Trade Costs, Limited Enforcement and Risk Sharing: A Joint Test*

Preliminary and Incomplete

Abstract

This paper addresses the question of whether goods or asset market frictions are necessary to explain the failure of consumption risk sharing across countries. I present a multi-country DSGE model with Armington specialization. There are iceberg costs of shipping goods across countries. In asset markets, contracts are imperfectly enforceable. Both frictions separately limit the extent to which countries can pool risk. The model suggests a test for the presence of each of the two types of friction that can be implemented using data on bilateral imports. I implement this test using a sample of developed and developing countries. I find that both trade costs and asset market imperfections are necessary in order to explain the failure of perfect consumption risk sharing. However the null hypothesis of financial autarky is rejected.

Keywords: Risk sharing, trade costs, asset market frictions

1 Introduction

In a world where there are no frictions in goods markets, and a full set of contingent claims can be traded, consumption growth will be perfectly correlated across countries [Lucas (1982)]. However this prediction is strongly rejected by the data [see Backus, Kehoe and Kydland

(1992)]. Considerable progress has been made in understanding how different types of goods market frictions and different types of asset market frictions can help resolve this puzzle. This paper contributes to this literature by providing a new type of test for the role of goods and asset market frictions in explaining failures of risk sharing. I present a multi-country DSGE model with Armington specialization and iceberg costs of shipping goods across countries. This is a dynamic stochastic "gravity" model of trade both within and across states and periods. In asset markets, contracts are imperfectly enforceable. Both frictions separately limit the extent to which countries can pool risk. But to the extent that there is risk sharing, this paper shows it must show up in bilateral imports. With sufficiently rich data on bilateral imports, it is possible to distinguish between the role of trade costs and asset market frictions in limiting risk sharing. I implement this test for a sample of developed and developing countries from 1970-2000. Both trade costs and asset market imperfections are necessary in order to explain the failure of perfect consumption risk sharing. However the null hypothesis of financial autarky is also rejected. Asset market frictions appear to be relatively less important for developed than developing countries, and both types of friction are less important at the end of the period than at the beginning.

The intuition for the results presented here can be understood by thinking of each country as being endowed with a tree that produces a stochastic amount of a particular type of fruit (this abstracts from investment, which is included in the formal model). Consumers in these countries wish to smooth consumption along several dimensions. They prefer to consume a variety rather than one single type of fruit. They also wish to smooth their consumption across states of the world and over time. However some of the fruit spoils during shipping, so the quantity received by the importer is less than the quantity sent by the exporter. The fraction that spoils varies with the bilateral distance between the countries. This resource cost of smoothing implies first, that the composition of each country's consumption basket is tilted towards the fruits produced in countries that are "close." Second, even if the full set of Arrow-Debreu securities is traded, and all contracts are perfectly enforced, consumption growth rates will differ across countries.

Now suppose that in addition, contracts (other than spot trades) cannot be perfectly enforced. Even though the full set of Arrow-Debreu securities can be traded, countries cannot commit ex-ante to make transfers that are not ex-post optimal. Unless they are very patient, the extent of possible risk sharing across countries will be further reduced. In the

extreme case of financial autarky, countries will engage only in spot trades, and the value of a country's exports must equal the value of its imports. Even in this case, however, there will be *some* risk sharing, through movements in the terms of trade.

Clearly, in order for any degree of consumption smoothing to take place, there must be bilateral flows of fruits. This is the insight that motivates the empirical part of the paper. In particular, the value of bilateral imports is given by a "gravity equation." Once trade costs (if present) have been controlled for, the value of bilateral imports always moves one-for-one with the value of output of the exporting country. However the response of imports to the value of output of the importing country varies depending on whether or not there are frictions in asset markets. This allows the hypotheses of trade costs and frictions in asset markets to be tested against the alternative of a frictionless world using a panel of data on bilateral imports.

As already noted, this paper contributes to a very large literature that tries to explain the failure of international consumption risk sharing. There are two strands of the literature that focus primarily on goods market frictions: those that examine the role of non-traded goods, and those that examine the role of transactions costs on goods trade. This paper falls into the second category, which includes Backus, Kehoe and Kydland (1992, 1995), Heathcote and Perri (2004a, b), Kose and Yi (2005), Mazzenga and Ravn (2004), and Obstfeld and Rogoff (2000). This paper advances this literature by integrating costs of trading goods into a multi-country DSGE model in a way that is consistent with a gravity model of bilateral trade. The gravity equation is one of the outstanding successes of the empirical trade literature, and it has recently received rigorous theoretical foundations in both Eaton and Kortum (2002) and Anderson and van Wincoop (2003, 2004). The assumption of specialization gives the model a chance to match facts about intra-state trade as well as inter-state and intertemporal trade, while simultaneously nesting risk sharing through the terms of trade as described in Cole and Obstfeld (1991). This treatment of trade costs paves the way for the new test for the presence of frictions presented in the paper.

The enormous literature on international asset market frictions initially focused on exogenously restricting the set of assets traded, but has recently explored the role of transactions costs, asymmetric information and sovereign risk. This paper follows the latter approach, in particular that of Kehoe and Perri (2002) who assume that contracts can only be enforced by the threat of future exclusion from asset markets. This is convenient in the context of

theoretical framework used here, but the empirical results should not be thought of as distinguishing between different types of asset market imperfection. In this, the paper is similar to Choi (2005) who looks at the effect of non-traded goods and asset market frictions on the relationship between real exchange rates and relative consumption. I also follow Heathcote and Perri (2002) in considering the case of perfect financial autarky.

The first section describes the theoretical framework. The second section outlines the empirical strategy. The third section describes the data and results. The final section concludes.

2 Theoretical framework

I first lay out the frictionless model, and develop its implications for international risk sharing. I then introduce in turn costs of trading goods and an enforcement friction in asset markets. Again, I focus on the implications of these frictions for risk sharing. I also consider the case of perfect financial autarky as an extreme alternative to complete financial markets. Throughout, the emphasis is on consumption allocations and the form of trade flows required to support those allocations, rather than on asset holdings. The section concludes with an illustrative special case which develops the intuition for the empirical tests outlined in the next section.

2.1 Frictionless model

Summary

There are N countries in the world, indexed $i = 1, \ldots, N$. Each country produces a distinct intermediate good, (also indexed i) using capital and labor. Capital is accumulable, while labor is fixed in supply. Productivity in the production of intermediates differs across countries, and is stochastic. The intermediate goods are tradeable. They are combined using a CES production function, identical in all countries, to produce an aggregate non-traded good used for consumption and investment.

Uncertainty

The structure of uncertainty is as follows. In each period t, the economy experiences one event, $s_t \in S$. Denote by s^t the history of events from date 0 to date t. The probability of history s^t at date t is given by $\pi\left(s^t\right)$.

Utility and production

Across periods, utility is isoelatic. Expected utility in country i is given by

$$U_i = \sum_{t=0}^{\infty} \sum_{s^t} \beta^t \pi\left(s^t\right) u\left(s^t\right)_i = \sum_{t=0}^{\infty} \sum_{s^t} \beta^t \pi\left(s^t\right) \frac{\left[C\left(s^t\right)_i\right]^{1-\rho}}{1-\rho} \tag{1}$$

The production function for the agregate non-traded good, X, used for consumption and investment is:

$$X\left(s^t\right)_i = \left(\sum_{k=1}^{N} Z\left(k, s^t\right)_i^{\frac{\eta-1}{\eta}}\right)^{\frac{\eta}{\eta-1}} \tag{2}$$

where $Z\left(k, s^t\right)_i$ is absorption in country i of intermediate good k at time t after history s^t. The aggregate good resource constraints are given by

$$X\left(s^t\right)_i = C\left(s^t\right)_i + I\left(s^t\right)_i = C\left(s^t\right)_i + K\left(s^t\right)_i - K\left(s^{t-1}\right)_i \tag{3}$$

where $K\left(s^{t-1}\right)_i$ is the capital available for use in production in country i at time t (predetermined) and $I\left(s^t\right)_i$ is investment in country i at time t after history s^t. Investment need not be positive (capital can be eaten). The world intermediate goods resource constraints are given by:

$$Y\left(s^t\right)_i = A\left(s^t\right)_i K\left(s^{t-1}\right)_i^{\alpha} L_i^{1-\alpha} = \sum_{k=1}^{N} Z\left(i, s^t\right)_k \tag{4}$$

where $A\left(s^t\right)_i$ is the realization of productivity in country i at time t after history s^t.

Planner's problem

I study the social planning problem where the planner chooses sequences $\{C\left(s^t\right)_i\}$, $\{K\left(s^t\right)_i\}$ and $\{Z\left(k, s^t\right)_i\}$ to maximize a weighted sum of country utilities:

$$\sum_{i=1}^{N} \lambda_i U_i = \sum_{i=1}^{N} \sum_{t=0}^{\infty} \sum_{s^t} \lambda_i \beta^t \pi\left(s^t\right) u\left(s^t\right)_i \tag{5}$$

subject to $2N$ resource constraints for every period t and history s^t. Let the Lagrange multipliers on the aggregate good resource constraints be denoted

$$\sigma\left(s^t\right)_i = \beta^t \pi\left(s^t\right) P\left(s^t\right)_i \tag{6}$$

and let the Lagrange multipliers on the intermediate good resource constraints be denoted:

$$\mu\left(i, s^{t}\right) = \beta^{t} \pi\left(s^{t}\right) Q\left(i, s^{t}\right) \tag{7}$$

The multiplier $\sigma\left(s^{t}\right)_{i}$ is the date-0 price of a unit of the final good in country i at time t following history s^{t}. $P\left(s^{t}\right)_{i}$ is its date-t price. The multiplier $\mu\left(i, s^{t}\right)$ is the date-0 price of a unit of good i in country i at time t following history s^{t}. $Q\left(i, s^{t}\right)$ is then its date-t price.

I focus on the first order conditions of the planner's problem with respect to consumption, C and absorption of intermediates, Z (the first order condition with respect to capital is not necessary for what follows). They are ($C\left(s^{t}\right)_{i}$):

$$\lambda_{i} C\left(s^{t}\right)_{i}^{-\rho} = P\left(s^{t}\right)_{i} \tag{8}$$

and ($Z\left(k, s^{t}\right)_{i}$):

$$Q\left(k, s^{t}\right) = P\left(s^{t}\right)_{i} X\left(s^{t}\right)_{i}^{\frac{1}{\eta}} Z\left(k, s^{t}\right)_{i}^{-\frac{1}{\eta}} \tag{9}$$

Equilibrium

Together with the two sets of resource constraints, the first order conditions (including the first order condition with respect to capital) determine consumption of each good by each country in every period and state. The appropriate values of λ_{i} in the decentralized equilibrium without transfers can in principle be recovered by combining the first order conditions with the resource constraints and the individual country budget constraints.

Consumption correlations

Using the production function for the aggregate good X combined with the first order conditions with respect to absorption of individual intermediate goods, the date-t state-s^{t} aggregate price level in country i can be written:

$$P\left(s^{t}\right)_{i} = \left[\sum_{k=1}^{N} Q\left(k, s^{t}\right)^{1-\eta}\right]^{\frac{1}{1-\eta}} \tag{10}$$

The real exchange rate between i and j is given by the ratio of the price levels. In the absence of frictions, the real exchange rate between any pair of countries is always equal to 1.

The first order condition for consumption implies a monotonic relationship between the

real exchange rate and relative consumption, given by

$$RER\left(s^t\right)_{ij} = \frac{P\left(s^t\right)_j}{P\left(s^t\right)_i} = \frac{\lambda_j}{\lambda_i}\left[\frac{C\left(s^t\right)_i}{C\left(s^t\right)_j}\right]^{\rho} \tag{11}$$

Since the real exchange rate between any pair of countries is always equal to 1, this implies that relative consumption is constant, given by:

$$\frac{C\left(s^t\right)_i}{C\left(s^t\right)_j} = \left[\frac{\lambda_i}{\lambda_j}\right]^{1/\rho}$$

In order for this to be the case, the growth rate of consumption must be the same in all countries. This is the expression from which standard tests of consumption risk sharing are derived.

Bilateral imports

Risk sharing across countries takes place through bilateral trade flows The first order conditions with respect to consumption and absorption of intermediates can be combined with the resource constraints to yield the following expression for the value of country i's absorption of k's output in period t following history s^t:

$$
\begin{aligned}
& Q\left(k, s^t\right) Z\left(k, s^t\right)_i \\
= \ & \left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right] \frac{\lambda_i^{\eta-1} C\left(s^t\right)_i^{\rho(1-\eta)}}{\sum_{j=1}^{N} \lambda_j^{\eta} C\left(s^t\right)_j^{-\rho\eta} X\left(s^t\right)_j}
\end{aligned}
\tag{12}
$$

This expression bears a strong resemblance to the standard gravity relationship between the value of bilateral imports and the size of the exporting and importing countries in the absence of trade costs. This form of the "gravity" relationship is unorthodox, but it turns out to be useful for testing for the presence of frictions in goods and asset markets.

Appropriate substitution yields the more standard expression (noting the absence of trade costs):

$$Q\left(k, s^t\right) Z\left(k, s^t\right)_i = \frac{\left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right]}{\sum_{j=1}^{N} Q\left(j, s^t\right) Y\left(s^t\right)_j}$$

2.2 Trade costs

Resource cost of trade

The setup is exactly as before, except that intermediate goods trade is costly: in order for one unit of j's good to arrive in i, $t\left(s^t\right)_{ij}$ units must be shipped, with $t\left(s^t\right)_{ii} = 1$, $t\left(s^t\right)_{ij} \geq 1$ and $t\left(s^t\right)_{ij} t\left(s^t\right)_{jk} \geq t\left(s^t\right)_{ik}$. The intermediate goods resource constraints must be modified to take account of this fact:

$$Y\left(s^t\right)_i = A\left(s^t\right)_i K\left(s^{t-1}\right)_i^\alpha L_i^{1-\alpha} = \sum_{k=1}^{N} t\left(s^t\right)_{ki} Z\left(i, s^t\right)_k \tag{13}$$

where $t\left(s^t\right)_{ki}$ is the quantity of good i that must be shipped from i to k in order for one unit to arrive in k.

Planner's problem and equilibrium

The planner's problem is modified from the zero trade cost case in that the weighted sum of country utilities is maximized subject to the modified resource constraints. The first order conditions with respect to consumption is unchanged. The first order condition with respect to absorption of intermediates is modified:

$$Q\left(k, s^t\right) t\left(s^t\right)_{ik} = P\left(s^t\right)_i X\left(s^t\right)_i^{\frac{1}{\eta}} Z\left(k, s^t\right)_i^{-\frac{1}{\eta}} \tag{14}$$

As in the zero trade cost case, the two sets of resource constraints and the first order conditions (including the first order condition with respect to capital) determine consumption of each good by each country in every period and state. The appropriate values of λ_i in the decentralized equilibrium without transfers can in principle be recovered by combining the first order conditions with the resource constraints and the individual country budget constraints. Allowing for specialized endowments and costly trade modifies several of the predictions of the standard frictionless model. These modifications are now summarized:

Consumption correlations

Marginal utilities are not equalized across countries because relative prices differ due to trade costs. Using the production function for the aggregate good X combined with the first order conditions with respect to absorption of individual intermediate goods, the date-t state-s^t aggregate price level in country i can be written:

$$P\left(s^t\right)_i = \left[\sum_{k=1}^{N} \left(t\left(s^t\right)_{ik} Q\left(k, s^t\right)\right)^{1-\eta}\right]^{\frac{1}{1-\eta}} \tag{15}$$

8

Purchasing power parity fails. The real exchange rate between i and j can differ from 1. However the first order condition for consumption still implies a monotonic relationship between the real exchange rate and relative consumption, given by:

$$RER\left(s^t\right)_{ij} = \frac{P\left(s^t\right)_j}{P\left(s^t\right)_i} = \frac{\lambda_j}{\lambda_i}\left[\frac{C\left(s^t\right)_i}{C\left(s^t\right)_j}\right]^\rho \tag{16}$$

But since price levels differ across countries in a way that varies over time, this implies that relative consumption is not constant.

Relative consumption can be rewritten:

$$\frac{C\left(s^t\right)_i}{C\left(s^t\right)_j} = \left[\frac{\lambda_i}{\lambda_j}\right]^{1/\rho}\left[\frac{\sum_{k=1}^N \frac{t\left(s^t\right)_{ik}^{1-\eta}}{\phi(s^t)_k}Y\left(s^t\right)_k^{\frac{\eta-1}{\eta}}}{\sum_{k=1}^N \frac{t(s^t)_{jk}^{1-\eta}}{\phi(s^t)_k}Y\left(s^t\right)_k^{\frac{\eta-1}{\eta}}}\right]^{\frac{1}{(\eta-1)\rho}} \tag{17}$$

with

$$\phi\left(s^t\right)_k = \left[\sum_{h=1}^N \lambda_h^\eta t\left(s^t\right)_{hk}^{1-\eta} C\left(s^t\right)_h^{-\rho\eta} X\left(s^t\right)_h\right]^{\frac{\eta-1}{\eta}} \tag{18}$$

The response of relative consumption between i and j to a shock to productivity in country k clearly depends on the trade cost between i and k relative to the trade cost between j and k. In order for consumption risk sharing to take place, goods must be shipped internationally, and since it is costly to do so, agents will optimally choose not to smooth consumption perfectly. In contrast to models with separable preferences over traded and non-traded goods, this trade cost model predicts less than perfect correlation of the growth of traded goods consumption across countries. In a world with trade costs, there is no "world consumption growth rate," or "world output growth rate," as world consumption and output are different depending on where they are measured.

Bilateral imports

The risk sharing that takes place across countries must still be reflected in trade flows. The value of country i's absorption of k's output in period t following history s^t is given by

the expression:

$$t\left(s^t\right)_{ik} Q\left(k, s^t\right) Z\left(k, s^t\right)_i \tag{19}$$
$$= \frac{\left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right]}{t\left(s^t\right)_{ik}^{\eta-1}} \frac{\lambda_i^{\eta-1} C\left(s^t\right)_i^{\rho(1-\eta)}}{\sum_{j=1}^N \lambda_j^\eta C\left(s^t\right)_j^{-\rho\eta} X\left(s^t\right)_j t\left(s^t\right)_{kj}^{1-\eta}}$$

Again, this is a slightly unorthodox formulation of the standard gravity relationship in the presence of trade costs, where bilateral imports depend on the size of the two countries, bilateral trade costs, and "multilateral resistance" terms [see Anderson and van Wincoop (2003), 2004)]. Appropriate substitution yields the more standard form of the relationship:

$$t\left(s^t\right)_{ik} Q\left(k, s^t\right) Z\left(k, s^t\right)_i = \left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right]\left(\frac{P\left(s^t\right)_i \Pi\left(s^t\right)_k}{t\left(s^t\right)_{ik}}\right)^{\eta-1} \tag{20}$$

where

$$\Pi\left(s^t\right)_k^{1-\eta} = \sum_{j=1}^N P\left(s^t\right)_j X\left(s^t\right)_j \left(t\left(s^t\right)_{kj}/P\left(s^t\right)_j\right)^{1-\eta} \tag{21}$$

As will become clear presently, the former expression has the advantage over the latter that it allows us to distinguish whether or not there are frictions in asset markets.

2.3 Enforcement constraint

Suppose now that output is perfectly observable, but countries cannot commit ex ante to make payments that are not ex post optimal. Intertemporal and interstate trade across countries is then feasible only to the extent to which payment can be enforced by the threat of exclusion from future intertemporal, interstate and possibly intratemporal trade. This will limit the degree of risk-sharing that can be supported. There are various possible equilibria of this game. The degree of risk sharing that can be sustained is increasing in the severity of the punishment. I assume that there exists a subgame perfect equilibrium of this game where a country that defaults on its obligations to another country is excluded from participating in some markets by all countries, forever.

Planner's problem

The planner maximizes a weighted sum of country utilities subject to the standard re-

source constraints and the incentive compatibility constraints:

$$\sum_{r=t}^{\infty} \sum_{s^r} \beta^{r-t} \pi\left(s^r | s^t\right) u\left(s^r\right)_i \geq V\left(s^t\right)_i \tag{22}$$

where

$$V\left(s^t\right)_i = \sum_{r=t}^{\infty} \sum_{s^r} \beta^{r-t} \pi\left(s^r | s^t\right) u^{Autarky}\left(s^r\right)_i \tag{23}$$

The Lagrange multipliers on the resource constraints are as before. Let the Lagrange multipliers on the IC constraints be denoted

$$\gamma\left(s^t\right)_i = \beta^t \pi\left(s^t\right) \delta\left(s^t\right)_i \tag{24}$$

The Lagrangian for the planner's problem can be written:

$$\mathcal{L} = \sum_{i=1}^{N} \sum_{t=0}^{\infty} \sum_{s^t} \beta^t \pi\left(s^t\right) \left[\begin{array}{l} M\left(s^{t-1}\right)_i u\left(s^t\right)_i + \delta\left(s^t\right)_i \left[u\left(s^t\right)_i - V\left(s^t\right)_i\right] + \\ Q\left(i, s^t\right) \left[A\left(s^t\right)_i K\left(s^{t-1}\right)_i^{\alpha} L_i^{1-\alpha} - \sum_{k=1}^{N} t\left(s^t\right)_{ki} Z\left(i, s^t\right)_k\right] + \\ P\left(s^t\right)_i \left[\left(\sum_{j=1}^{N} Z\left(j, s^t\right)_i^{\frac{\eta-1}{\eta}}\right)^{\frac{\eta}{\eta-1}} - C\left(s^t\right) i - K\left(s^t\right)_i + K\left(s^{t-1}\right)_i\right] \end{array} \right]$$

with

$$M\left(s^t\right)_i = M\left(s^{t-1}\right)_i + \delta\left(s^t\right)_i \tag{25}$$

and $M\left(s^{-1}\right)_i = \lambda_i$.

The first order conditions for this problem with respect to $C\left(s^t\right)_i$ is:

$$M\left(s^t\right)_i C\left(s^t\right)_i^{-\rho} = P\left(s^t\right)_i \tag{26}$$

and with respect to $Z\left(k, s^t\right)_i$ is:

$$Q\left(k, s^t\right) t\left(s^t\right)_{ik} = P\left(s^t\right)_i X\left(s^t\right)_i^{\frac{1}{\eta}} Z\left(k, s^t\right)_i^{-\frac{1}{\eta}} \tag{27}$$

Equilibrium

The two sets of resource constraints, the IC constraints, the dynamic game which determines $u^{Autarky}\left(s^t\right)_i$ and $V\left(s^t\right)_i$ and the first order conditions (including the first order condition with respect to capital) together determine consumption of each good by each

11

country in every period and state. However it is not necessary to characterize the equilibrium allocation in order to derive a number of results on consumption correlations and the reflection of consumption risk sharing in bilateral imports.

Consumption correlations

The relationship between the domestic price levels, trade costs and the price of intermediates in the country of production is exactly as in the case with no asset market friction. If trade costs are non-zero, purchasing power parity fails. The relationship between the real exchange rate and relative consumption implied by the first order condition with respect to consumption is:

$$RER\left(s^t\right)_{ij} = \frac{P\left(s^t\right)_i}{P\left(s^t\right)_j} = \frac{M\left(s^t\right)_i}{M\left(s^t\right)_j}\left[\frac{C\left(s^t\right)_j}{C\left(s^t\right)_i}\right]^{\rho} \tag{28}$$

The relative sum of multipliers $M\left(s^t\right)_i / M\left(s^t\right)_j$ will in general depend on the consumption allocation, so the relationship between the real exchange rate and relative consumption need not be monotonic.[1]

Relative consumption can be written:

$$\frac{C\left(s^t\right)_i}{C\left(s^t\right)_j} = \left[\frac{M\left(s^t\right)_i}{M\left(s^t\right)_j}\right]^{1/\rho}\left[\frac{\sum_{k=1}^{N}\frac{t\left(s^t\right)_{ik}^{1-\eta}}{\phi(s^t)_k}Y\left(s^t\right)_k^{\frac{\eta-1}{\eta}}}{\sum_{k=1}^{N}\frac{t\left(s^t\right)_{jk}^{1-\eta}}{\phi(s^t)_k}Y\left(s^t\right)_k^{\frac{\eta-1}{\eta}}}\right]^{\frac{1}{(\eta-1)\rho}} \tag{29}$$

with

$$\phi\left(s^t\right)_k = \left[\sum_{h=1}^{N}M\left(s^t\right)_h^{\eta}t\left(s^t\right)_{hk}^{1-\eta}C\left(s^t\right)_h^{-\rho\eta}X\left(s^t\right)_h\right]^{\frac{\eta-1}{\eta}} \tag{30}$$

Clearly, even if there are no trade costs, relative consumption is not constant, and consumption growth rates are not perfectly correlated, due to the friction in asset markets.

Bilateral imports

In the presence of both types of friction, the risk sharing that takes place across countries must still be reflected in trade flows. The first order conditions together with the resource constraints yield the following expression for the value of country i's consumption of k's

---

[1]This implication of financial frictions for the Backus-Smith puzzle is pointed out by Choi (2005).

endowment in period t following history s^t:

$$t\left(s^t\right)_{ik} Q\left(k,s^t\right) Z\left(k,s^t\right)_i \tag{31}$$

$$= \frac{\left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k,s^t\right) Y\left(s^t\right)_k\right]}{t\left(s^t\right)_{ik}^{\eta-1}} \frac{M\left(s^t\right)_i^{\eta-1} C\left(s^t\right)_i^{\rho(1-\eta)}}{\sum_{j=1}^N M\left(s^t\right)_j^{\eta} C\left(s^t\right)_j^{-\rho\eta} X\left(s^t\right)_j t\left(s^t\right)_{jk}^{1-\eta}}$$

Again, this is a slightly unorthodox formulation of the standard gravity relationship. Appropriate substitution yields the more standard form of the relationship:

$$t\left(s^t\right)_{ik} Q\left(k,s^t\right) Z\left(k,s^t\right)_i = \left[P\left(s^t\right)_i X\left(s^t\right)_i\right]\left[Q\left(k,s^t\right) Y\left(s^t\right)_k\right]\left(\frac{P\left(s^t\right)_i \Pi\left(s^t\right)_k}{t\left(s^t\right)_{ik}}\right)^{\eta-1} \tag{32}$$

with

$$\Pi\left(s^t\right)_k^{1-\eta} = \sum_{j=1}^N P\left(s^t\right)_j X\left(s^t\right)_j \left(t\left(s^t\right)_{kj}/P\left(s^t\right)_j\right)^{1-\eta} \tag{33}$$

Notice that the former expression has the advantage over the latter that it differs depending on whether or not there are asset market frictions.[2]

2.4 Financial autarky

Under financial autarky, trade must be balanced in all periods and states of the world, but spot trades are not restricted. At each point in time and for every realized history, the representative agent in each country maximizes utility $u\left(s^t\right)_i$ subject to the i-country aggregate good resource constraint and the balanced trade condition:

$$\sum_{k=1}^N t\left(s^t\right)_{ik} Q\left(k,s^t\right) Z\left(k,s^t\right)_i = Q\left(i,s^t\right) A\left(s^t\right)_i K\left(s^{t-1}\right)_i^{\alpha} L_i^{1-\alpha} \tag{34}$$

where $Q\left(k,s^t\right)$ is the spot price in country k of good k. Denote the multipliers on the aggregate good resource constraint

$$\sigma\left(s^t\right)_i = \beta^t \pi\left(s^t\right) \tilde{P}\left(s^t\right)_i \tag{35}$$

---

[2]However from (31) it is not possible to distinguish enforcement frictions of the type presented here from other types of asset market friction.

and the multipliers on the balanced trade condition

$$\varphi\left(s^{t}\right)_{i} = \beta^{t} \pi\left(s^{t}\right) R\left(s^{t}\right)_{i} \tag{36}$$

The first order conditions with respect to $C\left(s^{t}\right)_{i}$ are given by:

$$C\left(s^{t}\right)_{i}^{-\rho} = \tilde{P}\left(s^{t}\right)_{i} \tag{37}$$

and with respect to $Z\left(k, s^{t}\right)_{i}$ are given by:

$$\tilde{P}\left(s^{t}\right)_{i} X\left(s^{t}\right)_{i}^{1/\eta} Z\left(k, s^{t}\right)_{i}^{-1/\eta} = R\left(s^{t}\right)_{i} t\left(s^{t}\right)_{ik} Q\left(k, s^{t}\right) \tag{38}$$

For the purpose of comparing the financial autarky case with the cases previously considered, define

$$P\left(s^{t}\right)_{i} = \tilde{P}\left(s^{t}\right)_{i} R\left(s^{t}\right)_{i} \tag{39}$$

Equilibrium

The two sets of resource constraints, the budget constraints and the first order conditions (including the first order condition with respect to capital) together determine consumption of each good by each country in every period and state. However it is not necessary to characterize the equilibrium allocation in order to derive results on consumption correlations and the reflection of consumption risk sharing in bilateral imports.

Consumption correlations

The relationship between the domestic price levels, trade costs and the spot price of intermediates in the country of production is exactly as in the case of no asset market frictions. If trade costs are non-zero, purchasing power parity fails. The relationship between the real exchange rate and relative consumption is:

$$RER\left(s^{t}\right)_{ij} = \frac{P\left(s^{t}\right)_{i}}{P\left(s^{t}\right)_{j}} = \frac{R\left(s^{t}\right)_{i}}{R\left(s^{t}\right)_{j}} \left[\frac{C\left(s^{t}\right)_{j}}{C\left(s^{t}\right)_{i}}\right]^{\rho} \tag{40}$$

The relative multipliers $R\left(s^{t}\right)_{i} / R\left(s^{t}\right)_{j}$ will in general depend on the consumption allocation, so as in the enforcement friction case, the relationship between the real exchange rate and relative consumption need not be monotonic.

Relative consumption can be written

$$\frac{C\left(s^{t}\right)_{i}}{C\left(s^{t}\right)_{j}}=\left[\frac{R\left(s^{t}\right)_{i}}{R\left(s^{t}\right)_{j}}\right]^{1/\rho}\left[\frac{\sum_{k=1}^{N}\frac{t\left(s^{t}\right)_{ik}^{1-\eta}}{\phi(s^{t})_{k}}Y\left(s^{t}\right)_{k}^{\frac{\eta-1}{\eta}}}{\sum_{k=1}^{N}\frac{t(s^{t})_{jk}^{1-\eta}}{\phi(s^{t})_{k}}Y\left(s^{t}\right)_{k}^{\frac{\eta-1}{\eta}}}\right]^{\frac{1}{(\eta-1)\rho}} \tag{41}$$

with

$$\phi\left(s^{t}\right)_{k}=\left[\sum_{h=1}^{N}R\left(s^{t}\right)_{h}^{\eta}t\left(s^{t}\right)_{hk}^{1-\eta}C\left(s^{t}\right)_{h}^{-\rho\eta}X\left(s^{t}\right)_{h}\right]^{\frac{\eta-1}{\eta}} \tag{42}$$

Even if there are no trade costs, relative consumption is not constant, and consumption growth rates are not perfectly correlated. However, as in Cole and Obstfeld (1991), there is some risk sharing through movements in the terms of trade, as long as trade costs and the elasticity of substitution between different goods are less than infinite.

Bilateral imports

The first order conditions together with the resource constraints yield the following expression for the value of country i's consumption of k's endowment in period t following history s^{t}:

$$t\left(s^{t}\right)_{ik}Q\left(k,s^{t}\right)Z\left(k,s^{t}\right)_{i} \tag{43}$$
$$=\frac{\left[P\left(s^{t}\right)_{i}X\left(s^{t}\right)_{i}\right]\left[Q\left(k,s^{t}\right)Y\left(s^{t}\right)_{k}\right]}{t\left(s^{t}\right)_{ik}^{\eta-1}}\frac{R\left(s^{t}\right)_{i}^{\eta-1}C\left(s^{t}\right)_{i}^{\rho(1-\eta)}}{\sum_{j=1}^{N}R\left(s^{t}\right)_{j}^{\eta}C\left(s^{t}\right)_{j}^{-\rho\eta}X\left(s^{t}\right)_{j}t\left(s^{t}\right)_{jk}^{1-\eta}}$$

Making use of the fact that under financial autarky, the value of a country's output is equal to the value of its expenditure , this can be rewritten:

$$t\left(s^{t}\right)_{ik}Q\left(k,s^{t}\right)X\left(k,s^{t}\right)_{i} $$
$$=\frac{\left[P\left(s^{t}\right)_{i}X\left(s^{t}\right)_{i}\right]\left[Q\left(k,s^{t}\right)Y\left(s^{t}\right)_{k}\right]}{t\left(s^{t}\right)_{ik}^{\eta-1}}\left(R\left(s^{t}\right)_{i}C\left(s^{t}\right)_{i}^{-\rho}R\left(s^{t}\right)_{k}C\left(s^{t}\right)_{k}^{-\rho}\right)^{\eta-1} \tag{44}$$

or

$$t\left(s^{t}\right)_{ik}Q\left(k,s^{t}\right)X\left(k,s^{t}\right)_{i}=\frac{\left[P\left(s^{t}\right)_{i}X\left(s^{t}\right)_{i}\right]\left[Q\left(k,s^{t}\right)Y\left(s^{t}\right)_{k}\right]}{t\left(s^{t}\right)_{ik}^{\eta-1}}\left(P\left(s^{t}\right)_{i}P\left(s^{t}\right)_{k}\right)^{\eta-1} \tag{45}$$

which closely resembles the form of the gravity equation derived by Anderson and van Wincoop (2003).

2.5 A special case

For the purpose of building intuition, it is worth considering a special case of the above model. Suppose that each of the N countries in the world is *endowed* with a distinct tradeable intermediate. These intermediates are combined to produce a non-tradeable final consumption good using the same Dixit-Stiglitz aggregator as before. There is no production or investment. Suppose that preferences are such that $\rho = 1/\eta$.[3] In this case, when there are no frictions in asset markets, bilateral imports are given by:

$$t\left(s^t\right)_{ik} P\left(k, s^t\right) C\left(k, s^t\right)_i = \frac{\left[\lambda_i^\eta\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right]}{t\left(s^t\right)_{ik}^{\eta-1}} \frac{1}{\sum_{j=1}^N \lambda_j^\eta t\left(s^t\right)_{kj}^{1-\eta}} \tag{46}$$

With the enforcement friction in asset markets, bilateral imports are given by:

$$t\left(s^t\right)_{ik} P\left(k, s^t\right) C\left(k, s^t\right)_i = \frac{\left[M\left(s^t\right)_i^\eta\right]\left[Q\left(k, s^t\right) Y\left(s^t\right)_k\right]}{t\left(s^t\right)_{ik}^{\eta-1}} \frac{1}{\sum_{j=1}^N M\left(s^t\right)_j^\eta t\left(s^t\right)_{kj}^{1-\eta}} \tag{47}$$

Under financial autarky, bilateral imports are given by:

$$t\left(s^t\right)_{ik} P\left(k, s^t\right) C\left(k, s^t\right)_i = \frac{\left[Q\left(i, s^t\right) Y\left(s^t\right)_i\right]\left[Q\left(k, s^t\right)_t Y\left(s^t\right)_k\right]}{t\left(s^t\right)_{ik}^{\eta-1}} \left(P\left(s^t\right)_i P\left(s^t\right)_k\right)^{\eta-1} \tag{48}$$

When there are no frictions in asset markets, bilateral imports do not respond to shocks to the value of importer GDP. Country i's consumption of good k does not depend on i's current income. Under financial autarky, bilateral imports move one-for-one with the value of importer GDP. Country i's consumption of good k moves one-for-one with i's current income. When there is a friction in asset markets, but some cross-state and cross-period trade is possible, bilateral imports move with the value of importer GDP to the extent that $M\left(s^t\right)_i^\eta$, the multiplier on i's IC constraint, depends on i's current GDP. It is tempting to hypothesize that i's consumption of good k moves with i's current income, but less than one-for-one.

---

[3]This is the special case of preferences consdered in Obstfeld and Rogoff (1996), Chapter 5.

3 Empirical strategy

The predictions of the models outlined above with respect to the relationship between bilateral imports, output, consumption and trade costs can be conveniently summarized. Let IM_{ikt} denote the value of country i's imports from country k in period t. Let EXP_{it} denote the value of i's absorption $(C + I)$ in period t. Let GDP_{kt} denote the value of k's output in period t. Then:

$$\frac{IM_{ikt}}{EXP_{it}GDP_{kt}} = \Theta_{it}\Phi_{kt}t_{ikt}^{1-\eta} \tag{49}$$

where the implications of the different assumptions are given by:

Assumption	Θ_{it}	Φ_{kt}	$t_{ikt}^{1-\eta}$
(1) Enforcement friction, trade costs	$M_{it}^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$1/\sum_{j=1}^{N}\Theta_{jt}EXP_{jt}t_{kjt}^{1-\eta}$	$t_{ikt}^{1-\eta}$
(2) Financial autarky, trade costs	$R_{it}^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$R_{kt}^{\eta-1}C_{kt}^{-\rho(\eta-1)}$	$t_{ikt}^{1-\eta}$
(3) Complete financial markets, trade costs	$\lambda_i^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$1/\sum_{j=1}^{N}\Theta_{jt}EXP_{jt}t_{kjt}^{1-\eta}$	$t_{ikt}^{1-\eta}$
(4) Enforcement friction, no trade costs	$M_{it}^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$1/\sum_{j=1}^{N}\Theta_{jt}EXP_{jt}$	1
(5) Financial autarky, no trade costs	$R_{it}^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$R_{kt}^{\eta-1}C_{kt}^{-\rho(\eta-1)}$	1
(6) Complete financial markets, no trade costs	$\lambda_i^{\eta-1}C_{it}^{-\rho(\eta-1)}$	$1/\sum_{j=1}^{N}\Theta_{jt}EXP_{jt}$	1

Given data on bilateral imports and the other relevant variables, it is possible to test which of these alternatives fits the data best. Taking logs of (49) and substituting in the standard assumption about the form of trade costs,[4]

$$t_{ikt} = \prod_{m=1}^{M}(Z_{ikt}^m)^{\gamma_t^m}, \ Z_{ikt}^m = 1 \text{ if } i = k, z_{ikt}^m \geq 1 \text{ otherwise} \tag{50}$$

the six different assumptions about the configuration of frictions can be implemented by estimating six different linear models. Let $w_{ikt} = \ln(IM_{ikt}/EXP_{it}GDP_{kt})$, $c_{it} = \ln C_{it}$ and $z_{ikt}^m = \ln Z_{ikt}^m$. Let θ_{it} be an importer-year fixed effect, ϕ_{kt} an exporter-year fixed effect and ψ_i an importer fixed effect. Then the six models are given by:

---

[4]See Anderson and van Wincoop (2004).

Assumption	Estimating equation
(1) Enforcement friction, trade costs	$w_{ikt} = \theta_{it} + \phi_{kt} + \sum_{m=1}^{M} \gamma_t^m z_{ikt}^m + \varepsilon_{ikt}$
(2) Financial autarky, trade costs	$w_{ikt} = \phi_{it} + \phi_{kt} + \sum_{m=1}^{M} \gamma_t^m z_{ikt}^m + \varepsilon_{ikt}$
(3) Complete financial markets, trade costs	$w_{ikt} = \psi_i + \phi_{kt} + \beta_c c_{it} + \sum_{m=1}^{M} \gamma_t^m z_{ikt}^m + \varepsilon_{ikt}$
(4) Enforcement friction, no trade costs	$w_{ikt} = \theta_{it} + \phi_{kt} + \varepsilon_{ikt}$
(5) Financial autarky, no trade costs	$w_{ikt} = \phi_{it} + \phi_{kt} + \varepsilon_{ikt}$
(6) Complete financial markets, no trade costs	$w_{ikt} = \psi_i + \phi_{kt} + \beta_c c_{it} + \varepsilon_{ikt}$

Notice that it is appropriate to impose the restrictions on the relationship between ϕ_{kt} and the other variables in models (1), (2), (4) and (5) only if they are estimated using data on the universe bilateral pairs (including imports from self). However, because of data availability constraints, these restrictions will not be imposed.

The enforcement friction, trade cost model nests all the other possible configurations of frictions. Hence, a likelihood ratio test can be used to test null hypotheses against the alternative of frictions in both markets. The data used to implement this strategy is described below. For many bilateral pairs in the sample used, bilateral imports are recorded as zero. In order to avoid dropping these observations, one is added to all bilateral imports, so w_{ikt} is constructed as $\ln\left[(1 + IM_{ikt})/EXP_{it}GDP_{kt}\right]$. All cases are estimated as two-way fixed effect models, as the number of dummy variables would otherwise be very large. The full set of time-varying coefficients on the gravity variables are not included, but these coefficients are allowed to vary across five-year periods.

4   Data and results

Annual bilateral merchandise imports in current dollars from 1970 to 2000 are taken from the *NBER-United Nations Trade Data* prepared by Feenstra and Lipsey. Household plus government consumption measured in constant dollars, the current dollar value of GDP, the current dollar value of total expenditure and the current dollar value of total imports are taken from the World Bank's *World Development Indicators* (WDI). The largest possible sample given the requirement that all of these variables be available for all sample years consists of 70 developed and developing countries. The list of countries is in the Appendix.

For the purposes of estimating the gravity equation, data on variables that are correlated

with trade costs are required. In choosing which variables to include, attention is restricted to the subset of standard gravity variables that is least likely to be endogenously determined. Bilateral distance in miles is calculated using the great circle distance algorithm provided by Gray (2001). Dummy variables indicating common language, contiguity and a colonial relationship post-1945 are constructed based on the *CIA World Factbook*.

One issue in mapping the model into the data is that we have data on the value of bilateral *merchandise* imports, not bilateral imports. Data on bilateral service trade are not available. It is implicitly assumed that bilateral service flows follow the same pattern as bilateral merchandise flows.

4.1 Results

Baseline results

Table 1 reports the results from estimating the six models described above using all bilateral pairs in the 70-country sample. The estimated coefficients on the gravity variables in the models with trade costs are fairly standard and do not change much across specifications. They strongly suggest that trade costs are falling over time, most rapidly in the first half of the sample period.

Table 2 reports the likelihood ratio test statistics and p-values for the five hypothesis tests, taking the trade cost and enforcement friction model as the alternative hypothesis in each case. The null of no frictions in asset markets is rejected at all significance levels. The null of financial autarky is rejected at all significance levels. The null of no trade costs is also rejected at all significance levels. Data on bilateral imports strongly suggests that both types of friction are necessary to explain the failure of international risk sharing, while at the same time financial autarky is rejected.

The estimated coefficients on the gravity variables in Table 1 can be used to construct fitted values of bilateral trade costs between all country pairs for the 6 five-year intervals covered by the sample. This requires an estimate of the elasticity of substitution, η. Following Anderson and van Wincoop, a baseline elasticity of 6 is used. Table 3 reports summary statistics of the implied trade costs. Using this elasticity, the predicted trade costs are very high, much higher than the measured costs of trade for goods that are actually traded. One way to understand this is to think of the costs constructed here as a weighted average applying to all of output, including the large fraction that is non-traded. Another possible explanation

19

is that there are both fixed and per unit costs of trade. The failure of the empirical model used here to take account of fixed costs may lead to upwardly-biased estimates of per unit trade costs [see Helpman, Melitz and Rubinstein (2004)]. At any rate, the evidence presented here strongly suggests a much greater macroeconomic role for trade costs than usually presumed in the international real business cycle literature.

Results by level of development

To test the plausibility of these results, the same models are estimated on two subsamples of the data, one containing only observations on bilateral imports between 21 OECD countries, and the other containing only observations on bilateral imports between the remaining 49 countries. These results are reported in Table 4 and Table 7. The coefficients on the gravity variables in the models with trade costs are quite different in the two samples. The implied trade costs are substantially larger in the non-OECD sample than in the OECD sample (see Tables 6 and 9).

Tables 5 and 8 report the likelihood ratio test statistics and p-values for the two samples. In both samples, the null of no asset market frictions but costly trade is rejected against the alternative of frictions in both goods and asset markets. For the non-OECD sample, the rejection is at all significance levels. For the OECD sample, the null is rejected at all conventional levels of significance, but the p-value is just under one half. In both samples, the null of asset market frictions but no trade costs is rejected against the alternative of frictions in both goods and asset markets at all levels of significance. The null of financial autarky is also rejected in favor of some degree of risk sharing through intertemporal trade.

Results by period

As a further test of plausibility, the same models are estimated separately on the first half of the time-period (1970-1984) and the second half of the time period (1985-2000). The estimation results are reported in Table 10 and Table 12. The implied trade costs are on average lower in the second period compared with the first period. Tables 11 and 13 report the likelihood ratio test statistics and p-values for the two samples. In both samples, the null of no asset market frictions but costly trade is rejected against the alternative of frictions in both goods and asset markets. Similarly, the null of financial autarky is rejected in favor of the alternative of some risk sharing through financial markets. It is interesting to note that the rejection of the null of trade cost frictions but no asset market frictions is weaker in the second period than in the first period.

5   Conclusion

This paper presents a multi-country model with frictions in goods and asset markets. The goods market friction takes the form of costs of trading goods, while the friction in asset markets takes the form of limited enforcement. Both of these frictions separately reduce the extent to which countries can pool risk. The model suggests a test for the presence of each of the two types of friction that can be implemented using data on bilateral imports. I implement this test using a sample of developed and developing countries. The results suggest that both trade costs and asset market imperfections are necessary in order to explain the failure of perfect consumption risk sharing. However there is some risk sharing through intertemporal trade, and asset market frictions are less important for developed than for developing countries.
