it is possible to identify several situations in which the peptide seems to co-localize with mycobacteria, as noted by the overlapping of the fluorescent labels (Fig. 4B). This suggests a possible direct antimycobacterial effect of the peptide inside macrophages. Both peptide and mycobacteria were detected throughout the cytosol, implying that such co-localization may be non-specific. Using the 3.5 h time point as an example, it was also possible to observe the uptake of free peptide (Fig. 4C). However, as previously noted, the free peptide is not able to reduce the infection burden in the macrophages, again highlighting the role of the nanogel as a targeting carrier.

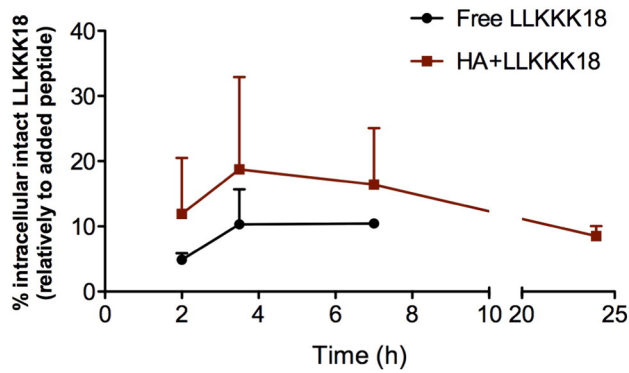

**Fig. 4.** Internalization of LLKKK18 into macrophages. (A) BMM $\Phi$  were incubated with LLKKK18-loaded nanogels and at different timepoints, the internalization of the peptide was ascertained by confocal microscopy. LLKKK18 was labeled with TAMRA (red) to allow its detection and BMM $\Phi$  nuclei were stained with DAPI (blue). (B) In addition to fluorescently-tagged LLKKK18, a GFP-expressing *M. avium* strain was used to observe the possible co-localization of the peptide with mycobacteria. Images shown in this condition were collected after 7 h of incubation. (C) Free peptide also seemed to be internalized by macrophages, as it was detected intracellularly 3.5 h after its addition to the cells. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

To further understand the extent of peptide internalization and its fate inside the cell, this was further analyzed and quantified through mass spectrometry (MS). MS spectra allowed the identification of LLKKK18 collected from lysed macrophages (Fig. 5A). The percentage of intact peptide found within the macrophages was estimated by comparing its peak area ( $m/z = 2783.5$ ) with the peak area obtained for a known amount of a bi-deuterated standard peptide ( $m/z = 2791.5$ ), added after cell lysis.

Contrarily to what would be expected from the microscopy images, we observed no significant differences between the amount of internalized intact LLKKK18 after 3.5 and 7 h of incubation. Noteworthy, at 7 h MS spectra show some peaks with lower  $m/z$  than the intact peptide, suggesting the presence of smaller peptide fragments (Fig. SI-1). Twenty-four hours after addition of the loaded nanogels only small traces of peptide were found inside macrophages. MS spectra also indicated that free peptide enters BMM $\Phi$ . However, also in this case, the peaks

**Fig. 5.** Quantification of intracellular intact peptide. BMM $\Phi$  were incubated in the presence of a biotinylated version of the peptide, comprising an isotope tag of four non-deuterated glycines ( $[^1\text{H}]\text{LLKKK18}$ ). These were added to cells either in a free form or loaded into HA nanogels for different time periods. 1 pmol of an internal standard, consisting of the peptide with four bi-deuterated glycines ( $[^2\text{H}]\text{LLKKK18}$ ) was added after cell lysis. The percentage of intact LLKKK18 present intracellularly at each timepoint was calculated from the area ratio obtained from the area of the peaks of the  $[\text{M} + \text{H}]^+$  signals (including all isotopes) of intact  $[^1\text{H}]\text{LLKKK18}$  and  $[^2\text{H}]\text{LLKKK18}$ .

detected at low  $m/z$  in the MS spectra suggest that most of this peptide is rapidly degraded inside macrophages.

### 3.5. LLKKK18 effect on pro-inflammatory cytokines expression

Cathelicidins like LL37 and its analogues have been associated with immunomodulatory properties [50]. Here we analyzed the effects on the expression of two cytokines, IL-6 and TNF- $\alpha$ , which play a key role in the immune response to infection. IL-6 expression was increased in the control (non-treated) BMM $\Phi$  24 h after infection with *M. tuberculosis* (Fig. 6A). The expression of this cytokine then decreased over time up to 72 h. However, in the presence of the HA nanogels, IL-6 levels were significantly lower than in the control at 24 h. A further reduction in this cytokine expression to non-detectable levels was induced by the presence of LLKKK18. In fact, IL-6 expression is not detected at any time point in the presence of the peptide, similarly to what is observed in non-infected BMM $\Phi$ .

Similarly, no TNF- $\alpha$  expression was identified at any timepoint or at any condition in the non-infected cells (Fig. 6B). Also in accordance with the IL-6 results, the nanogel containing the peptide induced a significant decrease in TNF- $\alpha$  levels over time to almost basal values. However, it appears that the HA nanogel stimulated an increase of this cytokine, being statistically significant compared to the untreated control, at 24 h.

### 3.6. Peptide-loaded nanogel action on *M. tuberculosis*

Fig. 7A shows that free LLKKK18 leads to a dose-dependent reduction of *M. tuberculosis* load growing in axenic cultures. The Minimum

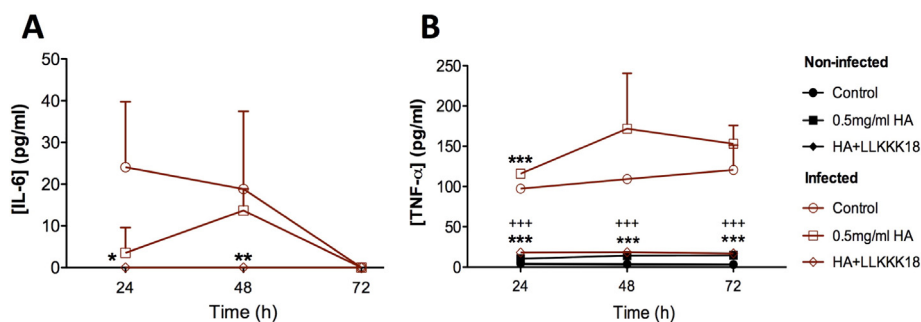

Inhibitory Concentration ( $\text{MIC}_{50}$ ), i.e. the peptide concentration resulting in a 50% mycobacteria growth reduction, was estimated to be  $49.23 \pm 5.44 \mu\text{M}$ , slightly lower than the one previously obtained for *M. avium* 2447 ( $58.81 \pm 0.07 \mu\text{M}$ ) [26]. Once again, these values (corresponding to about  $114 \mu\text{g/ml}$ ) are higher than the ones previously reported for conventional antibiotics against *M. tuberculosis*: 0.025–0.05  $\mu\text{g/ml}$  for isoniazid,  $<100 \mu\text{g/ml}$  for pyrazinamide, 0.06–0.25  $\mu\text{g/ml}$  for rifampicin and 0.94–3.8  $\mu\text{g/ml}$  for ethambutol [46]. However, higher MIC values have been reported for other peptides. For example, MIC values of 300 and 1200  $\mu\text{g/ml}$  have been reported for MIAP and Magainin-1, respectively [51]. Azurocidin has been reported to kill 55% of *M. tuberculosis* H37Rv at 100  $\mu\text{g/ml}$  [52]. Also, the  $\text{M}(\text{LLKK})_2\text{M}$  peptide series presented a MIC of 125  $\mu\text{g/ml}$  [16].

Also in a similar fashion to what occurred with *M. avium* strains, 100  $\mu\text{M}$  LLKKK18-loaded nanogel reduced ( $\sim 1.5$  log) the *M. tuberculosis* load within infected BMM $\Phi$  (Fig. 7B). Moreover, treatment of *M. tuberculosis*-infected mice with the peptide-containing nanogel resulted in a significant effect of LLKKK18 against these pathogenic mycobacteria (Fig. 7C). Two different therapy regimens were tested, comprising either 5 or 10 administrations of the peptide-nanogel formulations, administered every other day. Results in Fig. 7C show that the shorter therapy with the nanogel alone induced a decrease in mycobacteria levels, whereas this effect disappears for a longer administration regimen. Nevertheless, the shorter peptide-nanogel regimen led to a 0.7-log reduction in mycobacteria levels, significantly different from the nanogel alone. This effect was further augmented to  $\sim 1.2$ -log decrease ( $p < 0.01$ ) by doubling the number of administrations.

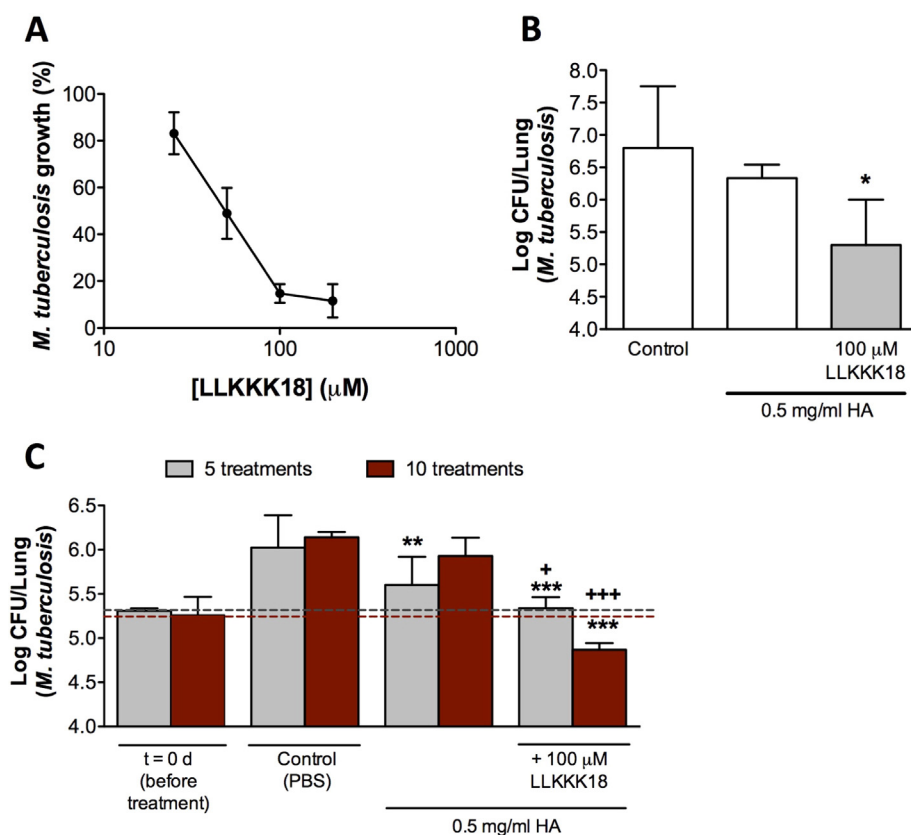

Histology sections of the lung tissues do not show any visible differences between the different treatment conditions (HA alone and peptide-loaded nanogel) in terms of lesion extent and severity, although there seems to be an improvement regarding the number and size of granulomas relatively to the non-treated tissues (Fig. 8).

## 4. Discussion

Despite the plethora of applications provided by antimicrobial peptides, their use in the biomedical field is often disregarded due to toxicity, stability and solubility issues [53]. In the present work, we encapsulated the LL37's analogue LLKKK18 in self-assembling HA nanogels previously developed by our group [29]. This loading resulted in increased average particle size and neutralization of the HA anionic charge. The cationicity and hydrophobicity of the peptide may act as a driving force leading to its encapsulation within the hydrophobic core of the negatively charged nanogel. Such encapsulation may, at least partially, account for the increase in the average diameter of the particles, as a similar event has been reported with insulin-loaded poly(lactide-co-glycolide) nanoparticles [54]. On the other hand, it is possible that the increase in particle size upon peptide loading reflects the formation of self-assembling macromolecular micelles. Although they might undergo extrusion upon filtration, they re-assemble afterwards to reach

**Fig. 6.** Cytokine expression on *M. tuberculosis*-infected BMM $\Phi$  treated with LLKKK18-loaded nanogel. BMM $\Phi$  were infected or not with *M. tuberculosis* H37Rv (M.O.I. = 2) and further incubated in the presence of blank or peptide-loaded nanogels for 72 h. The expression levels of (A) IL-6 and (B) TNF- $\alpha$  were measured using an ELISA assay. Data represents the mean  $\pm$  SD, for at least 3 independent experiments. \*  $p < 0.05$ , \*\*  $p < 0.01$ , \*\*\*  $p < 0.001$ , compared to control (PBS). +++  $p < 0.001$ , compared to HA.

**Fig. 7.** Activity of LLKKK18 against *M. tuberculosis* H37Rv. (A) Dose-response curve demonstrating the ability of LLKKK18 to directly suppress the growth of *M. tuberculosis* in axenic conditions, after 4 days. (B) Blank and peptide-loaded nanogels (containing 100 μM LLKKK18) were added to *M. tuberculosis*-infected BMMΦ. After 4 days, cells were lysed and the number of mycobacteria CFUs counted. Data represents the mean ± SEM, for at least 3 independent experiments performed in triplicates. \*  $p < 0.05$ , compared to control (PBS). (C) The *in vivo* activity of LLKKK18-loaded nanogels was ultimately tested in C57BL/6 animals infected with *M. tuberculosis*. The treatments were administered intra-tracheally using a Microsprayer aerosolizer. Therapy regimens with the nanogel consisted of either 5 or 10 administration, every other day. A PBS solution was administered to the control group. Data represents the mean ± SD, for 6–9 mice per group. \*\*  $p < 0.01$ , \*\*\*  $p < 0.001$ , compared to control (PBS) with respective number of administrations. +  $p < 0.05$ , +++  $p < 0.001$ , compared to HA with respective number of administrations.

an equilibrium state at a particle size of 500 nm. Nevertheless, it should be noted that this is a highly reproducible process, as indicated by the small error bars and low polydispersity index ( $0.1 \pm 0.1$ ). The neutralization of the net electrical charge produced by the peptide suggests the binding of LLKKK18 to the surface of the nanogel. Altogether, peptide-induced modifications may be advantageous, as uptake by macrophages is enhanced for particles larger than 0.5 μm [55,56], and charge neutralization may decrease the nanogels cytotoxicity (known to increase in the presence of charged - especially anionic - nanoparticles) [57,58]. Moreover, the particles size distribution becomes monomodal in the presence of the peptide, resulting in more homogeneous emulsions.

Nagaoka and colleagues [59] reported the toxicity of free LLKKK18 in peritoneal macrophages and RAW 264.7 cells at concentrations above 10 μg/ml (approximately 4.3 μM). Indeed, here we showed that a similar concentration (5 μM) of free peptide reduced the viability of bone marrow-derived macrophages in 21–26% and that at 100 μM, almost all cells were non-viable. However, we also demonstrated that LLKKK18 loaded into the nanogel displayed no cytotoxic effects, in terms of intracellular esterase activity and plasma membrane integrity, up to 100 μM (more than 23-fold the toxic concentration reported for free peptide). This is a relevant result, as we clearly show that peptide loading into the HA nanogels overcomes one of the major problems associated with the exogenous administration of these peptides.

Up to this concentration, the total number of apoptotic cells also remained at basal levels. Nevertheless, a slight nitric oxide production was observed in the presence of the peptide. Indeed, reactive nitrogen species (RNS), like •NO, are usually produced by macrophages as a

way of eliminating invading bacteria [44], suggesting that this •NO induction by the peptide may contribute to the increased mycobactericidal activity.

Taken together, the modifications in particle size, charge and cytotoxicity proved important to facilitate the intracellular delivery of the peptide to macrophages. Although the uptake of HA should not be expected from macrophages in normal physiological conditions, we observed that infected macrophages successfully internalized this nanogel. The overexpression of the CD44 receptor by activated macrophages, previously reported by Underhill and co-workers [31], might positively influence the nanogel uptake. Most importantly, the nanogel facilitated the peptide targeting to mycobacteria residing within intracellular compartments. Such targeting assumes great relevance considering the modifications in vacuolar trafficking that allow the masking of mycobacteria within macrophages [6] and potentiates a direct killing mechanism. The detection of both peptide and mycobacteria throughout the cytoplasm suggests that the co-localization of peptide with mycobacteria may be non-specific. However, additional experiments will be required to find any co-localization in specific intracellular compartments.

Most importantly, *in vitro* incubation of macrophages with LLKKK18-loaded nanogel reduced the intracellular levels of both *M. avium* and *M. tuberculosis*. These results strengthen the importance of using a proper carrier to deliver anti-TB drugs. Indeed, despite its uptake by cultured macrophages, free LLKKK18 failed to reach mycobacteria and reduce infection levels, which is in accordance with previous work regarding the induction of intracellular overexpression of its murine counterpart cRAMP [26].

**Fig. 8.** Representative histology images of lung sections stained with hematoxylin & eosin. At the end of the *in vivo* experiments with *M. tuberculosis*, mice were sacrificed, lungs removed and fixed in 3.7% formaldehyde. Lungs were then sectioned and stained with hematoxylin and eosin. (A) Non-infected; (B) 3-month infection (before the beginning of the treatments); (C) PBS, 10 administrations; (D) HA nanogels, 10 administrations; (E) LLKKK18-loaded nanogels, 10 administrations.

Compared with data reported in the literature for other drugs, in particular standard antibiotics, the concentration of LLKKK18 herein reported to inhibit 50% of mycobacteria growth may be considered high. However, is not uncommon to find some variability among MIC values for a drug against the same mycobacterial strain. This is the case of rifampicin, whose MIC against *M. avium* may range from 0.03 µg/ml [60] to 0.5 µg/ml [61]. Differences in terms of methodologies may account for this variability and include: 1) the use of different strains (some are more susceptible/resistant than others); 2) the method used to determine the MIC (e.g. resazurin, which gives an indication of the cells metabolic activity vs CFU counting, which correlates with total bacteria number); 3) testing conditions (e.g. initial inoculum, culture media, incubation period). This variability is further noticed in *in vivo* testing. Parameters like administration route, dose regimen (concentration and frequency), period post-infection or initial inoculum greatly influence the outcome of infection and make it difficult to compare different studies.

It is also relevant noting that diminished levels of two pro-inflammatory cytokines, IL-6 and TNF- $\alpha$ , accompanied the decrease of *M. tuberculosis* load in infected macrophages treated with HA + LLKKK18. IL-6, in particular, may be considered a potent biomarker of mycobacterial infection due to its *in vitro* overexpression in mycobacteria-infected cells [62]. Moreover, our data on TNF- $\alpha$  expression is consistent with previous

findings using LL37 [63] and further support the modulation of macrophages response to infection by cathelicidins. Considering the key role of these two cytokines in stimulating the immune response during infection [64,65], a decrease in their expression levels may indeed be associated with the reduced mycobacterial load within macrophages.

It has been long known that results obtained *in vitro* for anti-TB drugs may not exactly match their efficacy *in vivo* [66,67]. This was not the case with LLKKK18-loaded nanogel, as the peptide induced a significant decrease of the mycobacterial burden in mice infected with mycobacteria of different virulence and pathogenicity.

Some discrepancies were observed regarding the mycobactericidal activity against the two *M. avium* strains tested, with a higher effect during *M. avium* 2447 infection. The growth of this strain is arrested as a result of both innate and adaptive immune mechanisms whereas *M. avium* 25291, known for its higher virulence, continues to proliferate until it eventually kills the animal [68,69]. In view of the fact that one of the major issues related with the failure of some anti-TB drugs, including the standard antibiotic isoniazid, is their inefficacy against mycobacteria in stationary phase or with very low proliferating rates [70], these results are unexpected. Two different hypothesis may help explain such findings: 1) *M. avium* 25291 may be more resistant to the peptide; 2) despite same inoculum and peptide concentration

were used, the every other day therapy regimen gives time for the mycobacteria that are not eliminated to continue proliferating. In this sense, it is reasonable to expect only a slight reduction of *M. avium* 25291 burden.

Most importantly, a significant reduction in mycobacterial levels was found in the lungs of mice infected with *M. tuberculosis* after treatment with peptide-loaded nanogel. This effect appeared to be dose-dependent, as doubling the number of administrations resulted in a more pronounced reduction of the bacterial load, reaching levels below the ones observed before the beginning of the treatment. Of note, administration of empty HA nanogels also reduced the infection levels in mice infected with either *M. tuberculosis* (only after 5 doses of HA) or *M. avium* 25291. This is not completely unexpected, as the CD44 receptor has been reported to mediate the entry of mycobacteria into macrophages [71]. The interaction of HA with CD44 receptors may thus block the entry of newly proliferating bacteria or prevent the activation of pathways that may lead to the induction of residing mycobacteria proliferation, in similar fashion to what has been described in *Listeria monocytogenes* [72].

Although MIC values obtained in axenic conditions may not be considered very impressive, the observed LLKKK18-induced reduction of the mycobacterial load in infected macrophages and in infected animals is of great relevance. Achieving a ~1.2-log reduction in *M. tuberculosis* levels in the lungs of infected mice is *per se* an important result, considering that: the peptide-loaded nanogels were administered only 10 times (every other day); and the therapy comprised a single bioactive molecule, contrasting with the standard multiple drug regimens. De Groote and co-workers [41] evaluated the outcome of the 6-month standard drug regimen of isoniazid, rifampicin and pyrazinamide. The authors showed that it takes that long period, with daily administrations of the three drugs combined, to achieve a complete elimination of the infection. Additionally, the authors showed that even after 6 months a combination of pyrazinamide and rifampicin only resulted in a 2-log reduction. Kalita et al. [73] reported the effect of a combined therapy of isoniazid and rifampicin, administered daily during 4–6 weeks, against *M. tuberculosis*. According to that study, when both drugs were administered at 12.5 mg/kg/day, using the referred therapy regimen, less than 1-log reduction was attained. Doubling of both drugs concentration to 25 mg/kg/day only resulted in an overall reduction of mycobacterial load in mice lungs of about 1.5-log.

Having attained such an effect with LLKKK18 in particular is even more relevant taking into consideration that previous experiments comprising the induction of intracellular overexpression of LL37 (LLKKK18's "parent" peptide) failed to eliminate mycobacteria within host macrophages, as it was rapidly cleared from the intracellular milieu [26].

Moreover, it is reasonable to expect that optimization of the formulation may result in higher efficacy, while reducing peptide concentration and dosage regimen. Such optimization will be important to reduce the costs of production, which are currently higher than the \$19–22 required for a standard antibiotic therapy of 6 months [11]. Nevertheless, costs associated with the 24-month, multiple antibiotic therapies required for the treatment of multidrug-resistant tuberculosis remain elevated (ranging between \$4000–6000). Although further studies need to be performed, given the lower probability of mycobacteria acquiring resistance to AMPs as compared to antibiotics, due to their non-specific killing mechanism [18,19], these LLKKK18-loaded nanogels may assume particular interest for the treatment of multidrug- (MDR) or extremely drug-resistant (XDR) forms of tuberculosis, as well as atypical mycobacterioses showing resistance to conventional therapies.

## 5. Conclusions

Administration of LLKKK18 loaded into self-assembling hyaluronic acid nanogels holds promising indications as a novel method to treat mycobacterial infections. The nanogel target the peptide towards the main infected sites, while boosting its potential by: 1) allowing the use of high therapeutic doses; 2) facilitating peptide uptake by infected

macrophages; 3) stabilizing the peptide within their hydrophobic core; and 4) reducing proteolytic degradation.

Long-term and expensive standard therapies based on multiple drug cocktails often result in low patient compliance, with subsequent emergence of multidrug-resistant strains and proliferation of the disease. Our data thus suggest that LLKKK18-loaded nanogel may hold great potential as an alternative approach to control tuberculosis and other mycobacterioses, finding particular interest for treatment of antibiotic-resistant forms.
