Education and Freedom of Choice: Evidence from Arranged Marriages in Vietnam

This Version: November 2009

ABSTRACT

Using household data from Vietnam, we provide evidence on the causal effects of education on freedom of spouse choice. We use war disruptions and spatial indicators of schooling supply as instruments. The point estimates indicate that a year of additional schooling reduces the probability of an arranged marriage by about 14 percentage points for an individual with 8 years of schooling. We also estimate bounds that do not rely on the exact exclusion restrictions (lower bound is 6-7 percentage points). The impact of education is strong for women, but much weaker for men.

JEL Classification Number: I2, O12, D1, J12

Key Words: Arranged Marriage, Education, Schooling, Freedom of choice, Development, Vietnam, Social Interactions.

(1) Introduction

There is a broad consensus among development practitioners, policy makers, and academic researchers that education is one of the most effective interventions to reduce poverty and promote development. A large empirical literature on economics of education, in the context of both developed and developing countries, focuses on the labor market returns to education (Card (1995, 2001), Angrist and Krueger (1990, 1992), Duflo (2001), Alderman et al (1996), Heckman (2005), Heckman and Li (2003), Glewwe (1996), among others). There is a relatively small literature that focuses on the direct productivity effects of education, especially in the context of self-employment in agriculture and non-farm activities (Jamison and Lau (1982), Yang and An (2002), Kurosaki and Khan (2006)). A substantial literature in growth theory identifies human capital as a critical ingredient for long-run growth (see, for example, Romer (1989,1994), Aghion et al (1998), Acemoglu (2009)), although the empirical literature has been more mixed in identifying the effects of human capital in cross-country growth regressions (Durlauf et. al. (2005)). A related literature addresses whether social returns to education are significantly higher than the private returns due to positive externalities (Acemoglu and Angrist (2000), Basu et al (2001)).

However, education confers many benefits to an individual (and the society) beyond the returns in the labor market or its direct productivity and growth effects. As Amartya Sen noted “[Education] can add to the value of production in the economy and also to the income of the person who has been educated. But even with the same level of income, a person may benefit from education in reading, communicating, arguing, in being able to choose in a more informed way, in being taken more seriously by others and so on” (Sen (1999), p. 294). The returns to education in non-market activities, especially as an input in the household

production function have been the focus of a significant strand of literature (Haveman and Wolfe (1984, 2002), Kenkel (1991), Behrman and Wolfe (1987), Rosenzweig and Schultz (1989)). The focus of this paper is on non-market returns to education beyond health and productivity gains emphasized in the current literature; broadly, we are interested in returns to education in social interactions. More specifically, we focus on the question of whether education improves an individual's freedom of choice by strengthening his/her bargaining position in social interactions, within the household and in other social settings. We address this question using freedom to choose ones own spouse, one of the most important decisions in human life, as an indicator of freedom of choice.

The existing literature on intra-household bargaining focuses on the conflict of preference between husband and wife, and analyzes its implications for control over resources (Browning (1998), Lundberg and Pollak (1996), Haddad and Kanbur (1990)). In contrast, our focus is on the bargaining between the parents and children under the assumption that the preferences of parents with respect to the spouse choice is not fully aligned with the preference of children. Since our interest lies in understanding the implications of education for freedom of choice, we define *arranged marriage* as the cases where parents wield the primary decision making power; they choose the spouse of children with or without children's input. Conversely, *freedom of choice* refers to the cases where children are the primary decision makers; they choose their spouse with or without parental input.²

Parents in developing countries make decisions about the education of their children when they are young, taking into account a multitude of factors including old-age support,

²The binary arranged marriage variable used in this paper, by definition, cannot capture finer shades in the bargaining game between the parents and children. We, however, believe that our definition is a reasonable representation of the idea that arranged marriage indicates less freedom of choice for the children.

social status, and pure altruism. There is, however, a trade-off from the parents' perspective: a more educated child may be more able to take care of them in old age and bring in social prestige, but he/she is also likely to exert more bargaining power in decision making (because of better outside options derived from improved economic opportunities and social networks). The bargaining game between children and parents thus changes significantly after education is acquired. This implies that, *ceteris paribus*, better educated children would be more likely to choose their own spouse. We use household survey data from Vietnam in 1995 (from Vietnam Longitudinal Survey (VLS), 1995-98) to examine whether better education among children reduces the incidence of arranged marriage.

To the best of our knowledge, there is no empirical analysis of the causal effects of education on the arranged marriage in economics literature. There is a sociological literature that uses rich case study methods and multivariate statistical models to investigate the relationship between arranged marriage and education of children (e.g. Jejeebhoy, 1995). In general, they however do not disentangle the causality issue. This paper is thus the first attempt in the literature to estimate the causal effects of education on arranged marriage.

Identification of the causal effects of education on choice of spouse can be challenging. Addressing omitted variables bias due to unobserved individual ability as well as unobserved individual and parental preferences is important in estimating the effects of education on spouse choice. Any observed negative partial correlation between the probability of arranged marriage and the level of education might be driven by such unobserved heterogeneity that affects both schooling attainment and spouse choice decisions. For example, more "progressive" parents are more likely to invest in the education of children and also find it acceptable to allow the children to choose their own spouse. A stubborn

child might be more successful in withstanding the pressure to drop out of school for early marriage, and thus may have higher education. He/she is also likely to be more emphatic in defending his/her own choice of spouse. It is, however, also possible that a stubborn child drops out of school as a rebellion to parental preference for education, and also does not allow the parents to choose the spouse for him/her. Such unobserved heterogeneity would lead to a biased estimate of the effects of children's education on spouse choice in an OLS regression. Note also that it is not possible to pin down the direction of such bias from a priori reasoning.

The household survey from Vietnam used in this paper is especially suitable for isolating the effects of education for a number of reasons. There is good information on individual and parental characteristics and labor market opportunities. Also, the data come from 10 communes located in the Red River Delta region in Vietnam, and thus exhibit little or no variations in cultural practices. This implies that cultural heterogeneity is not likely to drive the results we report in this paper.³ The empirical results provide robust evidence in favor of a statistically significant and numerically important negative effect of education on the probability of arranged marriage.⁴

The presence of multi-level unobserved characteristics makes it much harder to find suitable instrumental variables, especially to defend the exclusion restrictions.⁵ Note that

³The Red River Delta is the center of ethnic Vietnamese culture. Vietnamese families are usually characterized as part of a Confucian patrilineal, patrilocal, and patriarchal cultural heritage (Keyes, 1996).

⁴The incidence of arranged marriage in the sample used for estimation is 25 percent. The survey was carried out by a group of Vietnamese and American sociologists in 1995, and a large number of respondents (63 percent) belong to birth cohorts before 1960. The incidence of arranged marriage is likely to have declined significantly in recent years in Vietnam because of expansion of education and improved labor market opportunities, among other things. In fact, the results presented in this paper imply that the probability of arranged marriage should become very small once an individual in Vietnam attains 10 years of schooling.

⁵The randomized assignment of one year of additional schooling is not possible, a point emphasized by Angrist and Krueger (2001). Thus one has to rely on other sources of potential exogenous variations in

the exclusion restrictions imposed in an IV framework are *exact*, i.e., the coefficient of the excluded instruments are assumed to have exactly zero coefficients in the structural equation (in our case, the equation for arranged marriage). This sharp exclusion restriction needed for the validity of the IV approach has led to increasing skepticism in the literature. As pointed out recently by Conley et al. (2008) it may be more credible to assume that the instruments satisfy the exclusion restrictions approximately, i.e., the instruments may have non-zero but very small effects in the structural equation. In addition to the standard IV results, we thus report estimates from the bounds approach developed by Conley et al. (2008) under the assumption that the instruments satisfy the exclusion restrictions only approximately.

We follow a large and mature literature on returns to education and use indicators of supply of schooling and exogenous shocks to schooling attainment as instruments (see, Card (2001), Blundell et al. (2005)). More specifically, we use birthplace and a binary cohort dummy for birth year 1955 and earlier as identifying instruments in this paper.⁶ Birthplace represents variations in schooling supply across geographic locations, while the 1955 cohort dummy captures positive shocks to educational attainment of 1955 and earlier cohorts due to lower intensity of conflicts in North Vietnam over 1954-1965 (see below). Birthplace is a good indicator of access to schools only if someone grows up in the same place. In our data set, 98.7 percent of individuals grew up in the place of birth.⁷

The cohort dummy represents differences in schooling attainment of the cohort born

years of schooling for identification.

⁶The birthplace and cohort dummies have been used as instruments for education for example by Schultz (2002), among others.

⁷There are 27 birthplace dummies we can use as instruments. With only one endogeneous regressor, this is likely to create a weak IV problem due to too many instruments. As a result, we reduce the dimension of the the instruments sets in the empirical implementation. For details, please see P.17 below.

after 1955 compared to the older cohort (above 40 years of age in 1995). In our sample 43 percent of individuals are born before 1955. A plausible interpretation of this dummy variable is that it captures the effects of varying intensity of conflicts and war experienced by different age cohorts when they were school aged. The history of war and conflict in Vietnam is long and complex; the intensity of conflict varied over time and space significantly. The cohorts born before 1955 in the Red River Delta region experienced a relatively stable period from 1954 to 1965 which is expected to improve their educational attainment compared to the later cohorts.⁸ For the Red River Delta region, the disruptions caused by US bombing in the late sixties to mid seventies were severe and the later cohorts are likely to suffer negative shocks to their educational attainment.⁹ Especially, the 10 communes surveyed for our data set were bombed heavily because of their proximity to important rail road links and industrial installations (Merli, 2000, P. 4). The education of the later cohorts were affected adversely also because of mass mobilization for the American war. The empirical results reported later show that the earlier cohorts did experience systematically higher educational attainment after controlling for a vector of individual and household level variables and the rural-urban dummy.¹⁰ One might worry that intensity of conflict can have direct effect on marriage market because it affects the sex ratio. The changing sex ratio may also affect the incentives for human capital investment by parents if such

⁸For discussions on wars in Vietnam, see Harrison, 1989; Young, 1991.

⁹The US aerial bombing of North Vietnam started on March 2 1965 with Operation Rolling Thunder. Another major air campaign was waged in December 1972 which came to be known as Operation Linebacker II.

¹⁰One can argue that the oldest age cohort, born long before 1954, would not experience the fruits of relative calm during the 1954-65 period, as they would have been past their school age. Thus one should focus on an interval of age cohort excluding the oldest age cohorts. As part of robustness checks, we exclude the too old cohorts and define a dummy for year of birth between 1945-55. The main conclusion of this paper is not sensitive to this alternative definition of the cohort dummy and we omit the results for sake of brevity.

investments respond to potential returns in the marriage market (LaFortune, 2009). We thus include age cohort specific sex ratio as an additional control in the regressions (calculated using the 1979 census in Vietnam).¹¹ Another potential objection to the exclusion restriction imposed on the cohort dummy is that it might proxy for changing formal rules or informal norms regarding marriage. We control for age of the respondent to account for changing views regarding arranged marriage across different generations. In addition, a dummy for marriages before 1960 is included to account for reform of marital law in Vietnam enacted in 1960.

For birthplace to qualify as a reasonable instrument in our context, we need to control for differences in the labor market opportunities. Such opportunities are likely to vary across geographic locations, and are important determinants of both the incidence of arranged marriage (Goode (1963)) and investment in human capital.¹² Better labor market opportunities improve children's outside option if they have to leave their parental house and are deprived from parental wealth as a consequence of choosing their own spouse. We include an indicator of non-agricultural occupational opportunities at the time of marriage, a rural urban dummy, and household's wage income to control for local labor market opportunities.¹³ The rural-urban dummy also captures differences in living costs, especially housing costs. As mentioned before, in addition we control for a number of individual, and

¹¹Observe that the changing sex ratio primarily affects the bargaining between the bride and bridegroom. Since war is likely to negatively affect the availability of eligible men in the marriage market, it would tend to improve the bargaining position of men (and their parents) vis a vis the women (and their parents). However, there are no compelling reasons to believe that it would affect the bargaining between the parents and children which is the focus of this paper.

¹²For an analysis of role of labor market opportunities for transition from arranged marriage to free spouse choice in medieval Europe, see de Moor and Van Zanden (2005).

¹³Since most of agriculture consists of self employment, the non-farm occupation is a reasonable indicator of labor market opportunities. If we use finer occupational categories at the time marriage instead, the main results of the paper remain robust.

parental characteristics that help isolate the causal effects of education on spouse choice.

The evidence from the formal test of exogeneity discussed below (see section 4.1 and Table 3) show that conditional on the set of control variables, the birthplace and age cohort dummy satisfy the exclusion restrictions unambiguously (P-value of Hansen's J statistic is 0.81).¹⁴

The empirical results indicate that education does significantly reduce the likelihood of having an arranged marriage. Averaging the point estimates from linear probability (2SLS, GMM, CUE-GMM) and Probit (Control Function and IV Probit) models imply that one year of additional schooling reduces the probability of arranged marriage by about 14 percentage points for an individual with 8 years of education. The probability that an individual will have an arranged marriage is close to zero when he/she has about ten years of schooling. The results from bounds analysis using the Conley et al (2008) approach provide strong evidence of a negative causal effect of education on the probability of arranged marriage; none of the bounds contain zero. The lower bound estimates indicate a smaller effect of education; one year of additional schooling reduces the probability of arranged marriage by about 6-7 percentage points for an individual with 8 years of education. The results from the bounds analysis are important as they show that the central conclusion in this paper does not depend on the exclusion restrictions imposed in the IV approach. The results also suggest that the effects of education has important gender dimension. The impact of education is very strong for women; the marginal effect is about 17 percentage points for a woman with the average level of education (7.77 years of schooling). The evidence in favor of a significant causal effect of education on arranged marriage in case

¹⁴For more complete discussion of the identification issues and the roles played by different control variables, please see section 4 below.

of men is, however, much weaker. To the best of our knowledge, this is the first paper in the literature to provide evidence on the causal effects of education on freedom of spouse choice.

We organize the remainder of the paper as follows. The first section discusses the conceptual framework which helps us identify the relevant control variables. The next section provides a brief discussion of the data source and variables descriptions. Section 4, arranged in subsections, is devoted to the empirical strategy used in this paper to identify and estimate the causal effects of education on freedom of spouse choice. Section 5 presents estimates of causal effects of education on arranged marriage using an instrumental variables approach and the bounds approach due to Conley et al (2008). In the conclusions, we provide a summary and context of the results and contributions of the paper.

(2) Conceptual Framework

Arranged marriage is common in many developing countries, especially in Asia and Africa. There are reasons to believe that in many cases it is not a cooperative outcome where parents and children jointly choose a spouse to maximize family welfare.¹⁵ There are no a priori reasons to expect that the preferences of parents and children would be perfectly aligned.¹⁶ Parents might be interested in arranged marriage to further their

¹⁵To the best of our knowledge there is no evidence on the suitability of a unitary model to explain intrahousehold decisions between parents and children. There is, however, overwhelming evidence against the unitary model in the context of intrahousehold allocations between husband and wife (see, for example, Haddad and Kanbur (1990), Lundberg and Pollak (1996)).

¹⁶We would also note that even in the cases of apparent general agreement, there is plenty of room for specific disagreement. Even if the principle of arranged marriage is agreed, in most cases there are likely to be several potential partners, and the parents and children may rank order them differently. It is not possible to analyze this type of conflict of preference within the arranged marriage with our data.

objectives of strengthening their own social and business network, to improve their standing in the community, and to uphold cultural traditions. Another important motive is old-age support; if the parents choose the spouse it is less likely that the spouse of their children will skew the distribution of resources against them, especially in old age. It has been argued that the transition from arranged marriage to own choice redistributes resources away from the parents to the children, and it might have implications for savings and growth (Edlund and Lagerlof (2006)).

The practice of arranged marriage seems to decline generally with economic development; the expansion of education and labor market opportunities for children are negatively correlated with the incidence of arranged marriage (for a discussion, see Goode (1963)). There is a substantial literature in sociology that provides suggestive evidence of a negative correlation between education and the probability of having arranged marriage in a society (for a summary, see Jejeebhoy (1995)). Education can influence the spouse choice through a variety of channels. It may mould children's preference, enrich the pool of potential partners, and alter the threat point in the bargaining game in favor of children. The changes in preference can be due to interactions with people with different attitudes to arranged marriage, exposure to other cultural norms, and in general through a broadening of outlook. Social interactions at the school and college may increase the pool of potential partners with similar values and thus of better compatibility. Education alters the threat point in the bargaining game between parents and children, because educated children in general have better outside options (labor market prospects and higher permanent income). In the event of a conflict regarding spouse choice, the parents can use a prospective bequest as a threat, i.e., they might redistribute away from a son or daughter who choose

his/her own spouse. They can also threaten to drive the newly married couple from the parental home, an effective deterrent when the housing and other related costs of starting a separate household is high enough.¹⁷ Educated children are also more equipped to handle the pressure from parents which sometimes may take the form of legal and other forms of harassment when they choose their own spouse. Finally, extended schooling tends to delay the age at marriage, thereby placing the spouse choice decision at a time when the children are more mature and capable of making better choices.

As mentioned before, the fact that education may weaken parent's influence on children in general, and on spouse choice in particular, also implies that parents will take into account this additional cost when making the education decisions for their children. This has interesting implications for allocation of resources across different children for education. Parents might trade off potentially higher earnings for more compliant behavior of children, assuming that the correlation between ability and assertiveness is positive. This is likely to result in a negative selection effect in our context because parents would invest more in educating the more pliant children even though they may be of lower ability, and the more pliant a child is, the easier it is for parents to overrule his/her spouse choice. A related issue which might create a spurious negative correlation between education and arranged marriage is the possibility that the parents arrange marriage while the child is attending school, and his/her education is truncated as a result of the marriage. This, however, seems not to be a problem in our data set, as there are only a few observations (21 observations out of 4464) where the timing of marriage corresponds to that of withdrawal from school.

¹⁷For a theoretical analysis of arranged marriage where fixed costs of new household formation plays an important role, see Dasgupta et al (2008).

(3) Data

We use data from the Vietnam Longitudinal Survey (VLS, 1995-98) conducted by researchers from the University of Washington and Institute of Sociology in Hanoi¹⁸. The choice of this data set is motivated by the fact that it has information on choice of spouse in addition to information on individual and parental characteristics, and on labor market opportunities. The data set is composed of 1185 households and covers 4464 individuals. It is a 4 year panel data set. It would have been econometrically advantageous to exploit the panel data, but for our variables of interest, in particular regarding the marital status, there is no significant changes across various years. For example, only 42 among the 4464 have changed marital status during those 4 years. The empirical analysis of this paper is based on the 1995 data. Because of missing observations for various variables (such as years of schooling, age at marriage, number of parental siblings), our analysis is based on a sample of 3219 observations.

The survey covers areas around the Red River Delta where there are a total of 10 communes partitioned into four groups: urban communes (3), within 3km of highway or inter-provincial highway (2) and within 3-10km (2) and more distant than 10 km (3). About 80% of the 4,464 individuals interviewed were married. The characteristics of the sample used for estimation (3219 observations) are reported in Table 1. For our variable of interest ‘arranged marriage’, the parents chose the spouse with or without consultation with children for 25% of married individuals. Interestingly, there is no evidence of gender differences in the incidence of arranged marriages. The average age in the survey year (1995) is 39 years, with 63 percent of the sample born before 1960. The average education

¹⁸<http://csde.washington.edu/research/projects/hirschman/vietnam/vls.html>

is about 8.07 years of schooling, and 82 percent of individuals had more than 5 years of schooling. The educational attainment for men is higher; the average education in the sample of men is 8.58 years of schooling, while the average for women is 7.77 years. The education system in Vietnam is standard in that students graduate from high-school after 12 years of schooling. We recoded the years of schooling variable by assigning 13.5 years of education if the person has attended college but did not finish, and 15 if the person has attended and finished college. The average age at marriage is 22.54 years which indicates that early marriage may not be that common (6.5 percent below 18 years). Only 4 percent of individuals met their spouse at school. This implies that schools do not play an important role as a meeting place for potential marriage partners.

(4) Empirical Strategy

To test the hypothesis that education has a causal effect on the incidence of arranged marriage, we estimate the following Probit model:¹⁹

$$P(Y_i = 1|X_i) = \Phi\left(\beta_0 + \beta_1 E_i + X_i' \Pi + \epsilon_i\right) \quad (1)$$

Y_i is a binary variable that takes on the value of 1 if the marriage was decided by the parents for individual i and 0 if he/she chose his/her own spouse with or without parent approval and $\Phi(\cdot)$ is the standard normal CDF. The level of educational attainment by individual i is represented by E_i , and X_i is a vector of relevant control variables. The error term in equation (1) captures unobserved heterogeneity of both parents and individ-

¹⁹In the empirical implementation, we also report results from linear probability model which do not depend on distributional assumption.

ual i . Educational attainment is measured by ‘years of schooling’. The vector of control variables include a rich set of household and individual level characteristics. As mentioned before, an advantage of the data set used in this paper is that it has good information on characteristics of an individual, his/her parents (both mother and father) and also on labor market opportunities.²⁰ The parental characteristics include occupation, birth order (if first born), and number of sibling. Occupation is a choice variable of the parents and thus would reflect their preference and ability. The number of siblings and birth order of a child might plausibly affect the the nature of the bargaining game between parents and children. We also include indicators of fertility choices of both parents and grand parents (the numbers of own and parents’ siblings). A smaller family size may be an indicator of more “progressive” views in general.²¹ Individual level variables for children include age, gender, age at marriage, a dummy for no religious affiliation, and number of siblings. It is important to control for the gender of the child as parents may have son preference. The age at marriage may influence the nature of bargaining between parents and children. Religious affiliation is likely to influence ones views about acceptability of parental choice.²²

We also control for a set of household level variables that might affect investment in human capital and may also influence preference regarding arranged marriage (i.e., both education and freedom of choice may be normal good). Higher income households are, *ceteris*

²⁰The data set also has information on the characteristics of the spouse. The characteristics of spouse can potentially be proxy variables for unobserved preference of parents and children. In the context of arranged marriages, the characteristics of spouse might capture parental unobserved heterogeneity, as they reflect parental preference. In case of own choice of spouse, they might reveal the preference of children. However, the characteristics of spouse are not exogeneous as they depend on the nature of spouse choice. We thus chose not to use them as controls. We, however, note that the estimates of the causal effect of education on arranged marriage presented in this paper remain virtually identical if we include the spousal characteristics.

²¹We thank James Foster for suggesting this interpretation.

²²The sample consists of 17 percent Christian and 20 percent Buddhist, and 63 percent with no religion.

paribus, more likely to invest in children's education because of relaxed credit constraint. We use household's agricultural and wage income as controls for income. In addition, a dummy for brick-wall house and dummies for ownership of radio and TV are also included. These are indicators for household wealth, and ownership of TV and radio also controls for access to information which might affect views regarding acceptability of arranged marriage. As we discuss in the following, children's own age, wage income and the rural-urban dummy play a critical role in our identification strategy.

As discussed before education may affect the probability of arranged marriage through a number of channels including changes in the bargaining game and also better search and information regarding the pool of partners in school. To isolate better the role played by bargaining, we need to control for the fact that at least part of the effect of education would capture the information and matching effect. We control for this information and matching channel by including a dummy for the case when a person met his/her spouse at school.

(4.1) Approaches to Identification

Identification of the causal effects of education on probability of arranged marriage is difficult due to multi-level unobserved heterogeneity in ability and preference. We use an instrumental variables strategy and the recent bounds approach under the assumption that instruments are 'plausibly exogeneous' to provide evidence on the causal effects of education on arranged marriage.

Instrumental Variables Approach

Following a large literature on returns to education in the labor market, we use indicators of schooling supply and shocks due to war as instruments for children's education.

More specifically, the instruments used in this paper are birthplace and a dummy for birth cohort above 40 years of age (born in or before 1955). The birthplace represents variations in the supply of schooling across geographic locations, while the cohort dummy represents variations over time due to varying intensity of conflict. The birthplace is a good indicator of schooling supply only if the respondent grew up in the place of birth. In our data set, 98.7 percent of the respondents grew up in their place of birth. Labor market opportunities and housing costs have been identified in the sociological literature as important determinants of arranged marriage (Goode (1963)). We use an indicator of non-farm opportunities at the time of marriage, wage income and a rural-urban dummy to capture the labor market opportunities and housing market conditions. Controlling for labor market opportunities is important for consistent estimation of the causal effects of education, because both education and outside options of a child in the bargaining game depend on it. Better market opportunities might induce the parents to invest more in children and also allow the children to assert their preferences *ex post* by improving their outside option. The rural-urban dummy also controls for differences in exposure to cultural factors (modernization).

One might argue that the birthplace of children is the location chosen by parents (especially by father in a patriarchal and patrilocal society like Vietnam), and some fathers might choose location close to the school if they value education more. If the fathers who value education more also differ systematically from other parents in their attitude to arranged marriage (for example, they may be more “progressive”), then this will weaken the case for the exclusion restriction. However, there are good reasons to believe that, in the specific context of our data set, this is not a concern. First, in our sample, the household location seems static and historically determined for most of the parental generation;

about 70 percent of fathers were born in the same place as the children. For the other 30 percent of cases, the birthplace of children reflects parental choice. However, unlike many developed countries, the location choice in Vietnam is primarily determined by parental occupation and labor market opportunities, and children's school choice usually plays a minor role. In the regressions, we thus control for parental occupation (both father's and mother's occupation).²³ The evidence presented below shows that conditional on the set of observed covariates, the instruments comfortably satisfy the formal test of exogeneity (P-value for Hansen's J statistics is 0.81).

There are 27 birthplace dummies we can use as instruments along with the cohort dummy. This, however, is likely to create weak IV problems due to too many instruments, as we have only one endogenous regressor. We thus need to reduce the dimension of the instruments. Although the respondents in the survey were born in 27 different birthplaces, most of the sample is concentrated in a few places. We define two dummies, one for the case when the respondent was born in the same commune he/she is currently located in, and the second one for the cases where respondent was not born in the current commune, and the birthplace is the location with largest number of respondents among all the 'other' birthplaces. These two dummies represent 86 percent of the sample. The other 25 birthplaces together represent the excluded category. We also use an alternative approach where the first two principal components (based on Eigen values) of the 27 birthplace dummies represent the schooling supply variations across space. As noted early on by Amemia (1966) and emphasized more recently by Bai and Ng (2008), using principal components to reduce the dimension of the set of instruments work well in such cases. The results using this

²³The lack of spatial mobility in Vietnam was reinforced, especially in the rural areas, by an identity card system known as *ho khau* (residence registration book). The *ho khau* system was initiated in 1960.

alternative set of instruments are consistent with the conclusions reported in this paper. For the sake of brevity, we do not report these alternative results.²⁴

The cohort dummy (that equals 1 if born in or before 1955) reflects the difference in schooling attainment between the cohorts born in 1955 and earlier and those born after 1955. Although Vietnam suffered a series of wars and conflicts, there was a relative calm in North Vietnam from 1954 to 1965 (Harrison, 1989, Young, 1991, Merli, 2000). The age cohorts born in 1955 and earlier, and in school during this period experienced a positive shock to their schooling attainment. The later cohorts (born after 1955) experienced a negative shock to education attainment which can be attributed, among other things, to intensified US bombings in the Red River Delta region during Vietnam war and related disruptions such as mass mobilization. As mentioned before, the communes that consist the survey area of VLS 1995 used in this paper were heavily bombed because of their proximity to important rail links or industrial installations. Using the VLS panel data set, Merli (2000) shows that the war mortality was much higher during the US bombings in the Red River Delta region compared to earlier periods.

An alternative discussed earlier is to use a cohort dummy for birth year between 1945-55 to capture the positive shock to education due to the stability from 1954-65 in the Red River Delta region. The results from this alternative formulation of the cohort dummy are very similar to the ones based on the 1955 cohort dummy, and thus are omitted to save space.

One might argue that the cohort dummy may also reflect changes in the informal social norms or formal legal codes regarding acceptability of arranged marriage. If there are

²⁴The results are available from the authors.

significant changes in social norms or formal legal codes over the relevant time period, it would result in heterogeneity in the incidence of arranged marriage across different cohorts of children. To account for slowly changing social norms, we include age and age squared of children. Age controls for possible generational changes in the views regarding arranged marriage. There was also significant change in the marital law in Vietnam; the practice of arranged marriage (and dowry) was made illegal in 1960. Not surprisingly, however, the formal law did not take hold on the ground for a long time (Van Bich, 1999).²⁵ We include a dummy for marriage before 1960 to capture possible impact of this change in the formal legal code on incidence of arranged marriage. Another potential objection to the exclusion restriction on the cohort dummy mentioned before is that the conflict might affect the marriage market directly through its effects on the sex ratio. We thus include cohort specific sex ratio as an additional control.

Set Identification: Bounds Under Approximate Exclusion Restrictions

The instrumental variables approach outlined above is attractive because it provides us with point identification. However, as mentioned before, the IV approach relies on exact exclusion restrictions on the instruments which some readers might find too restrictive. We thus use the recent approach developed by Conley et al (2008) where the exclusion restrictions on the instruments are relaxed, but point identification is not possible. In the context of our model, the exact exclusion restrictions imposed in the IV approach implies

²⁵According to one observer, "(I)n fact, the implementation of these laws has not been simple, and the social reality is often far cry from the ideals posited by the law-makers. A massive effort is needed to modify peoples thinking and to establish in the minds and behavior of the masses the new ideas about marriage and the family. This requires education, and the elimination of not only long-standing traditions, but also misconceptions, and even strong opposition. The question is how to educate people to renounce the traditions of polygamy, child marriages, arranged marriages," P.59, Van Bich, 1999.

that $H_0 : \theta_1 = \theta_2 = 0$ in the following specification of the spouse choice function:

$$P(Y_i = 1|X_i) = \Phi \left(\beta_0 + \beta_1 E_i + X_i' \Pi + \theta_1 V_i + \theta_2 D_c + \epsilon_i \right) \quad (2)$$

where V_i is birthplace, and D_c is a dummy for age cohort (40 years cut-off). It may be more plausible to argue that these exclusion restrictions hold only approximately, i.e., $H_0 : \theta_1 = \theta_2 \simeq 0$, especially in an application like ours where there are multiple sources of unobserved heterogeneity, and the instruments might have very small direct effects on arranged marriage if they are proxy variables for omitted heterogeneity. Under the approximate exclusion restrictions, the instruments are “plausibly exogeneous” in the terminology of Conley et. al. (2008) who develop a set of approaches under this weaker exogeneity condition, and show that one can estimate bounds on the causal effect of the endogenous variable.

We implement a simple and intuitive approach to modeling “plausible exogeneity” of the instruments as developed in Conley et. al. (2008); it specifies a support of possible values for $\theta_j \in [-\delta, +\delta]$ where $\delta > 0$ can be arbitrarily small. Under this assumption, we estimate the lower and upper bounds for the estimate of the parameter of interest β_1 . We report results for a number of alternative values of δ .

(5) Empirical Results

Preliminary Results

Figure 1 shows the predicted probability of arranged marriage (dummy equals 1 if marriage was arranged by parents with or without children’s inputs) against different years of

schooling from a simple Probit regression of arranged marriage on education without any controls. There is a clear negative relationship between education and the probability of arranged marriage. As discussed before, this bivariate correlation-while interesting in its own right-cannot inform us about the possible causal effect of education due to omitted variables bias. Table 2 presents results from estimating equation (1) above using Probit for different sets of control variables. The corresponding results from OLS estimation are very similar, and are reported in the Table A.1 in the appendix. The first column reports estimates with only individual level controls and then we progressively include parental characteristics, household level variables, labor market opportunities at the time of marriage and a rural-urban dummy. The estimates show a consistently negative and statistically significant effect of education on the probability of arranged marriage.²⁶ Although suggestive of a statistically significant negative effect of education on the probability of arranged marriage, these results may suffer from omitted variables bias because of unobserved heterogeneity in ability and preference of both parents and children. Another source of possible bias is measurement error in schooling which would result in estimates biased downward. It is thus not possible to pin down the direction of the bias from a priori reasoning.

Estimates from the IV Approach

The estimated effects of education on the probability of arranged marriage from the IV approach are reported in Table 3. For estimation, we use IV Probit and a control function

²⁶The Probit (Table 2) and linear probability model (Table A.1 in appendix) estimates show that the Parents' number of siblings (both father and mother) exerts a robust positive effect on the probability of arranged marriage, while own number of siblings is not significant. Also, wage income is a robust negative determinant of arranged marriage. The 1960 legal reform dummy is significant indicating that the change in the formal law had some impact on the incidence of arranged marriage. Access to information (TV and radio) seems to reduce the probability of arranged marriage.

approach for the Probit model (Blundell and Smith (1986), Rivers and Vuong (1988)); while for the linear probability model 2SLS and GMM are used. With a binary dependent variable, control function with Probit may provide more efficient estimates compared to 2SLS and GMM that ignore the binary nature of the dependent variable. The linear probability model, on the other hand, has the advantage that it does not require any distributional assumption.

The IV diagnostics show that the instruments pass the test of exogeneity convincingly; the P-value of Hansen's J statistic is 0.81. The estimates from first stage show that the instruments have reasonable power; the F statistic for exclusion of the instruments is 12.49 which is higher than the Bound et al (1995) rule of thumb of 10 for one endogenous regressor. In the first stage regression, the cohort dummy is significant at the 5 percent level, and the birthplace dummies are significant at the 1 percent level. Consistent with the discussion before, the estimated coefficient on the cohort dummy shows that the cohort born after 1955 has significantly lower educational attainment.

The first column in Table 3 (Panel A) shows the estimated effect of education using the control function approach and the second column presents the results from IV Probit (estimates are marginal effects evaluated at the sample mean). The control function results show that education is clearly endogenous in the arranged marriage equation, as the residual from the first stage is significant at the 1 percent level. The estimated marginal effect of education on arranged marriage is significant both statistically and numerically. According to the control function estimate, one year of additional schooling reduces the probability of arranged marriage by 17 percentage points for an individual with 8.07 years of education (the average level of education in the sample). The estimated marginal effect from IV

Probit is somewhat smaller; one year of additional schooling reduces the probability of arranged marriage by 13 percentage points. The third (2SLS) and fourth (GMM) columns in Table 3 report the results from the linear probability model. The estimated marginal effects from these alternative estimators are identical to that from the IV Probit. The estimates are statistically significant at the 1 percent level. The IV estimates from Probit and linear probability models thus provide robust evidence in favor of a strong negative effect of education on the probability of arranged marriage.

Although the strength of the instruments is reasonable, One might still worry about possible weak IV bias. To address any such concerns, we report results from two alternative checks. First, we use CUE-GMM to estimate the linear probability model and compare the estimates with those from 2SLS. As pointed out by Hansen et al (1996) and emphasized recently by Stock and Watson (2008), if the instruments are weak, then the CUE-GMM estimates perform better than 2SLS, and would differ significantly from the 2SLS estimates. The results from CUE-GMM are reported in the last column of Table 3. The estimated marginal effect of education is 13 percentage points, exactly equal to the common estimate from IV Probit, 2SLS, and GMM. Second, we use the recently developed tests for weak IV robust inference in binary choice models with heteroskedasticity developed by Magnusson (2008), and Finlay and Magnusson (2009). Panel B in Table 3 reports the results from the Finlay and Magnusson (2009) approach to weak IV robust inference for the linear probability and the Probit models. Note that the Probit results are for the estimated coefficients, not for the marginal effects. We report the results from the Conditional Likelihood Ratio (CLR) and Anderson-Rubin test. According to the conditional likelihood ratio (CLR) and Anderson-Rubin (A-R) tests, the null of no effect of education on arranged marriage is

rejected at the 1 percent level (P-value=0). The 95 percent confidence intervals for CLR and Anderson-Rubin tests do not include zero. The lower bound estimate from the 95 percent confidence interval gives an estimated marginal effect of about 7 percentage points reduction in the probability of arranged marriage (estimates from linear probability model).

Relaxing the Exact Exclusion Restrictions: Estimated Bounds

In this section, we report results from the recent bounds approach developed by Conley et. al. (2008). As discussed before, the exact exclusion restrictions are relaxed and we model ‘plausible exogeneity’ of the instruments by assuming that the coefficients on the instruments in the arranged marriage equation belong to an interval, i.e., $\theta_k \in [-\delta, +\delta]$ $\forall k$ with $\delta > 0$. The estimated bounds are reported for 95 percent confidence intervals in Table 4 with $\delta = 0.0001, 0.0005, 0.001, 0.005, 0.01$. The reported results are from the 2SLS estimator.

The results show that the estimated bounds do not vary significantly with the value of δ . More importantly, none of the 95 percent confidence intervals contain zero. This is strong evidence in favor of a robust negative effect of education on the probability of arranged marriage. The negative causal effect identified earlier in Table 3 are thus robust to relaxation of the exact exclusion restrictions imposed on the instruments for the IV estimates. It is reassuring that even if we allow for non-zero but low-level direct influence of the instruments on the probability of arranged marriage, the central conclusion that education reduces probability of having an arranged marriage remains intact. Even if one uses the most conservative estimate from the lower bound, one year of additional schooling still reduces the probability of arranged marriage substantially, by 6-7 percentage points.²⁷

²⁷Note that $\delta = 0.01$ implies that each of the instruments can affect the probability of arranged marriage

Gender, Education and Arranged Marriage

The results discussed so far do not consider possible gender differences in the effects of education on probability of arranged marriage. The results reported in Table 2 from Probit model show that the gender of the respondent matters for arranged marriage. The results reported in Table 2, however, cannot answer the question whether the effects of education on arranged marriage are significantly different for a female compared to a male. In this section we explore the issue of gender differences in the effects of education. Table 5 reports the results from estimating equation (1) separately for male and female sub-samples using control function, IV Probit, 2SLS, GMM and CUE-GMM estimators. The instruments used are the same as in Table 3. The IV diagnostics show that, for both the sub-samples, the instruments satisfy the exogeneity condition comfortably (the lowest P-value for Hansen's J statistics is 0.57). The strength of the instrument set is reasonably good for the female sub-sample (Cragg-Donald F= 8.76), but the instruments lack power in case of the male sub-sample (Cragg-Donald F=4.32). Thus weak IV bias is a concern for the male sub-sample. To address this concern, we report estimates using CUE-GMM estimator which is robust to weak instruments, and also report results from Finaly-Magnusson (2008) weak IV robust inference procedure.

The results differ significantly between male and female sub-samples. The marginal effect of education on the probability of arranged marriage is much higher for a female compared to a male. For a woman with average level of education (7.77 years), one year of additional schooling reduces the probability of arranged marriage by about 17 percentage

by up to 1 percentage point. Since we use three instruments, together they can affect the probability of arranged marriage by 3 percentage points. This allows for substantial direct effects of the instruments, and thus the estimated lower bound should probably be interpreted as a conservative estimate of the causal effects of education on arranged marriage.

points (averaging over estimates from alternative estimators in Table 5). The corresponding estimate for a male with average education (8.58 years of schooling) is about 7 percentage points. The marginal effect of education in the male sub-sample is, however, not always precisely estimated; it is not significant at the 10 percent level according to 2SLS and Control function estimates, but is significant according to GMM and CUE-GMM and IV Probit estimates. The results from weak IV robust inference are also not unambiguous. According to the Conditional Likelihood Ratio (CLR) test for linear probability model, the null of no effect of education on arranged marriage for men can be rejected at the 10 percent level (P-value equals 0.07), but the null cannot be rejected at the 10 percent level according to the Anderson-Rubin test. The weak IV robust results for IV Probit also indicate that education does not have significant effect on arranged marriage for men at the 10 percent level. Taken together, the evidence of a causal effect of education on arranged marriage for men is thus much weaker than the evidence for women.

Conclusions

This paper provides evidence of broader returns to education beyond the labor market and direct productivity effects with a focus on benefits of education in social interactions. As noted by Amartya Sen, among others, an educated person is treated with more respect (“taken more seriously”) in social interactions. Thus education may enable an individual to assert his/her choices within the household and in broader social interactions. We focus on the bargaining between parents and children, and provide estimates of the causal effects of education on freedom to choose ones own spouse. Education improves the outside option of children in bargaining with parents due to better labor market opportunities, among

other things. The choice of spouse is among the most important decisions in human life, and freedom in spouse choice is used here as an indicator of freedom of choice in general in social interactions.

Using data from 10 communes in Red River Delta region in Vietnam, we estimate the causal effect of education on the probability of arranged marriage where parents choose the spouse with or without inputs from children. For identification, we rely on instruments representing variations in school supply across geographic space and exogenous shocks to schooling attainment for different birth cohorts because of varying intensity of war and conflicts and associated disruptions. To capture geographic variations in schooling supply we use birthplace. Birthplace is a good indicator of relevant schooling supply in our data set as more than 98 percent respondents grew up in their place of birth. We use a dummy for cohorts born in 1955 and earlier to capture the variations in schooling attainment over time. The cohort dummy represents the positive shock to the educational attainment of the older cohorts (born in 1955 or earlier) because of relative stability during 1954-65 in the Red River Delta region. This also captures the negative shock to educational attainment of later cohorts caused by the US bombing in Red River delta region during Vietnam war.

We also use an alternative strategy that does not rely on the exact exclusion restrictions needed for the validity of the standard IV approach. We implement the recent bounds approach developed by Conley et al (2008) where the exclusion restrictions are relaxed and we allow for low-level direct influence of the instruments on the probability of arranged marriage.

The empirical results provide strong evidence in favor of a both numerically and statistically significant negative effect of education on the probability of arranged marriage.

According to the estimates from the instrumental variables approach, one year of additional schooling reduces the probability of arranged marriage by approximately 14 percentage points for an individual with 8 years of education. The estimates from Probit model imply that 10 years of schooling for an individual would reduce the probability of arranged marriage close to zero in Vietnam. There is significant gender differences in the causal effects of education; the impact of education is numerically higher and statistically stronger in the case of women. The evidence of a causal effect of education on arranged marriage in the case of men is, in contrast, much weaker, both in terms of numerical magnitude and statistical significance.

The conclusion that education has a negative causal effect on the probability of arranged marriage does not depend on the exclusion restrictions imposed in the IV approach. The results from the Conley et al (2008) bounds approach under weaker exclusion restrictions also support this conclusion. Although the lower bound estimate from the Conley et al (2008) approach is significantly smaller, the effect of education is still substantial; one year of additional schooling leads to an approximately 6-7 percentage points reduction in the probability of arranged marriage for an individual with average level of education (8 years of schooling). The empirical evidence presented in this paper points to important benefits of education to individuals in social interactions. The focus on labor market returns to education in economics literature thus might be understating the full private and social returns to education.
